Our knowledge of the world around us is limited to those characteristics that stimulate our sensory receptors. We humans may not realize it, but our picture of the environment is incomplete. Colors that humans cannot see guide insects to flowers. Sounds humans cannot hear and smells humans cannot detect give dolphins, dogs, and cats key information about their surroundings.

Perception varies considerably with the state of the nervous system. For example, during sympathetic activation, people experience a heightened awareness of sensory information. Sounds are heard that normally would not be noticed. Yet, when concentrating on a difficult problem, a person may be unaware of loud noises.

Finally, a person's perception of any stimulus reflects activity in their cerebral cortex, but that activity can be generated by the nervous system itself. For example, in cases of phantom pain syndrome, a person feels pain in a missing limb. During an epileptic seizure, a person may experience sights, sounds, or smells that have no physical basis.

In our discussion of the general senses and sensory pathways in Chapter 15, we introduced basic principles of receptor function and sensory processing. We now focus on the five *special senses*: *olfaction* (smell), *gustation* (taste), *vision*, *equilibrium* (balance), and *hearing*. The sense organs involved are structurally more complex than those of the general senses, yet the same basic principles of receptor function apply. That is, all the special sense receptors also transduce an arriving stimulus into action potentials that are then sent to the CNS for interpretation and possible response.

17-1 Olfaction, the sense of smell, involves olfactory receptors responding to airborne chemical stimuli

Learning Outcome Describe the sensory organs of smell, trace the olfactory pathways to their destinations in the brain, and explain the physiological basis of olfactory discrimination.

The sense of smell, called **olfaction**, is made possible by paired **olfactory organs**. These olfactory organs, which are in the **nasal cavity** on either side of the nasal septum, contain *olfactory sensory neurons*. What happens when inhaling through the nose? The air swirls within the nasal cavity. This turbulence brings airborne substances, including water-soluble and lipid-soluble substances called *odorants*, to the olfactory organs. A normal, relaxed inhalation carries a small sample (about 2%) of the inhaled air to the olfactory organs. Repeated sniffing increases the flow of air and odorants, thereby increasing the stimulation of olfactory receptors. Once these receptors are stimulated, they send signals to the *olfactory cortex*, which interprets them. Let's turn our attention to how this process occurs.

Anatomy of the Olfactory Organs

The olfactory organs are made up of two layers: the *olfactory epithelium* and the *lamina propria* (**Figure 17-1a**). The **olfactory epithelium** contains the olfactory sensory neurons, supporting cells, and regenerative *basal epithelial cells* (*stem cells*) (**Figure 17-1b**). This epithelium covers the inferior surface of the cribriform plate, the superior portion of the perpendicular plate, and the superior nasal conchae of the ethmoid. The second layer, the underlying lamina propria, consists of areolar tissue, numerous blood vessels, and nerves. This layer also

Figure 17-1 The Olfactory Organs.

contains **olfactory glands**. Their secretions absorb water and form thick, pigmented *mucus*.

Olfactory sensory neurons are highly modified nerve cells. The exposed tip of each sensory neuron forms a prominent dendritic bulb that projects beyond the epithelial surface (**Figure 17-1b**). The dendritic bulb is a base for up to 20 cilia-shaped dendrites that extend into the surrounding mucus. These dendrites lie parallel to the epithelial surface, exposing their considerable surface area to odorants.

Between 10 and 20 million olfactory receptors fill an area approximately 5 cm^2 (0.8 in.^2). However, if we consider the exposed dendritic surfaces, the actual sensory area probably approaches that of the entire body surface.

Olfactory Receptors and the Physiology of Olfaction

Olfactory reception begins with the binding of an odorant to a G protein-coupled receptor in the plasma membrane of an olfactory dendrite. This creates a depolarization called a **generator potential**. This potential leads to the generation of action potentials, which are then carried to the central nervous system by sensory afferent fibers. This process is illustrated in **Spotlight Figure 17-2**.

Olfactory Pathways

The olfactory pathway begins with afferent fibers leaving the olfactory epithelium that collect into 20 or more bundles. These bundles penetrate the cribriform plate of the ethmoid bone to reach the *olfactory bulbs* of the cerebrum, where the first synapse occurs (**Figure 17-1a**). Efferent fibers from nuclei elsewhere in the brain also innervate neurons of the olfactory bulbs. Axons leaving the olfactory bulb travel along the olfactory tract to the **olfactory cortex** of the cerebral hemispheres, the hypothalamus, and portions of the limbic system.

Olfactory stimulation is the only type of sensory information that reaches the cerebral cortex directly. All other sensations are relayed from processing centers in the thalamus. Certain smells can trigger profound emotional and behavioral responses, as well as memories, because olfactory information is also distributed to the limbic system and hypothalamus.

The activation of an afferent fiber does not guarantee an awareness of the stimulus. Considerable convergence takes place along the olfactory pathway, and inhibition at the intervening synapses can prevent the sensations from reaching the *olfactory cortex*. As shown in **Spotlight Figure 17-2**, the olfactory receptors themselves adapt very little to an ongoing stimulus.

Olfaction and gustation are special senses that give us vital information about our environment. Although the sensory information is diverse and complex, each special sense originates at receptor cells that may be neurons or specialized receptor cells that communicate with sensory neurons.

OLFACTION

Olfactory receptors are the dendrites of specialized neurons. When odorant molecules bind to the olfactory receptors, a depolarization known as a **generator potential** results. This graph shows the action potentials produced by a generator potential.

Olfactory reception occurs on the surface membranes of the olfactory dendrites. **Odorants**—substances that stimulate olfactory receptors—interact with receptors called odorant-binding proteins on the membrane surface.

In general, odorants are small organic molecules. The strongest smells are associated with molecules of either high water or high lipid solubilities. As few as four odorant molecules can activate an olfactory receptor.

- 1 The binding of an **odorant** to its receptor protein leads to the activation of adenylate cyclase, the enzyme that converts ATP to cyclic AMP (cAMP).

- 2 The cAMP opens sodium ion channels in the plasma membrane, which then begins to depolarize.

- 3 If sufficient depolarization occurs, an action potential is triggered in the axon, and the information is relayed to the CNS.

GUSTATION

The receptors for the senses of taste, vision, equilibrium, and hearing are specialized cells that have unexcitable membranes and form synapses with the processes of sensory neurons. As the left hand graph below shows, the membrane of the stimulated receptor cell undergoes a graded depolarization that triggers the release of chemical transmitters at the synapse. These transmitters then depolarize the sensory neuron, creating a generator potential and action potentials that are propagated to the CNS. Because a synapse is involved, there is a slight synaptic delay. However, this arrangement permits modification of the sensitivity of the receptor cell by presynaptic facilitation or inhibition.

Some 90% of the taste receptor cells respond to two or more different taste stimuli. The different tastes involve different receptor mechanisms. A salty stimulus involves the diffusion of Na^+ ions through a sodium ion leak channel common in epithelial cells. Stimuli for a sour or acidic taste include H^+ ions that diffuse through the same epithelial Na^+ channel. The intracellular increase in cations leads to depolarization and neurotransmitter release. Sweet, bitter, and umami stimuli bind to specific G protein-coupled receptors. The resulting multiple chemical pathways lead to depolarization and neurotransmitter release.

Salt and Sour Channels

The diffusion of sodium ions from salt solutions or hydrogen ions from acids or sour solutions into the receptor cell leads to depolarization.

Depolarization of membrane stimulates release of chemical neurotransmitters.

Sweet, Bitter, and Umami Receptors

Receptors responding to stimuli that produce sweet, bitter, and umami sensations are linked to G proteins called **gustducins** (GUST-dooz-inz) that use second messengers to produce their effects.

Activation of second messengers stimulates release of chemical neurotransmitters.

Rather, central adaptation (via innervation of the olfactory bulbs by other brain nuclei) ensures that humans quickly lose awareness of a new smell but remain sensitive to others.

Olfactory Discrimination

The human olfactory system can discriminate between, or make subtle distinctions among, 2000–4000 chemical stimuli. Yet our olfactory sensitivities cannot compare with those of other vertebrates such as dogs, cats, or fishes. A German shepherd dog sniffing for smuggled drugs or explosives has an olfactory receptor surface 72 times greater than that of the nearby customs inspector! Thus, the dog can smell 10,000 to 100,000 times better than a human.

No apparent structural differences exist among the human olfactory sensory neurons, but the epithelium contains populations with distinct sensitivities. Upwards of 50 “primary smells” are known, although it is almost impossible to describe these sensory impressions effectively. The central nervous system probably interprets each smell based on the overall pattern of receptor activity.

Human olfactory organs can discriminate among many smells, but sensitivity varies widely, depending on the nature of the odorant. We can detect many odorants in amazingly small concentrations. One example is mercaptan, an odorant commonly added to natural gas, which is otherwise odorless. Because we can smell mercaptan at an extremely low concentration (a few parts per billion), its addition enables us to detect a gas leak almost at once.

The olfactory receptor population is replaced frequently. Basal epithelial cells in the epithelium divide and differentiate to produce new sensory neurons. This turnover is one of the few examples of neuronal replacement in adult humans. Despite this process, the total number of neurons declines with age, and those that remain become less sensitive. As a result, older people may have difficulty detecting odors in low concentrations. This sensory neuron decline explains why a grandfather’s aftershave or a grandmother’s perfume smells so strong: Each must apply more to be able to smell it.

✓ Checkpoint

1. Define olfaction.
2. Trace the olfactory pathway, beginning at the olfactory epithelium.
3. When first entering the A&P lab for dissection, the odor of preservatives is strong. By the end of the lab period, the smell doesn’t seem to be nearly as strong. Why?

See the blue Answers tab at the back of the book.

17-2 Gustation, the sense of taste, involves gustatory receptors responding to dissolved chemical stimuli

Learning Outcome Describe the sensory organs of taste, trace the gustatory pathways to their destinations in the brain, and explain the physiological basis of gustatory discrimination.

Gustation, or the sense of *taste*, provides information about the foods we eat and the liquids we drink. *Taste receptor cells* (TRCs), also called *gustatory* (GUS-ta-tor-ē) *epithelial cells*, are found in *taste buds* that are distributed over the superior surface of the tongue and adjacent portions of the pharynx and larynx. These receptors are stimulated by dissolved food molecules. This stimulation leads to action potentials that are sent to the *gustatory cortex* for interpretation, as shown in **Spotlight Figure 17-2**.

Anatomy of Papillae and Taste Buds

The surface of the tongue has numerous variously shaped epithelial projections called *lingual papillae* (pa-PIL-ē; *papilla*, a nipple-shaped mound). The human tongue has four types of lingual papillae (**Figure 17-3a,b**): (1) **filiform** (*filum*, thread) **papillae**, (2) **fungiform** (*fungus*, mushroom) **papillae**, (3) **vallate** (VAL-āt; *vallum*, wall) **papillae**, and (4) **foliate** (FŌ-lē-āt) **papillae**. The distribution of these lingual papillae varies by region. Their components also vary—most contain the sensory structures called **taste buds** (**Figure 17-3c**). Filiform papillae are found in the anterior two-thirds of the tongue running parallel to the *midline groove*. They do not contain taste buds, but they do provide an abrasive coat that creates friction to help move food around the mouth. Fungiform papillae are scattered around the tongue with concentrations along its tip and sides. Each small fungiform papilla contains about five taste buds. Vallate papillae appear as an inverted “V” near the posterior margin of the tongue. There are up to 12 vallate papillae, and each contains as many as 100 taste buds. The foliate papillae are found as a series of folds along the lateral margins with taste buds embedded in their surfaces.

Taste Receptor Cells

Taste buds are sensory organs recessed into the surrounding epithelium, isolated from the unprocessed contents of the mouth. Each taste bud contains about 40–100 taste receptor cells and many small stem cells called basal epithelial cells (**Figure 17-3b,c**). The basal epithelial cells continually divide to produce daughter cells that mature in three stages—basal, transitional, and mature. Cells at all stages are innervated by sensory neurons. The mature cells of the last stage are the **taste receptor cells**. Each taste receptor cell extends microvilli, sometimes called *taste hairs*, into the surrounding fluids through the **taste pore**, a narrow opening. Despite this relatively protected position, a typical taste receptor cell survives for only about 10 days before it is replaced.

Gustatory Pathways

The gustatory pathway starts with taste buds, which are innervated by cranial nerves VII (facial), IX (glossopharyngeal), and X (vagus). The facial nerve innervates all the taste buds located on the anterior two-thirds of the tongue, from the tip to the

Figure 17-3 Papillae, Taste Buds, and Taste Receptor Cells.

line of vallate papillae. The glossopharyngeal nerve innervates the vallate papillae and the posterior one-third of the tongue. The vagus nerve innervates extralingual taste buds scattered on the surface of the epiglottis.

The sensory afferent fibers carried by these cranial nerves synapse in the solitary nucleus of the medulla oblongata. The axons of the postsynaptic neurons then enter the medial lemniscus. There, the neurons join axons that carry somatic sensory information on touch, pressure, and proprioception. After another synapse in the thalamus, the information is sent to the appropriate portions of the gustatory cortex of the insula.

Conscious perception of taste occurs as the brain correlates information received from the taste buds with other sensory data. Information about the texture of food, along with taste-related sensations such as “peppery,” comes from sensory afferent fibers in the trigeminal nerve (cranial nerve V).

In addition, the level of stimulation from the olfactory receptors plays a major role in taste perception. The combination of taste

and smell is what provides the *flavor*, or distinctive quality of a particular food or drink. A person is several thousand times more sensitive to “tastes” when their olfactory organs are fully functional. By contrast, when somebody has a cold and their nose is stuffed up, airborne molecules cannot reach their olfactory receptors, so meals may taste dull and unappealing. The reduction in flavor happens even though the taste buds may be responding normally. Without accompanying olfactory sensations, the person is now limited to the basic taste sensations provided by their gustatory receptors.

Gustatory Discrimination and Physiology of Gustation

There are four **primary taste sensations: sweet, salty, sour, and bitter**. There is some evidence for differences in sensitivity to tastes along the axis of the tongue, with greatest sensitivity to salty-sweet anteriorly and sour-bitter posteriorly. However, there are no differences in the structure of the taste buds. Taste buds in all portions of the tongue provide all four primary taste sensations.

Humans have two additional taste sensations that are less widely known. The first is called **umami** (oo-MAH-mē, derived from a Japanese word meaning “delicious”), a pleasant, savory taste imparted by the amino acid glutamate. The distribution of umami receptors is not known in detail, but they are present in taste buds of the vallate papillae. Second, although most people say that water has no flavor, research on humans and other vertebrates has demonstrated the presence of **water receptors**, especially in the pharynx. The sensory output of these receptors is processed in the hypothalamus and affects several systems that affect water balance and the regulation of blood volume. For example, the secretion of *antidiuretic hormone* (a hormone that regulates urination) is slightly reduced each time a person takes a long drink.

Gustation reception is described in **Spotlight Figure 17-2**. The threshold for receptor stimulation varies for each of the primary taste sensations. Also, the taste receptors respond more readily to unpleasant than to pleasant stimuli. For example, we are almost a thousand times more sensitive to acids, which taste sour, than to either sweet or salty chemicals. We are a hundred times more sensitive to bitter compounds than to acids. This sensitivity has survival value, because acids can damage the mucous membranes of the mouth and pharynx, and many potent biological toxins have an extremely bitter taste.

Taste sensitivity differs significantly among individuals. Many conditions related to taste sensitivity are inherited. The best-known example involves sensitivity to the compound *phenylthiocarbamide* (PTC). This substance tastes bitter to some people but is tasteless to others. PTC is not found in foods, but compounds related to PTC are found in Brussels sprouts, broccoli, cabbage, and cauliflower.

Our tasting abilities change with age. With advancing age, food may taste bland and unappetizing, while children tend to find the same foods too spicy. What accounts for these differences? We begin life with more than 10,000 taste buds, but by the time we reach adulthood, the taste receptors on the pharynx, larynx, and epiglottis have decreased in number. By age 50, the number begins declining dramatically. The sensory loss becomes especially significant because, as we have already noted, older individuals also experience a decline in the number of olfactory receptors.

✓ Checkpoint

4. Define gustation.
5. Completely drying the tongue surface and then placing salt or sugar on it results in the inability to taste either substance. Why?
6. An 80-year-old man can't understand why foods he used to enjoy just don't taste the same anymore. Explain the reason why this might be happening.

See the blue Answers tab at the back of the book.

17-3 Internal eye structures contribute to vision, while accessory eye structures provide protection

Learning Outcome Identify the internal and accessory structures of the eye and explain the functions of each.

We rely more on **vision** than on any other special sense. Our eyes are elaborate structures containing visual receptors that enable us not only to detect light, but also to create detailed visual images. We begin our discussion of these fascinating organs with the *accessory structures* of the eye (which provide protection, lubrication, and support), and then move on to the structures of the *eyeball*.

Accessory Structures of the Eye

The **accessory structures** of the eye include the eyelids and the superficial epithelium of the eye, as well as the structures involved with the production, secretion, and removal of tears. **Figure 17-4** shows the superficial anatomy of the eye and its accessory structures.

Eyelids and Superficial Epithelium of the Eye

The **eyelids**, or *palpebrae*, are a continuation of the skin. Their continual blinking keeps the surface of the eye lubricated. They also act like windshield wipers, removing dust and debris. The eyelids can also close firmly to protect the delicate surface of the eye.

The **palpebral fissure** is the gap that separates the free margins of the upper and lower eyelids. The two eyelids are connected, however, at the **medial angle** (*medial canthus*) and the **lateral angle** (*lateral canthus*) (**Figure 17-4a**). The **eyelashes**, along the margins of the eyelids, are very strong hairs. They help prevent foreign matter (including insects) from reaching the surface of the eye.

The eyelashes are associated with unusually large sebaceous glands. Along the inner margin of the lid are small, modified sebaceous glands called **tarsal glands** (not shown in the figure), or *Meibomian* (mī-BŌ-mē-an) *glands*. They secrete a lipid-rich substance that helps keep the eyelids from sticking together. At the medial angle of the eye, the **lacrimal caruncle** (KAR-ung-kul), a mass of soft tissue, contains glands producing the thick secretions that contribute to the gritty deposits that sometimes appear after a good night's sleep.

Bacteria occasionally invade and infect these various glands. A *chalazion* (kah-LĀ-zē-on; small lump) is a cyst that results from an infection of a tarsal gland. An infection in a sebaceous gland associated with an eyelash produces a painful localized swelling known as a *sty*.

The skin covering the visible surface of the eyelid is very thin. Deep to the skin lie the muscle fibers of the *orbicularis oculi* and *levator palpebrae superioris*. These skeletal muscles close the eyelids and raise the upper eyelid, respectively.

Figure 17-4 External Features and Accessory Structures of the Eye.**a** Gross and superficial anatomy of the accessory structures**b** The organization of the lacrimal apparatus

Choose the correct word from each pairing: The lacrimal gland is located (inferior, superior) and (lateral, medial) to the eye.

The epithelium covering the inner surfaces of the eyelids and the outer surface of the eyeball is called the **conjunctiva** (kon-junk-TĪ-vuh). It is a mucous membrane covered by a specialized stratified squamous epithelium. The **palpebral conjunctiva** covers the inner surface of the eyelids. It is continuous with the **bulbar conjunctiva**, or *ocular conjunctiva*, which covers the anterior surface of the eye (Figure 17-4b).

The bulbar conjunctiva extends to the edges of the **cornea** (KOR-nē-uh), a transparent part of the outer fibrous layer of the eye. The cornea is covered by a very delicate squamous *corneal epithelium*, five to seven cells thick, that is continuous with the bulbar conjunctiva. A constant supply of fluid washes over the surface of the eyeball, keeping the bulbar conjunctiva and cornea moist and clean. Goblet cells in the epithelium assist the accessory glands in lubricating the surfaces of the conjunctiva with mucus to prevent drying out and friction.

Conjunctivitis, or *pinkeye*, is an inflammation of the conjunctiva. The most obvious sign, redness, is due to the dilation of blood vessels deep to the conjunctival epithelium. This condition may be caused by pathogenic infection or by physical, allergic, or chemical irritation of the conjunctival surface.

The Lacrimal Apparatus

A constant flow of tears keeps conjunctival surfaces moist and clean. Tears reduce friction, remove debris, prevent bacterial

infection, and provide nutrients and oxygen to portions of the conjunctival epithelium. The **lacrimal apparatus** produces, distributes, and removes tears. The lacrimal apparatus of each eye consists of (1) a *lacrimal gland* with associated ducts, (2) paired *lacrimal canaliculi*, (3) a *lacrimal sac*, and (4) a *nasolacrimal duct* (Figure 17-4b).

The **fornix** of the eye is a pocket created where the palpebral conjunctiva becomes continuous with the bulbar conjunctiva. The lateral portion of the superior fornix receives 10–12 ducts from the **lacrimal gland**, or tear gland (Figure 17-4b). This gland is about the size and shape of an almond, measuring about 12–20 mm (0.5–0.75 in.). It nestles within a depression in the frontal bone, just inside the orbit and superior and lateral to the eyeball.

The lacrimal gland normally provides the key ingredients and most of the volume of the tears that bathe the conjunctival surfaces. The lacrimal secretions supply nutrients and oxygen to the corneal cells by diffusion. The lacrimal secretions are watery and slightly alkaline. They contain the antibacterial enzyme **lysozyme** and antibodies that attack pathogens before they enter the body.

Each lacrimal gland produces about 1 mL of tears each day. Once the lacrimal secretions have reached the ocular surface, they mix with the products of accessory glands and the oily secretions of the tarsal glands. The result is a superficial “oil slick” that aids lubrication and slows evaporation.

Blinking sweeps the tears across the ocular surface. Tears accumulate at the medial angle of eye in an area known as the *lacrimal lake*, or “lake of tears.” The lacrimal lake covers the lacrimal caruncle, which bulges anteriorly. The **lacrimal puncta** (singular, *punctum*), two small pores, drain the lacrimal lake. They empty into the **lacrimal canaliculi**, small canals that in turn lead to the **lacrimal sac**, which nestles within the lacrimal sulcus of the orbit (**Figure 17-4b**).

From the inferior portion of the lacrimal sac, the **nasolacrimal duct** passes through the *nasolacrimal canal*, formed by the lacrimal bone and the maxilla. This duct delivers tears to the nasal cavity on that side. The duct empties into the *inferior meatus*, a narrow passageway inferior and lateral to the inferior nasal concha. When a person cries, tears rushing into the nasal cavity produce a runny nose. If the lacrimal puncta can’t provide enough drainage, the lacrimal lake overflows, and tears stream across the face.

Anatomy of the Eyeball

17 The eyes are extremely sophisticated visual instruments. They are more versatile and adaptable than the most expensive cameras, yet compact and durable. Each **eyeball** is a slightly irregular spheroid (**Figure 17-5a**), a little smaller than a Ping-Pong ball, with an average diameter of 24 mm (almost 1 inch) and a weight of about 8 g (0.28 oz). Within the orbit, the eyeball shares space with the extrinsic eye muscles, the lacrimal gland, and the cranial nerves and blood vessels that supply the eye and adjacent portions of the orbit and face. **Orbital fat** cushions and insulates the eye.

The wall of the eyeball has three distinct layers, formerly called tunics (**Figure 17-5b**): (1) an outer *fibrous layer*, (2) an intermediate *vascular layer* (*uvea*), and (3) a deep *inner layer* (*retina*). The visual receptors, or *photoreceptors*, are found in the inner layer.

The eyeball itself is hollow and filled with fluid. Its interior can be divided into two cavities, anterior and posterior (**Figure 17-5c**). The **anterior cavity** has two chambers, the *anterior chamber* (between the cornea and the iris) and the *posterior chamber* (between the iris and the transparent *lens*). A clear, watery fluid called *aqueous* (Ā-kwē-us) *humor* fills the entire anterior cavity. The **posterior cavity**, or *vitreous chamber*, contains a gelatinous substance called the *vitreous body*.

The Fibrous Layer

The **fibrous layer**, the outermost layer of the eyeball, consists of the whitish *sclera* (SKLER-uh) and the transparent *cornea*. The fibrous layer (1) supports and protects the eye, (2) serves as an attachment site for the extrinsic eye muscles, and (3) contains structures that assist in focusing.

The Sclera. The **sclera**, or “white of the eye,” covers most of the ocular surface (**Figure 17-5c**). The sclera consists of a

dense fibrous connective tissue containing both collagen and elastic fibers. This layer is thickest over the posterior surface of the eye, near the exit of the optic nerve. The sclera is thinnest over the anterior surface. The six extrinsic eye muscles insert on the sclera, blending their collagen fibers with those of the fibrous layer.

The surface of the sclera contains small blood vessels and nerves that penetrate the sclera to reach internal structures. The network of small vessels interior to the bulbar conjunctiva generally does not carry enough blood to lend an obvious color to the sclera. On close inspection, however, the vessels are visible as red lines against the white background of collagen fibers.

The Cornea. The transparent **cornea** is structurally continuous with the sclera. The border between the two is called the **corneoscleral junction**, or *corneal limbus* (**Figure 17-5c**). Deep to the delicate corneal epithelium, the cornea consists primarily of a dense matrix containing multiple layers of collagen fibers, organized so as not to interfere with the passage of light. The cornea has no blood vessels. Its superficial epithelial cells obtain oxygen and nutrients by diffusion from the tears that flow across their free surfaces. The cornea also has numerous free nerve endings, making it the most sensitive portion of the eye.

Damage to the cornea may cause blindness even though the functional components of the eye—including the photoreceptors—are perfectly normal. The cornea has a very restricted ability to repair itself. For this reason, corneal injuries must be treated immediately to prevent serious vision losses.

Restoring vision after corneal scarring generally requires replacing the cornea through a *corneal transplant*. Corneal replacement is probably the most common form of transplant surgery. Such transplants can be performed between unrelated individuals because there are no blood vessels to carry white blood cells, which attack foreign tissues, into the area. Corneal grafts are obtained from donor eyes. For best results, the tissues must be removed within 5 hours after the donor’s death.

The Vascular Layer

The **vascular layer**, or *uvea* (YŪ-vē-uh), is a pigmented region that includes the *iris*, *ciliary body*, and *choroid* (**Figure 17-5b,c**). It contains numerous blood vessels, lymphatic vessels, and the intrinsic (smooth) muscles of the eye. This middle layer (1) provides a route for blood vessels and lymphatics that supply the tissues of the eye, (2) regulates the amount of light that enters the eye, (3) secretes and reabsorbs the aqueous humor that circulates within the chambers of the eye, and (4) controls the shape of the lens, an essential part of the focusing process.

The Iris. The **iris**, a pigmented, flattened ring structure, is visible through the transparent corneal surface. The iris contains

Figure 17-5 The Sectional Anatomy of the Eye.

blood vessels, pigment cells (melanocytes), and two layers of smooth muscle fibers called *pupillary muscles*. When these muscles contract, they change the diameter of the **pupil**, the central opening of the iris. There are two groups of pupillary muscles: *dilator pupillae* and *sphincter pupillae* (Figure 17-6). The autonomic nervous system controls both muscle groups. For example, in response to dim light, sympathetic activation results in dilated pupils. In response to bright light, parasympathetic activation results in constricted pupils.

How is eye color determined? Our genes influence the density and distribution of melanocytes in the iris, as well as the density of the pigmented epithelium. When the connective tissue of the iris contains few melanocytes, light passes through it and reflects off the pigmented epithelium. The eye then appears blue. Individuals with green, brown, or black eyes have increasing numbers of melanocytes in the body and on the surface of the iris. The eyes of people with albinism, whose cells do not produce melanin, appear a very pale gray or blue-gray.

The Ciliary Body. At its periphery, the iris attaches to the anterior portion of the **ciliary body**, a thickened region that begins deep to the corneoscleral junction. The ciliary body extends posteriorly to the level of the **ora serrata** (Ō-ra ser-RAH-tuh; serrated mouth), the serrated anterior edge of the neural layer of the retina (Figure 17-5c). The bulk of the ciliary body consists of the **ciliary muscle**, a ring of smooth muscle that projects into the interior of the eye. The epithelium covering this muscle has numerous folds called **ciliary processes**. The **ciliary zonule** (*suspensory ligament*) is the ring of fibers that attaches the lens to the ciliary processes. The connective tissue fibers hold the lens in place posterior to the iris and centered

on the pupil. As a result, any light passing through the pupil also passes through the lens.

The Choroid. The **choroid** (KOR-oyd) is a vascular layer that separates the fibrous layer and the inner layer posterior to the ora serrata (Figure 17-5c). The choroid is covered by the sclera and attached to the outermost layer of the retina. An extensive capillary network in the choroid delivers oxygen and nutrients to the retina. The choroid also contains melanocytes, which are especially numerous near the sclera.

The Inner Layer: The Retina

The **inner layer**, or **retina**, is the deepest of the three layers of the eye. It consists of a thin lining called the *pigmented layer* and a thicker covering called the *neural layer*. The pigmented layer contains pigment cells that support the functions of the photoreceptors, which are in the neural layer of the retina. These two layers of the retina are normally very close together, but not tightly interconnected. The pigmented layer of the retina continues over the ciliary body and iris, but the neural layer extends anteriorly only as far as the ora serrata. The neural layer of the retina forms a cup-like shape establishing the posterior and lateral boundaries of the posterior cavity (Figure 17-5b,c).

Pigmented Layer of the Retina. The pigmented layer of the retina absorbs light that passes through the neural layer, preventing light from bouncing (reflecting) back through the neural layer and producing visual “echoes.” The pigment cells also have important biochemical interactions with the retina’s photoreceptors.

Figure 17-6 The Pupillary Muscles.

Neural Layer: Cellular Organization. In sectional view, the neural layer of the retina contains several layers of cells (**Figure 17-7a**). The inner layers of the retina contain supporting cells and neurons that do preliminary processing and integration of visual information. The outermost part, closest to the pigmented layer of the retina, contains the **photoreceptors**, the cells that detect light.

The eye has two main types of photoreceptors: rods and cones. **Rods** do not discriminate among colors of light. Highly sensitive to light, they enable vision in dimly lit rooms, at twilight, and in pale moonlight. **Cones** provide color vision. Cones give sharper, clearer images than rods do, but cones require more intense light. When sitting outside at sunset while looking at a colorful illustration in a book, the gradual shift in the visual system from cone-based vision (a clear image in full color) to rod-based vision (a relatively grainy image in black and white) becomes obvious. A third type of photoreceptor is the *intrinsically photosensitive retinal ganglion cell* (ipRGC). The photopigment in the ipRGC is melanopsin. These cells are known to respond to different levels of brightness and influence the body's 24-hour circadian rhythm (biological clock).

Tips

Associate the **r** in **rod** with the **r** in **dark** and associate the **c** in **cones** with the **c** in **color** and in **acuity** (sharpness).

Rods and cones are not evenly distributed across the retina. Approximately 125 million rods form a broad band around the periphery of the retina. Moving toward the center of the retina, the density of rods gradually decreases. In contrast, most of the nearly 6 million cones are concentrated in the area where a visual image arrives after it passes through the cornea and lens. This region, known as the **macula** (MAK-yū-luh; spot), has no rods. The highest concentration of cones occurs at the center of the macula, an area called the **fovea centralis** (FŌ-vē-uh; shallow depression), or simply the **fovea** (**Figure 17-7b**). The fovea centralis is the site of sharpest color vision. When looking directly at an object, its image falls on this portion of the retina. An imaginary line drawn from the center of that object through the center of the lens to the fovea centralis establishes the **visual axis** of the eye (**Figure 17-5c**).

What are some of the visual consequences of this distribution of photoreceptors? When looking directly at an object, its image is placed on the fovea centralis. A very good image is seen if there is enough light to stimulate the cones. But in very dim light, cones cannot function. That is why humans can't see a dim star if they stare directly at it, but if the gaze is shifted to one side or the other, it can be seen. Shifting the gaze moves the image of the star from the fovea centralis, where it does not

provide enough light to stimulate the cones, to the periphery, where it can affect the more sensitive rods.

Rods and cones synapse with about 6 million neurons called **bipolar cells** (**Figure 17-7a**). These cells in turn synapse within the layer of the 1 million neurons called **ganglion cells**, which lie adjacent to the posterior cavity. A network of **horizontal cells** extends across the neural layer of the retina at the level of the synapses between photoreceptors and bipolar cells. A comparable network of **amacrine** (AM-ah-krin) **cells** occurs where bipolar cells synapse with ganglion cells. Horizontal and amacrine cells can facilitate or inhibit communication between photoreceptors and ganglion cells, altering the sensitivity of the retina. These cells play an important role in the eye's adjustment to dim or brightly lit environments.

Neural Layer: The Optic Disc. Axons from an estimated 1 million ganglion cells converge on the **optic disc**, a circular region just medial to the fovea centralis. The optic disc is the origin of the optic nerve (II). From this point, the axons turn, penetrate the wall of the eye, and proceed toward the diencephalon (**Figure 17-7c**). The *central retinal artery* and *central retinal vein*, which supply the retina, pass through the center of the optic nerve, and emerge on the surface of the optic disc (**Figure 17-7c**).

The optic disc has no photoreceptors or other structures typical of the rest of the retina. Because light striking the optic disc goes unnoticed, this area is commonly called the **blind spot**. Why isn't a blind spot in the field of vision seen?

Clinical Note Diabetic Retinopathy

A *retinopathy* is a disease of the retina. **Diabetic retinopathy** develops in many people with *diabetes mellitus*, an endocrine disorder that interferes with glucose metabolism. Diabetes affects many systems and is a risk factor for heart disease. Diabetic retinopathy develops over years. It results from the blockage of small retinal blood vessels, followed by excessive growth of abnormal blood vessels. These blood vessels invade the retina and extend into the space between its two parts—the pigmented layer and the neural layer. Visual acuity is gradually lost through damage to photoreceptors (which are deprived of oxygen and nutrients), leakage of blood into the posterior cavity, and the overgrowth of blood vessels. Laser therapy can seal leaking vessels and block new vessel growth. The posterior cavity can be drained and the cloudy fluid replaced by a suitably clear substitute. However, these are only temporary, imperfect fixes. Diabetic retinopathy is the primary cause of blindness in the United States.

Figure 17-7 The Organization of the Retina.

a The cellular organization of the retina. The photoreceptors are closer to the choroid than they are to the posterior cavity (vitreous chamber).

b A photograph of the retina as seen through the pupil.

c The optic disc in diagrammatic sagittal section.

Amacrine cells are found where bipolar cells synapse with what other types of cells? Horizontal cells are found where bipolar cells synapse with what other types of cells?

The reason is that involuntary eye movements keep the visual image moving and allow the brain to fill in the missing information. However, try the simple activity in **Figure 17-8** to prove that a blind spot really exists.

The Chambers of the Eye

Recall that the ciliary body and lens divide the interior of the eye into a large posterior cavity and a smaller anterior cavity made up of anterior and posterior chambers (**Figure 17-5c**). Both chambers are filled with aqueous humor. The posterior cavity also contains aqueous humor, but the gelatinous *vitreous body* takes up most of its volume.

Figure 17-8 A Demonstration of the Presence of a Blind Spot. Close your left eye and stare at the plus sign with your right eye, keeping the plus sign in the center of your field of vision. Begin with the page a few inches away from your eye, and gradually increase the distance. The dot will disappear when its image falls on the blind spot, at your optic disc. To check the blind spot in your left eye, close your right eye and repeat the sequence while you stare at the dot.

Aqueous Humor. **Aqueous humor** is a fluid that circulates within the anterior cavity. It passes from the posterior chamber to the anterior chamber through the pupil (**Figure 17-9**). It also freely diffuses through the posterior cavity and across the surface of the retina. Its composition resembles that of cerebrospinal fluid.

Aqueous humor forms through active secretion by epithelial cells of the ciliary body's ciliary processes. The epithelial cells regulate its composition. The circulation of aqueous humor provides an important route for nutrient and waste transport. It also serves as a fluid cushion.

Clinical Note Detached Retina

Photoreceptors depend entirely on the diffusion of oxygen and nutrients from blood vessels in the choroid. In a **detached retina**, the neural layer of the retina becomes separated from the pigmented layer. This condition can result from a variety of factors, including a sudden hard impact to the eye. This is a medical emergency—unless the two parts of the retina are reattached, the photoreceptors will degenerate and vision will be lost. Reattachment involves “welding” the two parts together using laser beams focused through the cornea. These beams heat the two parts, fusing them together at several points around the retina. However, the procedure destroys the photoreceptors at the “welds,” producing permanent blind spots.

Figure 17-9 The Circulation of Aqueous Humor. Aqueous humor, which is secreted at the ciliary body, circulates through the posterior and anterior chambers before it is reabsorbed through the scleral venous sinus.

Because the eyeball is filled with aqueous humor, pressure provided by this fluid helps retain the eye's shape. Fluid pressure also stabilizes the position of the retina, pressing the neural layer against the pigmented layer. In effect, the aqueous humor acts like the air inside a balloon.

The eye's **intra-ocular pressure** can be measured in the anterior chamber, where the fluid pushes against the inner surface of the cornea. Intra-ocular pressure is usually checked by applanation tonometry whereby a small, flat disk gently contacts the anesthetized cornea to measure the tension. Normal intraocular pressure ranges from 12 to 21 mm Hg.

Aqueous humor is secreted into the posterior chamber at a rate of 1–2 mL per minute. It leaves the anterior chamber at the same rate. After filtering through a network of connective tissues located near the base of the iris, aqueous humor enters the **scleral venous sinus** (*canal of Schlemm*), a passageway that extends completely around the eye at the level of the corneo-scleral junction. Collecting channels then deliver the aqueous humor to veins in the sclera.

17 Aqueous humor is removed and recycled within a few hours of its formation. The rate of removal normally keeps pace with the rate of generation at the ciliary processes.

The Vitreous Body. The posterior cavity of the eye contains the **vitreous body**, a gelatinous mass. Its fluid portion is called **vitreous humor**. The vitreous body helps stabilize the shape of the eye. Otherwise, the eye might distort as the extrinsic eye muscles change its position within the orbit. Specialized cells

embedded in the vitreous body produce the collagen fibers and proteoglycans that account for the gelatinous consistency of this mass. Unlike the aqueous humor, the vitreous body is formed during development and is not replaced.

The Lens

The **lens** is a transparent, biconvex (outwardly curving) flexible disc that lies posterior to the cornea and is held in place by the ciliary zonule that originates on the ciliary body of the choroid (**Figure 17-9**). The primary function of the lens is to focus the visual image on the photoreceptors. The lens does so by changing its shape.

The lens consists of concentric layers of cells. A dense fibrous capsule covers the entire lens. Many of the capsular fibers are elastic. Unless an outside force is applied, they will contract and make the lens spherical. Around the edges of the lens, these capsular fibers intermingle with those of the ciliary zonule.

The cells in the interior of the lens are called **lens fibers**. These highly specialized cells have lost their nuclei and other organelles. They are long and slender and are filled with transparent proteins called **crystallins**. These proteins give the lens both its clarity and focusing power. Crystallins are extremely stable proteins—they remain intact and functional for a lifetime.

The transparency of the lens depends on the crystallin proteins maintaining a precise combination of structural and biochemical characteristics. Because these proteins are not renewed, any modifications they undergo over time can accumulate and result in the lens losing its transparency. This condition is known as a **cataract**. Cataracts can result from injuries, UV radiation, or reaction to drugs. **Senile cataracts**, however, are a natural consequence of aging and are the most common form.

Over time, the lens turns yellowish and eventually begins to lose its transparency. As the lens becomes “cloudy,” the individual needs brighter and brighter light for reading. Visual clarity begins to fade. If the lens becomes completely opaque, the person will be functionally blind, even though the photoreceptors are normal.

Cataract surgery involves removing the lens, either intact or after it has been shattered with high-frequency sound waves. The missing lens is then replaced by an artificial substitute. Vision is then fine-tuned with glasses or contact lenses.

+ Clinical Note Glaucoma

If aqueous humor cannot drain into the scleral venous sinus, intra-ocular pressure rises due to the continued production of aqueous humor, and **glaucoma** results. The sclera is a fibrous coat, so it cannot expand like an inflating balloon, but it does have one weak point—the optic disc, where the optic nerve penetrates the wall of the eye. Gradually the increasing pressure pushes the optic nerve outward, damaging its nerve fibers. When the intra-ocular pressure has increased to about twice the normal level, the distortion of the optic nerve fibers begins to interfere with the propagation of action potentials, and peripheral vision begins to deteriorate. If this condition is not corrected, tunnel vision and then complete blindness may result.

Although the primary factors responsible are not known, glaucoma is relatively common. For this reason, most eye exams include a test of intra-ocular pressure. Glaucoma may be treated by topical drugs that constrict the pupil and tense the edge of the iris, making the surface more permeable to aqueous humor. Surgical correction involves perforating the wall of the anterior chamber to encourage drainage.

17-4 The focusing of light on the retina leads to the formation of a visual image

Learning Outcome Describe how refraction and the focusing of light on the retina lead to vision.

Each of the millions of photoreceptors monitors the light striking a specific site on the retina. The processing of information from all the receptors produces a visual image. To understand how this happens, we turn our attention to the properties of light itself, and how light interacts with the structures of our eyes.

An Introduction to Light

Light energy is a form of *radiant energy* that travels in waves with characteristic *wavelengths* (distances between wave peaks). Let's consider the relationship between wavelengths and color and learn what happens when light rays encounter an object such as our eyes.

Wavelength and Color

Our eyes are sensitive to wavelengths of 700–400 nm, the spectrum of visible light. To remember this spectrum, as seen in a rainbow, use the acronym ROY G. BIV (**R**ed, **O**range, **Y**ellow, **G**reen, **B**lue, **I**ndigo, **V**iolet). Visible light is also described as being made up of photons, small energy packets with characteristic wavelengths. Photons of red light carry the least energy and have the longest wavelength. Photons from the violet portion of the spectrum contain the most energy and have the shortest wavelength.

Refraction and Focusing of Light

The eye is often compared to a camera. To provide useful information, the lens of the eye, like a camera lens, must *focus* the arriving image. To say that an image is “in focus” means that the light rays arriving from an object strike the sensitive surface of the retina (or the semiconductor device that records light electronically in digital cameras) in precise order to form a miniature image of the object. If the rays are not perfectly focused, the image is blurry.

Focusing normally occurs in two steps, as light passes first through the cornea and then the lens. To focus the light on the retina, the lens must change shape, or undergo *accommodation*.

Refraction. Light is **refracted**, or bent, when it passes from one medium to another medium with a different density. This effect is demonstrated by sticking a pencil into a glass of water. The shaft of the pencil appears to bend sharply at the air–water interface. This effect occurs when the light reflected off the pencil shaft is refracted as it passes into the air from the much denser water.

In the human eye, the greatest amount of refraction occurs when light passes from the air into the corneal tissues, which have a density close to that of water. When a person opens their eyes under water, they cannot see clearly because refraction at the corneal surface has been largely eliminated. Light passes unrefracted from one watery medium to another.

Additional refraction takes place when the light passes from the aqueous humor in the anterior chamber into the relatively dense lens. The lens provides the extra refraction needed to focus the light rays from an object toward a **focal point**—a specific point of intersection on the retina.

The distance between the center of the lens and its focal point is the **focal distance** of the lens. Whether in the eye or in a camera, the focal distance is determined by two factors:

- *The Distance of the Object from the Lens.* The closer an object is to the lens, the longer the focal distance (**Figure 17–10a,b**).
- *The Shape of the Lens.* The rounder the lens, the more refraction occurs. So a very round lens has a shorter focal distance than a flatter one (**Figure 17–10b,c**).

If light passing through the cornea and lens is not refracted properly, the visual image will be distorted. In the condition called **astigmatism**, the degree of curvature in the cornea or lens varies from one axis to another. Minor astigmatism is very common. The image distortion may be so minimal that people are unaware of the condition.

Figure 17–10 Factors Affecting Focal Distance. Light rays from a source are refracted when they reach the lens of the eye. The rays are then focused onto a single focal point.

Figure 17–11 Accommodation. For the eye to form a sharp image, the lens becomes rounder for close objects and flatter for distant objects.

Accommodation. **Accommodation** is the automatic adjustment of the eye to give us clear vision (**Figure 17–11**). During accommodation, the lens becomes rounder to focus the image of a nearby object on the retina. The lens becomes flatter to focus the image of a distant object on the retina.

How does the lens change shape? The lens is held in place by the ciliary zonule that originates at the ciliary body. Smooth muscle fibers in the ciliary body act like sphincter muscles. When viewing a distant object, the ciliary muscle relaxes, the ciliary zonule pulls at the circumference of the lens, and the lens becomes flatter (**Figure 17–11a**). When viewing a nearby object, the ciliary muscle contracts, and the ciliary body moves toward the lens. This movement reduces the tension in the ciliary zonule, allowing the elastic capsule to pull the lens into a more rounded shape with greater refractive (bending) power (**Figure 17–11b**).

The greatest amount of refraction is required to view objects that are very close to the lens. The inner limit of clear vision, known as the *near point of vision*, is determined by the degree of elasticity in the lens. Children can usually focus on something 7–9 cm (3–4 in.) from the eye, but over time the lens tends to become stiffer and less responsive. A young adult can usually focus on objects 15–20 cm (6–8 in.) away. As we age, this distance gradually increases. The near point at age 60 is typically about 83 cm (33 in.).

Image Formation and Reversal

We have been discussing light that originates at a single point, either near or far from the viewer. However, an object humans see is really a complex light source that must be treated as several individual points. Light from each point is focused on the retina as in **Figure 17–12a,b**. The result is a miniature image of the original, but the image arrives upside down and reversed from left to right.

Why does an image arrive upside down? Consider **Figure 17–12c**, a sagittal section through an eye that is looking at a telephone pole. The image of the top of the pole lands at the bottom of the retina, and the image of the bottom hits the top of the retina. Now consider **Figure 17–12d**, a horizontal

section through an eye that is looking at a picket fence. The image of the left edge of the fence falls on the right side of the retina, and the image of the right edge falls on the left side of the retina. The brain compensates for this image reversal, so there is no awareness of any difference between the orientation of the image on the retina and that of the object.

Visual Acuity

How well a person can see, or their **visual acuity**, is rated by comparison to a “normal” standard. The standard vision rating of 20/20 is defined as the level of detail seen at 20 feet by a person with normal vision. That is, a person with a visual acuity of 20/20 sees clearly at 20 feet what should normally be seen at 20 feet. Vision rated as 20/15 is better than average, because at 20 feet the person can see details that would be clear to a normal eye only at 15 feet. Conversely, a person with 20/30 vision must be 20 feet from an object to discern details that a person with normal vision could make out at 30 feet.

When visual acuity falls below 20/200, even with the help of glasses or contact lenses, the individual is legally blind. It is estimated that there are 1.3 million legally blind people in the United States, and more than half of those are over 65 years old. The term *blindness* implies a total absence of vision due to damage to the eyes or to the optic pathways. Common causes of blindness include diabetes mellitus, cataracts, glaucoma, corneal scarring, retinal detachment, accidental injuries, and hereditary factors that are still not understood.

An abnormal blind spot, or **scotoma** (skō-TŌ-muh), may appear in the field of vision at positions other than at the optic disc. A scotoma is permanent and may result from compression of the optic nerve, damage to photoreceptors, or central damage along the visual pathway.

Floaters are small spots that drift across the field of vision. They are generally temporary and result from blood cells or cellular debris in the vitreous body. For example, little spots that appear after staring at a blank wall or a white sheet of paper are examples of these floaters. **Spotlight Figure 17–13** describes common visual problems.

Figure 17–12 Image Formation. These illustrations are not drawn to scale because the fovea centralis occupies a small area of the retina, and the projected images are very tiny. As a result, the crossover of light rays is shown in the lens, but it occurs very close to the fovea centralis.

a Light from a point at the top of an object is focused on the lower retinal surface.

b Light from a point at the bottom of an object is focused on the upper retinal surface.

c Light rays projected from a vertical object show why the image arrives upside down. (Note that the image is also reversed.)

d Light rays projected from a horizontal object show why the image arrives with a left and right reversal. The image also arrives upside down.

10. Define focal point.
11. When the lens of the eye is more rounded, is the person looking at an object that is close to them or far from them?

See the blue Answers tab at the back of the book.

17-5 Photoreceptors transduce light into electrical signals that are then processed in the visual cortex

Learning Outcome Explain color and depth perception, describe how light stimulates the production of nerve impulses, and trace the visual pathways to their destinations in the brain.

How does our special sense of vision work? Let's begin to answer this question by examining the structure of photoreceptors and then the physiology of vision, the way in which photoreceptors function. Finally, we will consider the structure and function of the visual pathways.

Physiology of Vision

The rods and cones of the retina are called photoreceptors because they detect *photons*, basic units of visible light. Rods

provide the central nervous system with information about the presence or absence of photons, with little regard to their wavelength. Cones provide information about the wavelength of arriving photons, giving us the perception of color.

Anatomy of Photoreceptors: Rods and Cones

Figure 17–14a compares the structures of **photoreceptors** (rods and cones). The names *rod* and *cone* refer to the shape of each photoreceptor's outer segment. Both rods and cones contain special organic compounds called *visual pigments*. These pigments are in each photoreceptor's outer segment, in flattened membranous plates called *discs*. Please study this figure before reading on.

Physiology of Photoreceptors

Visual pigments can absorb photons; this is the first key step in the process of **photoreception**—the detection of light. This section looks at the function of photoreceptors and the visual pigments they contain.

Visual Pigments. Visual pigments are derivatives of the compound **rhodopsin** (rō-DOP-sin), or *visual purple*, the visual pigment found in rods (**Figure 17–14b**). Rhodopsin consists of a protein, **opsin**, bound to the pigment **retinal** (RET-ih-nal),

A camera focuses an image by moving the lens toward or away from the film or semiconductor device. This method cannot work in our eyes, because the distance from the lens to the macula cannot change. We focus images on the retina by changing the shape of the lens to keep the focal distance constant, a process called **accommodation**.

The eye has a fixed focal distance and focuses by varying the shape of the lens.

A camera lens has a fixed size and shape and focuses by varying the distance to the film or semiconductor device.

Emmetropia (normal vision)

In the healthy eye, when the ciliary muscle is relaxed and the lens is flattened, a distant image will be focused on the retina's surface. This condition is called **emmetropia** (*emmetro-*, proper + *opia*, vision).

Myopia (nearsightedness)

If the eyeball is too deep or the resting curvature of the lens is too great, the image of a distant object is projected in front of the retina. The person will see distant objects as blurry and out of focus. Vision at close range will be normal because the lens is able to round as needed to focus the image on the retina.

Myopia corrected with a diverging, concave lens

Hyperopia (farsightedness)

If the eyeball is too shallow or the lens is too flat, hyperopia results. The ciliary muscle must contract to focus even a distant object on the retina. And at close range the lens cannot provide enough refraction to focus an image on the retina. Older people become farsighted as their lenses lose elasticity, a form of hyperopia called **presbyopia** (*presbys*, old man).

Hyperopia corrected with a converging, convex lens

Surgical Correction

Variable success at correcting myopia and hyperopia has been achieved by surgery that reshapes the cornea. In

photorefractive keratectomy (PRK) a computer-guided laser shapes the cornea to exact specifications. The entire procedure can be done in less than a minute. A variation on PRK is called **LASIK (Laser-Assisted in-Situ Keratomileusis)**. In this procedure the interior layers of the cornea are reshaped and then re-covered by the flap of original outer corneal epithelium. Roughly 70% of LASIK patients achieve normal vision, and LASIK has become the most common form of refractive surgery.

Even after surgery, many patients still need reading glasses, and both immediate and long-term visual problems can occur.

Figure 17-14 Structure of Rods, Cones, and the Rhodopsin Molecule.

which is synthesized from **vitamin A**. All rods contain the same form of opsin. Cones contain the same retinal pigment that rods do, but the retinal is attached to different forms of opsin.

We have three types of cones—**blue cones**, **green cones**, and **red cones**. Each type has a different form of opsin and is sensitive to a different range of wavelengths. Their sensitivities overlap, but each type is most sensitive to a specific portion of the visual spectrum (**Figure 17-15**). Their stimulation in various combinations is the basis for color vision. In an individual with normal vision, the cone population consists of 16% blue cones, 10% green cones, and 74% red cones.

The process of photoreception by visual pigments is described in **Spotlight Figure 17-16**.

Figure 17-15 Cone Types and Sensitivity to Color. This graph compares the absorptive characteristics of blue, green, and red cones with those of typical rods.

RESTING STATE DARKNESS

Sodium entry through gated channels produces dark current

The plasma membrane in the outer segment of the photoreceptor contains chemically gated sodium ion channels. In darkness, these gated channels are kept open in the presence of cyclic guanosine monophosphate (cGMP), a derivative of the high-energy compound guanosine triphosphate (GTP). Because the channels are open, the membrane potential is approximately -40 mV, rather than the -70 mV typical of resting neurons. At the -40 mV membrane potential, the photoreceptor is continuously releasing glutamate across synapses at the inner segment. The inner segment also continuously pumps sodium ions out of the cytosol.

The movement of ions into the outer segment, on to the inner segment, and out of the cell is known as the **dark current**.

1

Opsin activation occurs

The bound retinal molecule has two possible configurations: the 11-*cis* form and the 11-*trans* form.

The molecule is in the curved 11-*cis* form; as light is absorbed, it changes to the more linear 11-*trans* form. This change activates the opsin molecule.

ACTIVE STATE IN LIGHT

2 Opsin activates transducin, which in turn activates phosphodiesterase (PDE)

Transducin is a G protein.

In this case, opsin activates transducin, and transducin in turn activates **phosphodiesterase (PDE)**.

3 Cyclic GMP levels decrease and chemically gated sodium ion channels close

Phosphodiesterase is an enzyme that breaks down cGMP.

The removal of cGMP from the chemically gated sodium ion channels results in their inactivation. The rate of Na^+ entry into the cytosol then decreases.

4 Dark current is reduced and rate of neurotransmitter release decreases

The reduction in the rate of Na^+ entry reduces the dark current. At the same time, active transport continues to export Na^+ from the cytosol. When the sodium ion channels close, the membrane potential decreases toward -70 mV. As the plasma membrane hyperpolarizes, the rate of neurotransmitter release decreases. This decrease signals the adjacent bipolar cell that the photoreceptor has absorbed a photon. After absorbing a photon, retinal does not spontaneously revert to the 11-cis form. Instead, the entire rhodopsin molecule must be broken down into retinal and opsin, in a process called **bleaching**. It is then reassembled.

Figure 17-17 Bleaching and Regeneration of Visual Pigments.

Bleaching and Regeneration of Visual Pigments. Rhodopsin is broken apart into retinal and opsin through a process called **bleaching** (Figure 17-17). Before recombining with opsin, the retinal must be enzymatically converted back to its original shape. This conversion requires energy in the form of ATP (adenosine triphosphate), and it takes time. Then rhodopsin is regenerated by being recombined with opsin. Bleaching and regeneration is a cyclical process.

Bleaching contributes to the lingering visual impression seen after a camera's flash. Following intense exposure to light, a photoreceptor cannot respond to further stimulation until its rhodopsin molecules have been regenerated. As a result, a "ghost" afterimage remains on the retina. We seldom notice bleaching under ordinary circumstances, because our eyes are constantly making small, involuntary changes in position that move the image across the retina's surface.

While the rhodopsin molecule is being reassembled (regenerated), membrane permeability of the outer segment is returning to normal. Opsin is inactivated when bleaching occurs, and the breakdown of cGMP halts as a result. As other enzymes generate cGMP in the cytosol, the chemically gated sodium ion channels reopen.

Synthesis and Recycling of Visual Pigments. The body contains vitamin A reserves sufficient to synthesize visual pigments for several months. A significant amount is stored in the cells of the pigmented layer of the retina.

New discs containing visual pigment are continuously assembled at the base of the outer segment of both rods and cones. A completed disc then moves toward the tip of the segment. After about 10 days, the disc is shed in droplets of cytoplasm. The pigment cells then absorb droplets with shed discs, break down the disc membrane's components, and reconvert the retinal to vitamin A. The pigment cells then store the vitamin A for later transfer to the photoreceptors.

If dietary sources are inadequate, these reserves are gradually used up and the amount of visual pigment in the photoreceptors begins to decline. Daylight vision is affected, but in daytime the light is usually bright enough to stimulate any visual pigments that remain within the densely packed cone population of the fovea centralis. As a result, the problem first becomes apparent at night, when the dim light proves insufficient to activate the rods. This condition, known as **night blindness**, or **nyctalopia**, can be treated by eating a diet rich in vitamin A. The body can convert the carotene pigments in

many vegetables to vitamin A. Carrots are a particularly good source of carotene, leading to the adage that carrots are good for the eyes.

Light and Dark Adaptation of Visual Pigments

The sensitivity of the visual system varies with the intensity of illumination. After 30 minutes or more in the dark, almost all visual pigments will have recovered from photobleaching. This state in which the pigments are fully receptive to stimulation is called the **dark-adapted state**. When dark adapted, the visual system is extremely sensitive. For example, a single rod will hyperpolarize in response to a single photon of light. Even more remarkable, if as few as seven rods absorb photons at one time, a person will see a flash of light.

When the lights first come on in a dark room, they seem almost unbearably bright, but over the next few minutes eye sensitivity decreases as bleaching occurs. Eventually, the rate of bleaching is balanced by the rate at which the visual pigments reassemble. This condition is the **light-adapted state**. Moving from the depths of a cave to the full sunlight of midday would decrease receptor sensitivity by a factor of 25,000.

The autonomic nervous system adjusts to incoming light. The pupils constrict, reducing the amount of light entering the eye to 1/30th the maximum dark-adapted level. Conversely, dilating the pupil fully can produce a 30-fold increase in the amount of light entering the eye. In addition, facilitating some of the synapses along the visual pathway can perhaps triple its sensitivity. In these ways, the sensitivity of the entire system may increase by a factor of more than 1 million.

Retinitis pigmentosa (RP) is an inherited disease characterized by progressive retinal degeneration. As the visual receptors gradually deteriorate, blindness eventually results. The mutations that are responsible change the structure of the photoreceptors—specifically, the visual pigments of the membrane discs. We do not know how the altered pigments lead to the destruction of photoreceptors.

Color Vision

An ordinary lightbulb or the sun emits photons of all wavelengths, which stimulate both rods and cones. The eyes also detect photons that reach the retina after they bounce off objects in the area. If photons of all visible wavelengths bounce off an object, the object will appear white. If the object absorbs all the photons (so that none reaches the retina), the object will appear black.

An object appears to have a particular color when it reflects (or transmits) photons from one portion of the visible spectrum and absorbs the rest. Color discrimination takes place through the integration of information arriving from all three types of cones: blue, green, and red. A person who sees these three colors has normal color vision. For example, humans perceive yellow from a combination of inputs from highly stimulated green cones, less strongly stimulated red cones, and relatively

unaffected blue cones (**Figure 17-15**). If all three cone populations are stimulated, the color is perceived as white. White is also perceived if rods, rather than cones, are stimulated. For this reason, everything appears black and white when entering dimly lit surroundings or navigating by starlight.

Persons who have a color vision deficiency (*color blindness*) are unable to distinguish certain colors. The standard tests for color vision involve picking numbers or letters out of an image made up of colored dots, such as the one shown in **Figure 17-18**. Color blindness occurs when one or more types of cones are non-functional. The cones may be absent, or they may be present but unable to manufacture the necessary visual pigments. In the most common type of color blindness (red-green color blindness), the red cones are missing, so the individual cannot distinguish red light from green light. Inherited color blindness involving one or two cone pigments is not unusual. Ten percent of all males show some color blindness, but only about 0.67% of all females have color blindness. Total color blindness is extremely rare. Only one person in 300,000 does not manufacture any cone pigments. The inheritance of color blindness is considered in Chapter 29.

The Visual Pathways

The visual pathways begin at the photoreceptors and end at the *visual cortex* of the cerebral hemispheres. In other sensory pathways we have examined, only one synapse lies between a receptor and a sensory neuron that delivers information to the CNS. In the visual pathways, the message must cross two synapses (photoreceptor to bipolar cell, and bipolar cell to ganglion cell). Only then does it move toward the brain. The extra synapse increases the synaptic delay, but it provides an opportunity for the processing and integration of visual information before it leaves the retina. Let's look at both retinal and cortical processing of visual signals.

Figure 17-18 A Standard Test for Color Vision. People who lack one or more types of cones cannot see the number 12 in this pattern.

Processing by the Retina

Each of the millions of photoreceptors in the retina monitors a specific receptive field. Given that there are also millions of bipolar and ganglion cells, a considerable amount of convergence must take place at the start of the visual pathway. The degree of convergence differs between rods and cones; rods have a large degree of convergence, whereas cones typically show very little. Regardless of the amount of convergence, each ganglion cell monitors a specific portion of the field of vision, its *receptive field*.

As many as a thousand rods may pass information by their bipolar cells to a single ganglion cell. The large ganglion cells that monitor rods are called **M cells** (*magnocellular neurons*). They provide information about the general form of an object, motion, and shadows in dim lighting. Because so much convergence occurs, the activation of an M cell indicates that light has arrived in a general area rather than at a specific location.

The loss of specificity due to convergence from rod stimuli is partially overcome by the fact that the activity of ganglion cells varies according to the pattern of activity in their receptive field, which is usually shaped like a circle. Typically, a ganglion cell responds differently to stimuli that arrive in the center of its receptive field than to stimuli that arrive at the edges (Figure 17–19). Some ganglion cells, called **on-center neurons**, are excited by light arriving in the center of their receptive field and are inhibited when light strikes its edges. Others, known as **off-center neurons**, are inhibited by light in the central zone, but are stimulated by light at the edges. On-center and off-center neurons provide information about which portion of their receptive field is illuminated. This kind of retinal processing within ganglion receptive fields improves the detection of the edges of objects within the field of vision.

The processing of visual stimuli from cones is different because of their lack of convergence. In the fovea centralis, the ratio of cones to ganglion cells is 1:1. The ganglion cells that monitor cones, called **P cells** (*parvocellular neurons*), are smaller and more numerous than M cells. P cells are active in bright light, and they provide information about edges, fine detail, and color. Because little convergence occurs, the activation of a P cell means that light has arrived at one specific location. As a result, cones provide more precise information about a visual image than do rods. We could say that images formed by rods have a grainy, pixelated appearance that blurs details. By contrast, images produced by cones are sharp, clear, and of high resolution.

Central Processing of Visual Information

Axons from the entire population of ganglion cells converge on the optic disc, penetrate the wall of the eye, and proceed toward the diencephalon as the optic nerve (II). The two optic nerves, one from each eye, reach the diencephalon after

Figure 17–19 Convergence and Ganglion Cell Function.

Photoreceptors are organized in groups within a receptive field. Each ganglion cell monitors a well-defined portion of that field. Some ganglion cells (on-center neurons, labeled A) respond strongly to light arriving at the center of their receptive field. Others (off-center neurons, labeled B) respond most strongly to illumination of the edges of their receptive field.

a partial crossover at the **optic chiasm** (Figure 17–20). From that point, approximately half the fibers proceed toward the lateral geniculate body of the same side of the brain, whereas the other half cross over to reach the lateral geniculate body of the opposite side. From each lateral geniculate body, visual information travels to the **visual cortex** in the occipital lobe of the cerebral hemisphere on that side. The bundle of projection fibers linking the lateral geniculates with the visual cortex is known as the **optic radiation**. Collaterals from the fibers synapsing in the lateral geniculate continue to subconscious processing centers in the diencephalon and brainstem.

Figure 17–20 The Visual Pathways. The crossover of some nerve fibers occurs at the optic chiasm. As a result, each hemisphere receives visual information from the medial half of the field of vision of the eye on that side, and from the lateral half of the field of vision of the eye on the opposite side. Visual association areas integrate this information to develop a composite picture of the entire field of vision.

The Field of Vision. Humans perceive visual images due to the integration of information that arrives at the visual cortex of the occipital lobes. Each eye receives a slightly different visual image. One reason is that the foveae in the two eyes are 5–7.5 cm (2–3.0 in.) apart. Another is that the nose and eye socket block

the view of the opposite side. **Depth perception** is the ability to judge depth or distance by interpreting the three-dimensional relationships among objects in view. The brain resolves it by comparing the relative positions of objects within the images received by the two eyes.

When looking straight ahead, the visual images from the left and right eyes overlap (**Figure 17–20**); the combined areas are the **field of vision**. The image received by the fovea centralis of each eye lies in the center of the region of overlap. A vertical line drawn through the center of this region marks the division of visual information at the optic chiasm. Visual information from the left half of the combined field of vision reaches the visual cortex of the right occipital lobe. Visual information from the right half of the combined field of vision arrives at the visual cortex of the left occipital lobe.

The cerebral hemispheres thus contain a map of the entire field of vision. As in the case of the somatosensory cortex, the map does not faithfully duplicate the areas within the sensory field. For example, the area assigned to the macula and fovea centralis covers about 35 times the surface it would cover if the map were proportionally accurate. The map is also upside down and reversed, duplicating the orientation of the visual image at the retina.

The Brainstem and Visual Processing. Many centers in the brainstem receive visual information, either from the lateral geniculate bodies or through collaterals from the optic tracts. Collaterals that bypass the lateral geniculates synapse in the superior colliculi or in the hypothalamus. The superior colliculi of the midbrain issue motor commands that control unconscious eye, head, or neck movements in response to visual stimuli. For example, the pupillary reflexes and reflexes that control eye movement are triggered by collaterals carrying information to the superior colliculi.

Visual inputs to the suprachiasmatic nucleus of the hypothalamus affect the function of other brainstem nuclei. The suprachiasmatic nucleus and the *pineal gland* of the epithalamus receive visual information and use it to establish a **circadian** (ser-KĀ-dē-an) **rhythm** (*circa*, about + *dies*, day), which is a daily pattern of visceral activity that is tied to the day–night cycle. This circadian rhythm affects metabolic rate, endocrine function, blood pressure, digestive activities, sleep–wake cycle, and other physiological and behavioral processes.

17-6 Equilibrium sensations monitor head position and movement, while hearing involves the detection and interpretation of sound waves

Learning Outcome Describe the structures of the external, middle, and internal ear, explain their roles in equilibrium and hearing, and trace the pathways for equilibrium and hearing to their destinations in the brain.

Equilibrium sensations inform us of the position of the head in space by monitoring gravity, linear acceleration, and rotation. *Hearing* enables us to detect and interpret sound waves. Both senses are provided by the *internal ear*, a receptor complex located in the temporal bone of the skull.

The basic receptor mechanism for both senses is the same. The receptors, called *hair cells*, are mechanoreceptors. The complex structure of the internal ear and the different arrangement of accessory structures enable hair cells to respond to different stimuli. Once the hair cells have transduced these stimuli,

equilibrium input is sent to the brainstem, while hearing input is sent to the brainstem and/or *auditory cortex* for processing and possible response. In this section, we describe the anatomy of the ear before discussing the processes of equilibrium and hearing.

Anatomy of the Ear

The **ear** is divided into three anatomical regions: the external ear, the middle ear, and the internal ear (**Figure 17-21**). The *external ear*—the visible portion of the ear—collects and directs sound waves toward the *middle ear*, a chamber located within the petrous part of the temporal bone. Structures of the middle ear collect sound waves and transmit them to an appropriate portion of the *internal ear*, which contains the sensory organs for both hearing and equilibrium.

The External Ear

The **external ear** includes the outer fleshy and cartilaginous **auricle** (OR-ih-kul), or *pinna*, which surrounds a passageway

17

Figure 17-21 The Anatomy of the Ear. The dashed lines indicate the boundaries separating the three anatomical regions of the ear (external, middle, and internal).

The tympanic cavity and auditory ossicles are found in which anatomical region of the ear?

called the **external acoustic meatus**, or *auditory canal*. The auricle protects the opening of the canal and provides directional sensitivity. Sounds coming from behind the head are blocked by the auricle, but sounds coming from the side or front are collected and channeled into the external acoustic meatus. (When someone “cups” their ear with a hand to hear a faint sound more clearly, they are exaggerating this effect.) The external acoustic meatus ends at the **tympanic membrane** (*tympanon*, drum), or *eardrum*. This thin, semitransparent sheet separates the external ear from the middle ear.

The tympanic membrane is very delicate. The auricle and the narrow external acoustic meatus provide some protection for it from accidental injury. In addition, **ceruminous glands**—integumentary glands along the external acoustic

meatus—secrete a waxy material called **cerumen** (*earwax*) that helps keep out foreign objects or small insects. Cerumen also slows the growth of microorganisms and so reduces the chances of infection. In addition, the canal is lined with many small, outwardly projecting hairs. These hairs trap debris and provide increased tactile sensitivity through their root hair plexuses.

The Middle Ear

The **middle ear**, or **tympanic cavity**, is an air-filled chamber separated from the external acoustic meatus by the tympanic membrane (Figure 17-21). The middle ear communicates both with the *nasopharynx* (the superior portion of the pharynx), through the *auditory tube*, and with the mastoid air cells, through several small connections (Figure 17-22a).

Figure 17-22 The Middle Ear.

The **auditory tube** (also called the *pharyngotympanic tube* or the *Eustachian tube*) is about 4 cm (1.6 in.) long and consists of two portions. The portion near the connection to the middle ear is narrow and is supported by elastic cartilage. The portion near the opening into the nasopharynx is broad and funnel shaped. The auditory tube equalizes pressure on either side of the tympanic membrane. Unfortunately, the auditory tube can also allow microorganisms to travel from the nasopharynx into the middle ear. Invasion by microorganisms can lead to an unpleasant middle ear infection known as *otitis media*.

The Auditory Ossicles. The middle ear contains three tiny ear bones, collectively called **auditory ossicles** (OS-ih-kulz). These ear bones connect the tympanic membrane with the internal ear (Figure 17-21). The articulations between the auditory ossicles are the smallest synovial joints in the body. Each has a tiny joint capsule and supporting extracapsular ligaments. The three auditory ossicles are the malleus, the incus, and the stapes (Figure 17-22b,c). The **malleus** (*malleus*, hammer) attaches at three points to the interior surface of the tympanic membrane. The **incus** (*incus*, anvil), the middle ossicle, attaches the malleus to the **stapes** (STĀ-pēz; *stapes*, stirrup), the inner ossicle. The edges of the base of the stapes are bound to the edges of the *oval window*, an opening in the temporal bone that surrounds the internal ear.

Muscles of the Middle Ear. When sound waves cause the tympanic membrane to vibrate, the ossicles conduct the vibrations to the internal ear. When we are exposed to very loud noises, two small muscles in the middle ear (Figure 17-22a) protect the tympanic membrane and ossicles from violent movements:

- The **tensor tympani** (TEN-sor tim-PAN-ē) is a short ribbon of muscle originating on the petrous part of the temporal bone and the auditory tube and inserting on the “handle” of the malleus. When the tensor tympani contracts, it pulls the malleus medially, stiffening the tympanic membrane. This increased stiffness reduces the amount of movement possible. The tensor tympani muscle is innervated by motor fibers of the mandibular nerve (V_3), a division of the trigeminal nerve (V).
- The **stapedius** (sta-PĒ-dē-us), innervated by the facial nerve (VII), originates from the posterior wall of the middle ear, and it inserts on the stapes. Contraction of the stapedius pulls on the stapes, reducing its movement at the oval window.

The Internal Ear

The **internal ear** is a winding passageway called a **labyrinth** (*labyrinthos*, network of canals) (Figure 17-23). The superficial contours of the internal ear are formed by a layer of dense bone

Figure 17-23 The Internal Ear.

a A section through one of the semicircular canals, showing the relationship between the bony and membranous labyrinths, and the boundaries of perilymph and endolymph.

b The bony and membranous labyrinths. Areas of the membranous labyrinth containing sensory receptors (ampullary crests, maculae, and spiral organ) are shown in purple.

known as the **bony labyrinth**. The walls of the bony labyrinth are continuous with the surrounding temporal bone. The inner contours of the bony labyrinth are closely followed by the contours of the **membranous labyrinth**, a delicate, interconnected network of fluid-filled tubes. The receptors of the internal ear are found within these tubes.

Between the bony and membranous labyrinths flows **perilymph** (PEHR-ih-limf), while the membranous labyrinth contains **endolymph** (EN-dō-limf) (Figure 17-23a). Perilymph closely resembles cerebrospinal fluid. In contrast, endolymph has electrolyte concentrations that differ from those of typical body fluids. (See Appendix A, Table 1, for a chemical analysis of perilymph, endolymph, and other body fluids.)

We subdivide the bony labyrinth into the *vestibule*, the *semicircular canals*, and the *cochlea* (KOK-lē-ah) (Figure 17-23b). The **vestibule** (VES-tih-byūl) consists of a pair of membranous sacs: the *saccul*e (SAK-yūl) and the *utricle* (YŪ-trih-kul). Receptors in these sacs provide equilibrium sensations. The three **semicircular canals** enclose three slender *semicircular ducts*. The combination of vestibule and semicircular canals is called the *vestibular complex*. The fluid-filled chambers within the vestibule are continuous with those of the semicircular canals.

The **cochlea** (*cochlea*, a snail shell) is a spiral-shaped, bony chamber that contains the *cochlear duct* of the membranous labyrinth. Receptors within the cochlear duct provide the sense of hearing. The duct lies between a pair of perilymph-filled chambers. The entire complex spirals around a central bony hub, much like a snail shell.

The walls of the bony labyrinth consist of dense bone everywhere except at two small areas near the base of the cochlear spiral (Figure 17-21). The **round window** is a thin, membranous partition that separates the perilymph of the cochlear chambers from the air-filled middle ear. Collagen fibers connect the bony margins of the opening known as the **oval window** to the base of the stapes.

Equilibrium

Equilibrium is the state of physical balance. We now describe the structures within the internal ear that enable us to maintain this balance.

The Vestibular Complex and Physiology of Equilibrium

As just noted, receptors of the **vestibular complex** enable equilibrium sensations. In both the semicircular ducts and the vestibule, these receptors are **hair cells**. The hair cells of the semicircular ducts convey information about rotational movements of the head. The hair cells in the saccul and the utricle of the vestibule convey information about body position with respect to gravity and indicate acceleration or deceleration.

The Semicircular Ducts: Rotational Movements. The hair cells of the semicircular ducts are active during angular acceleration or deceleration of the head, but are quiet when the body is motionless. For example, when the head rotates to the left, receptors stimulated in the semicircular ducts indicate how rapid the movement is, and in which direction. The **anterior**, **posterior**, and **lateral semicircular ducts** are continuous with the utricle (Figure 17-24a). Each semicircular duct contains an **ampulla**, an expanded region that contains the receptors. The region in the wall of the ampulla that contains the hair cells is known as the **ampullary crest** (Figure 17-24b). Each ampullary crest is bound to an **ampullary cupula** (KŪ-pū-luh), a gelatinous structure that extends the full width of the ampulla.

Hair cells are always surrounded by supporting cells and monitored by the dendrites of sensory neurons. The free surface of each hair cell supports 80–100 long **stereocilia**, which resemble very long microvilli (Figure 17-24d). Each hair cell in the vestibular complex also contains a single large cilium called a **kinocilium** (kī-nō-SIL-ē-um). At an ampullary crest, the kinocilia and stereocilia of the hair cells are embedded in the ampullary cupula (Figure 17-24b).

Hair cells do not actively move their kinocilia or stereocilia. However, when an external force pushes against these processes, the distortion of the plasma membrane alters the rate at which the hair cell releases neurotransmitters. The action potentials generated in response to these neurotransmitters allow the hair cells to provide information about the direction and strength of mechanical stimuli. The stimuli involved, however, depend on the hair cell's location: gravity or acceleration in the vestibule and rotation in the semicircular canals (or sound in the cochlea). The sensitivities of the hair cells differ because each of these regions has different accessory structures that determine which stimulus will provide the force to deflect the kinocilia and stereocilia.

The ampullary cupula with its hair cells has a density very close to that of the surrounding endolymph, so it essentially floats above the receptor surface. When the head rotates in the plane of a semicircular duct, the movement of endolymph along the length of the duct pushes the ampullary cupula to the side and distorts the receptor processes (Figure 17-24c). Movement of fluid in one direction stimulates the hair cells, and movement in the opposite direction inhibits the hair cells. When the endolymph stops moving, the elastic nature of the ampullary cupula returns it to its normal, unstimulated position.

Even the most complex movement can be analyzed in terms of motion in three rotational planes. Each semicircular duct responds to one of these rotational movements. A horizontal rotation, as in shaking the head “no,” stimulates the hair cells of the lateral semicircular duct. A vertical rotation, such as nodding “yes,” excites the anterior duct, and tilting the head from side to side activates receptors in the posterior duct.

Figure 17-24 The Semicircular Ducts.

The Utricle and Saccule: Position and Linear Acceleration.

The hair cells of the **utricle** and **saccul**e provide position and linear movement sensations, whether the body is moving or stationary. For example, if a person stands with their head tilted to one side, these receptors report the angle involved and whether their head tilts forward or backward. The two chambers are connected by a slender passageway that is continuous with the narrow **endolymphatic duct** (Figure 17-24a). This duct ends in a closed cavity called the **endolymphatic sac**. This sac projects through the dura mater that lines the temporal bone and into the subarachnoid space, where a capillary network surrounds it.

Portions of the endolymphatic duct secrete endolymph continuously, and excess fluid returns to the general circulation at the endolymphatic sac. There the capillaries absorb endolymph removed by a combination of active transport and vesicular transport.

The hair cells of the utricle and saccul are clustered in oval structures called **maculae** (MAK-yū-lē; *macula*, spot) (Figure 17-25a). The **macula of utricle** is sensitive to changes in horizontal movement. The **macula of saccul** is sensitive to

changes in vertical movement. As in the ampullae, the hair cell processes are embedded in a gelatinous structure, here called the **otolithic membrane**. This membrane's surface contains densely packed calcium carbonate crystals called **otoliths** ("ear stones").

The macula of utricle is diagrammed in Figure 17-25b. Its functioning is shown in Figure 17-25c. When the head is in the normal, upright position, the otoliths sit atop the otolithic membrane of macula of utricle 1. Their weight presses on the macular surface, pushing the hair cell processes down rather than to one side or another. When the head is tilted, the pull of gravity on the otoliths shifts them to the side, distorting the hair cell processes and stimulating the macular receptors 2. The change in receptor activity signals the CNS that the head is no longer level.

A similar mechanism accounts for the perception of linear acceleration (or deceleration) when riding in a car that speeds up (or brakes) suddenly. The otoliths lag due to their inertia, and the effect on the hair cells is comparable to tilting the head back (or forward). Under normal circumstances, the nervous system distinguishes between the sensations of tilting and linear acceleration by integrating vestibular sensations with visual information.

Figure 17-25 The Saccul and Utricle.

b The structure of an individual macula of utricle

a The location of the maculae

c A diagram of the functioning of the macula of utricle when the head is held normally 1 and then tilted back 2

Many amusement park rides confuse the sense of equilibrium by combining rapid rotation with changes in position and acceleration while providing restricted or misleading visual information.

Pathways for Equilibrium Sensations

Hair cells of the vestibule and semicircular ducts are monitored by sensory neurons located in adjacent **vestibular ganglia**. Sensory fibers from these ganglia form the **vestibular nerve**, a division of the vestibulocochlear nerve (VIII). These fibers innervate neurons within the pair of **vestibular nuclei** at the boundary between the pons and the medulla oblongata.

The vestibular nuclei have four functions:

- Integrating sensory information about balance and equilibrium that arrives from both sides of the head.
- Relaying information from the vestibular complex to the cerebellum.
- Relaying information from the vestibular complex to the cerebral cortex, providing a conscious sense of head position and movement.
- Sending commands to motor nuclei in the brainstem and spinal cord.

The reflexive motor commands issued by the vestibular nuclei are distributed to the motor nuclei for cranial nerves

involved with eye, head, and neck movements (CN III, IV, VI, and XI). Instructions descending in the *vestibulospinal tracts* of the spinal cord adjust peripheral muscle tone and complement the reflexive movements of the head or neck. These pathways are indicated in **Figure 17–26**.

The automatic movements of the eyes in response to sensations of motion are directed by the *superior colliculi* of the midbrain. These movements attempt to keep the gaze focused on a specific point in space, despite changes in body position and orientation. If the body is turning or spinning rapidly, the eyes will fix on one point for a moment and then jump ahead to another in a series of short, jerky movements.

If either the brainstem or the internal ear is damaged, this type of eye movement can occur even when the body is stationary. Individuals with this condition, which is called **nystagmus** (nis-TAG-mus), have trouble controlling their eye movements. Physicians commonly check for nystagmus by asking patients to watch a small penlight as it is moved across the field of vision.

Hearing

The receptors of the cochlear duct provide a sense of **hearing** that enables humans to detect the quietest whisper yet remain

Figure 17–26 Pathways for Equilibrium Sensations.

Clinical Note Motion Sickness

The signs and symptoms of **motion sickness** are exceedingly unpleasant. They include headache, sweating, facial flushing, nausea, vomiting, and various changes in mental perspective. Motion sickness may result when central processing stations, such as the tectum of the midbrain, receive conflicting sensory information. Why and how these conflicting reports result in nausea, vomiting, and other signs and symptoms are not known. Sitting below decks on a moving boat or reading in a car or airplane tends to provide the necessary conditions. The eyes (which are tracking lines on a page) report that position in space is not changing, but the semicircular ducts report that the body is lurching and turning. To counter this effect, seasick sailors watch the horizon rather than their immediate surroundings, so that their eyes will provide visual confirmation of the movements detected by their internal ears. It is not clear why some individuals are almost immune to motion sickness, but others find travel by boat or plane almost impossible.

Drugs commonly used to prevent motion sickness include dimenhydrinate (Dramamine), scopolamine (Transderm Scop), and promethazine. These drugs depress activity at the vestibular nuclei. Sedatives, such as prochlorperazine (Compazine), may also be effective.

functional in a noisy room. The receptors responsible for auditory sensations are hair cells similar to those of the vestibular complex. However, their placement within the cochlear duct and the organization of the surrounding accessory structures shield them from stimuli other than sound.

In the process of hearing, arriving sound waves are converted into mechanical movements by vibration of the tympanic membrane. These vibrations are then conducted to the internal ear by the auditory ossicles. In the internal ear, the vibrations are converted to pressure waves in fluid, which eventually are detected by the hair cells in the cochlear duct. This sensory information is sent to the *auditory cortex* of the brain to be interpreted. Before discussing the mechanics of this remarkably elegant process, let's study the basic properties of sound, which are key to understanding this process.

An Introduction to Sound

Hearing is the perception of sound, but what is sound? It consists of waves of pressure conducted through a medium such as air or water. In air, each *pressure wave* consists of a region where the air molecules are crowded together and an

Figure 17-27 The Nature of Sound.

a Sound waves (here, generated by a tuning fork) travel through the air as pressure waves.

b A graph showing the sound energy arriving at the tympanic membrane. The distance between wave peaks is the wavelength. The number of waves arriving each second is the frequency, which we perceive as pitch. Frequencies are reported in cycles per second (cps), or hertz (Hz). The amount of energy carried by the wave is its amplitude. The greater the amplitude, the louder the sound.

adjacent zone where they are farther apart (**Figure 17-27a**). These waves are sine waves—that is, S-shaped curves that repeat in a regular pattern. They travel through the air at about 1235 km/h (768 mph).

The *wavelength* of sound is the distance between two adjacent wave crests (peaks), or the distance between two adjacent wave troughs (**Figure 17-27b**). The **frequency** of a sound is the number of waves that pass a fixed reference point in a given time. Physicists use the term **cycles** rather than *waves*. We measure the frequency of a sound in terms of the number of cycles per second (cps), a unit called **hertz (Hz)**. Wavelength and frequency are inversely related.

What we perceive as the **pitch** of a sound is our sensory response to its frequency. A *high-frequency* sound (high pitch, short wavelength) might have a frequency of 15,000 Hz or more. A very *low-frequency* sound (low pitch, long wavelength) could have a frequency of 100 Hz or less.

It takes energy to produce sound waves. When striking a tuning fork, it vibrates, pushing against the surrounding air (**Figure 17-27a**). The frequency of the sound waves produced depends on the tuning fork's frequency, or rate, of vibration.

The harder the tuning fork is struck, the more energy there is. The energy increases the **amplitude**, or height, of the sound wave (**Figure 17-27b**). The amount of energy in a sound wave, its **intensity**, determines how loud it seems. The greater the energy content, the larger the amplitude, and the louder the sound. We report sound energy in **decibels** (DES-ih-belz; dB). **Table 17-1** shows the decibel levels of familiar sounds.

When sound waves strike an object, their energy is a physical pressure. Examples are windows moving in a room where a stereo is blasting. The more flexible the object, the more easily it will respond to the pressure of sound waves. Even soft stereo music will vibrate a sheet of paper held in front of the speaker. Given the right combination of frequencies and amplitudes, an object, including the tympanic membrane, will begin to vibrate at the same frequency as the sound, a phenomenon called *resonance*.

Table 17-1 Intensity of Representative Sounds

Typical Decibel Level	Example	Dangerous Time Exposure
0	Lowest audible sound	
30	Quiet library; soft whisper	
40	Quiet office; living room; bedroom away from traffic	
50	Light traffic at a distance; refrigerator; gentle breeze	
60	Air conditioner at 20 feet; conversation; sewing machine in operation	
70	Busy traffic; noisy restaurant	Some damage if continuous
80	Subway; heavy city traffic; alarm clock at 2 feet; factory noise	More than 8 hours
90	Truck traffic; noisy home appliances; shop tools; gas lawn mower	Less than 8 hours
100	Chain saw; boiler shop; pneumatic drill	2 hours
120	"Heavy metal" rock concert; sandblasting; thunderclap nearby	Immediate danger
140	Gunshot; jet plane	Immediate danger
160	Rocket launching pad	Hearing loss inevitable

Anatomy of the Cochlear Duct

In sectional view (**Figure 17-28**), the **cochlear duct**, or **scala media**, lies between a pair of perilymphatic chambers, or *scalae*: the **scala vestibuli** (SKĀ-luh ves-TIB-yū-lē), or **vestibular duct**, and the **scala tympani** (TIM-pa-nē), or **tympanic duct**. The outer surfaces of all three ducts are encased by the bony labyrinth everywhere except at the oval window (the base of the scala vestibuli) and the round window (the base of the scala tympani). These *scalae* really form one long and continuous perilymphatic chamber because they are interconnected at the tip of the spiral-shaped cochlea. This chamber begins at the oval window; extends through the scala vestibuli, around the top of the cochlea, and along the scala tympani; and ends at the round window.

The hair cells of the cochlear duct are in a structure called the **spiral organ (organ of Corti)** (**Figure 17-28b** and **Figure 17-29**). This sensory structure sits on the **basilar membrane**, a membrane that separates the cochlear duct from the scala tympani. The hair cells are arranged in a series of longitudinal rows. They lack kinocilia, and their stereocilia are in contact with the overlying **tectorial** (tek-TOR-ē-al; *tectum*, roof) **membrane**. This membrane is firmly attached to the inner wall of the cochlear duct.

Auditory Discrimination

Our hearing abilities are remarkable, but it is difficult to assess the degree of auditory discrimination. The range from the softest audible sound to the loudest tolerable blast represents a trillion-fold increase in power. The receptor mechanism is so sensitive that, if we were to remove the stapes, we could, in theory, hear air molecules bouncing off the oval window. We never use the full potential of this system because body movements and our internal organs produce squeaks, groans, thumps, and other sounds that are tuned out by central and peripheral adaptation. When other environmental noises fade away, the level of adaptation drops and the system becomes increasingly sensitive. For example, when relaxing in a quiet room, the heartbeat seems to get louder and louder as the auditory system adjusts to the level of background noise.

Young children have the greatest hearing range: They can detect sounds ranging from a 20-Hz buzz to a 20,000-Hz whine. With age, damage due to loud noises or other injuries accumulates. The tympanic membrane gets less flexible, the articulations between the ossicles stiffen, and the round window may begin to ossify. As a result, older individuals show some degree of hearing loss.

Millions of people in the United States have at least a partial hearing deficit, either congenital (inborn) or acquired. Such deficits are due to problems with the transfer of vibrations by the auditory ossicles or damage to the receptors or the auditory pathways.

Figure 17-28 The Cochlea.

17

?

The scala vestibuli and scala tympani contain a different fluid than the cochlear duct. What type of fluid does each chamber contain?

The Physiology of Hearing

We divide the process of hearing into six basic steps (**Figure 17-30**):

1 Sound waves arrive at the tympanic membrane. Sound waves enter the external acoustic meatus and travel toward the

tympanic membrane. The orientation of this meatus, or canal, provides some directional sensitivity. Sound waves approaching a particular side of the head have direct access to the tympanic membrane on that side. Sounds arriving from another direction must bend around corners or pass through the auricle or other body tissues.

Figure 17-29 The Spiral Organ.

2 Movement of the tympanic membrane displaces the auditory ossicles. The tympanic membrane provides a surface for the collection of sound. The membrane vibrates in resonance to sound waves with frequencies between approximately 20 and 20,000 Hz. When the tympanic membrane vibrates, so do the malleus, incus, and stapes. The ossicles are connected in such a way that an in-out movement of the tympanic membrane produces a rocking motion of the stapes. In this way, the sound is amplified.

3 Movement of the stapes at the oval window produces pressure waves in the perilymph of the scala vestibuli. Liquids are not compressible. For example, squeezing one part of a water-filled balloon causes bulging somewhere else. Because the rest of the cochlea is sheathed in bone, pressure applied at the oval window can be relieved only at the round window. The movement of the stapes can be understood by focusing on just its in-out component. Basically, when the stapes moves inward, the round window bulges outward, into the middle ear cavity. As the stapes moves in and out,

Figure 17–30 Sound and Hearing. Steps in the reception and transduction of sound energy.

vibrating at the frequency of the sound arriving at the tympanic membrane, it produces pressure waves within the perilymph.

4 The pressure waves distort the basilar membrane on their way to the round window of the scala tympani. These pressure waves travel through the perilymph of the scala vestibuli and scala tympani to reach the round window. In doing so, the waves distort the basilar membrane. The location of maximum distortion varies with the frequency of the sound, due to regional differences in the width and flexibility of the basilar membrane along its length. High-frequency sounds, which have a very short wavelength, vibrate the basilar membrane near the oval window. The lower the frequency of the sound and the longer the wavelength, the farther the area of maximum distortion is from the oval window (**Figure 17–31**). In this way, information about frequency is translated into information about *position* along the basilar membrane.

The *amount* of movement at a given location depends on the amount of force applied by the stapes, which in turn depends on the energy content of the sound. The louder the sound, the more the basilar membrane moves.

5 Vibration of the basilar membrane causes hair cells to vibrate against the tectorial membrane. Vibration of the affected region of the basilar membrane moves hair cells against the tectorial membrane. This movement leads to the displacement of the stereocilia, which in turn opens ion channels in the plasma membranes of the hair cells. The resulting inrush of ions depolarizes the hair cells, leading to the release of neurotransmitters that stimulate sensory neurons.

The hair cells of the spiral organ are arranged in several rows. A very soft sound may stimulate only a few hair cells in a portion of one row. As the intensity of a sound increases, not only do these hair cells become more active, but additional

Figure 17–31 Frequency Discrimination.

hair cells—first in the same row and then in adjacent rows—are stimulated as well. The number of hair cells responding in a region of the spiral organ provides information on the intensity of the sound.

6 Information about the region and the intensity of stimulation is relayed to the CNS over the cochlear nerve, a division of cranial nerve VIII. The cell bodies of the bipolar sensory neurons that monitor the cochlear hair cells are located at the center of the bony cochlea, in the **spiral ganglion** (Figure 17–29a). From there, the information is carried by the cochlear nerve to the cochlear nuclei of the medulla oblongata for distribution to other brain centers.

Auditory Pathways

The ascending pathways for auditory sensations are shown in Figure 17–32. Stimulation of hair cells along the basilar membrane activates sensory neurons whose cell bodies are in the adjacent spiral ganglion **1**. The afferent fibers of those neurons form the **cochlear nerve**. These axons enter the medulla oblongata, where they synapse at the **cochlear nucleus** on that

side **2**. From there, information ascends to both **superior olivary nuclei** of the pons and both inferior colliculi of the midbrain **3**. This midbrain processing center coordinates a variety of unconscious motor responses to acoustic stimuli, including auditory reflexes that involve skeletal muscles of the head, face, and trunk **4**. These reflexes automatically change the position of the head in response to a sudden loud noise. A person usually turns their head and eyes toward the source of the sound.

Before reaching the cerebral cortex and awareness, ascending auditory sensations synapse in the medial geniculate body of the thalamus **5**. Projection fibers then deliver the information to the **auditory cortex** of the temporal lobe **6**. Information travels to the cortex over labeled lines: High-frequency sounds activate one portion of the cortex, low-frequency sounds another. In effect, the auditory cortex contains a map of the spiral organ. So information about frequency, translated into information about position on the basilar membrane, is projected in that form onto the auditory cortex. There it is interpreted, producing the subjective sensation of pitch.

Figure 17–32 Pathways for Auditory Sensations.

Most of the auditory information from one cochlea is projected to the auditory complex of the cerebral hemisphere on the opposite side of the brain. However, each auditory cortex also receives information from the cochlea on that side. These interconnections play a role in localizing left/right sounds. They can also reduce the functional impact of damage to a cochlea or ascending pathway.

An individual whose auditory cortex is damaged will respond to sounds and have normal acoustic reflexes but will find it difficult or impossible to interpret the sounds and recognize a pattern in them. Damage to the adjacent auditory association area leaves the ability to detect the tones and

patterns intact but produces an inability to comprehend their meaning.

✓ Checkpoint

- If the round window were not able to bulge out with increased pressure in the perilymph, how would the perception of sound be affected?
- How would the loss of stereocilia from hair cells of the spiral organ affect hearing?
- Why would blockage of the auditory tube produce an earache?

See the blue Answers tab at the back of the book.

17 Chapter Review

Study Outline

An Introduction to the Special Senses

1. The sense organs responsible for the five *special senses*—*olfaction* (smell), *gustation* (taste), *vision*, *equilibrium* (balance), and *hearing*—are structurally more complex than those of the general senses, but the same basic principles of receptor function apply.

17-1 Olfaction, the sense of smell, involves olfactory receptors responding to airborne chemical stimuli

2. The **olfactory organs** contain the **olfactory epithelium** with **olfactory receptors**, supporting cells, and **basal (stem) cells**. The surfaces of the olfactory organs are coated with the secretions of the **olfactory glands**. (Figure 17-1)
3. The olfactory receptors are highly modified neurons.
4. In olfaction, the arriving information reaches the information centers without first synapsing in the thalamus. (Figure 17-1)
5. Olfactory reception involves detecting dissolved chemicals as they interact with odorant-binding proteins. (Spotlight Figure 17-2)
6. The olfactory system can distinguish thousands of chemical stimuli. The CNS interprets smells by the pattern of receptor activity.
7. The olfactory receptor population shows considerable turnover. The number of olfactory receptors declines with age.

17-2 Gustation, the sense of taste, involves gustatory receptors responding to dissolved chemical stimuli

8. **Taste receptor cells**, also called *gustatory epithelial cells*, are clustered in **taste buds**.
9. Taste buds are associated with epithelial projections (*lingual papillae*) on the tongue. (Figure 17-3)
10. Each taste bud contains **basal epithelial cells** (stem cells) and taste receptor cells, which extend *taste hairs* through a narrow **taste pore**. (Figure 17-3)
11. The taste buds are monitored by cranial nerves that synapse within the solitary nucleus of the medulla oblongata. Postsynaptic neurons carry the nerve impulses on to the thalamus, where third-order neurons project to the somatosensory cortex.
12. The **primary taste sensations** are sweet, salty, sour, and bitter. Receptors also exist for **umami** and **water**. (Spotlight Figure 17-2)
13. Taste sensitivity exhibits significant individual differences, some of which are inherited.
14. The number of taste buds declines with age.

17-3 Internal eye structures contribute to vision, while accessory eye structures provide protection

15. The **accessory structures** of the eye include the **eyelids** (*palpebrae*), separated by the **palpebral fissure**, the **eyelashes**, and the **tarsal glands**. (Figures 17-4, 17-5)
16. An epithelium called the **conjunctiva** covers the inner surfaces of the eyelids and most of the exposed surface of the eye. The **cornea** is transparent. (Figures 17-4, 17-5)

- PhysioEx

17. The secretions of the **lacrimal gland** contain **lysozyme**. Tears collect in the *lacrimal lake* and reach the inferior meatus of the nose after they pass through the **lacrimal puncta**, the **lacrimal canaliculi**, the **lacrimal sac**, and the **nasolacrimal duct**. (Figure 17-4)
18. The eye has three layers, formerly called tunics: an outer **fibrous layer**, a middle **vascular layer** (uvea), and a deeper, **inner layer** (retina). (Figure 17-5)
19. The fibrous layer consists of the **sclera**, the **cornea**, and the **corneoscleral junction** (*corneal limbus*). (Figure 17-5)
20. The vascular layer, or **uvea**, includes the **iris**, the **ciliary body**, and the **choroid**. The iris contains muscle fibers that change the diameter of the **pupil**. The ciliary body contains the **ciliary muscle** and the **ciliary processes**, which attach to the **ciliary zonule** (*suspensory ligament*) of the lens. (Figures 17-5, 17-6)
21. The **inner layer**, or **retina**, consists of a thin lining called the *pigmented layer* and a thicker covering called the *neural layer*, which contains visual receptors and associated neurons. (Figures 17-5, 17-7)
22. The retina contains two types of **photoreceptors**: **rods** and **cones**.
23. Cones are densely clustered in the **fovea centralis** at the center of the **macula**. (Figure 17-7)
24. The direct line to the CNS proceeds from the photoreceptors to **bipolar cells**, then to **ganglion cells**, and, finally, to the brain by the optic nerve. The axons of ganglion cells converge at the **optic disc**, or **blind spot**. **Horizontal cells** and **amacrine cells** modify the signals passed among other components of the retina. (Figures 17-7, 17-8)
25. The ciliary body and lens divide the interior of the eye into a large **posterior cavity**, or *vitreous chamber*, and a smaller **anterior cavity**. The anterior cavity is subdivided into the **anterior chamber**, which extends from the cornea to the iris, and a **posterior chamber**, between the iris and the ciliary body and lens. (Figure 17-9)
26. The fluid **aqueous humor** circulates within the eye and reenters the circulation after diffusing through the walls of the anterior chamber and into the **scleral venous sinus** (*canal of Schlemm*). (Figure 17-9)
27. The **lens** lies posterior to the cornea and forms the anterior boundary of the posterior cavity. This cavity contains the **vitreous body**, a clear, gelatinous mass that helps stabilize the shape of the eye and support the retina. (Figure 17-9)
28. The lens focuses a visual image on the photoreceptors. A **cataract** is the condition in which a lens has lost its transparency.

17-4 The focusing of light on the retina leads to the formation of a visual image

29. Light is **refracted** (bent) when it passes through the cornea and lens. During **accommodation**, the shape of the lens changes to focus an image on the retina. “Normal” **visual acuity** is rated 20/20. (Figures 17–10 to Spotlight Figure 17–13)

17-5 Photoreceptors transduce light into electrical signals that are then processed in the visual cortex

30. The two types of photoreceptors are rods, which respond to almost any photon, regardless of its energy content, and cones, which have characteristic ranges of sensitivity. (Figure 17–14)
31. Each photoreceptor contains an **outer segment** with membranous **discs**. A narrow stalk connects the outer segment to the **inner segment**. Light absorption occurs in the **visual pigments**, which are derivatives of **rhodopsin** (opsin plus the pigment retinal, which is synthesized from vitamin A). (Figure 17–14)
32. Color sensitivity depends on the integration of information from **red**, **green**, and **blue** cones. **Color blindness** is the inability to detect certain colors. (Figures 17–15, 17–18)
33. In the absence of photons, a photoreceptor produces a dark current and constantly releases neurotransmitter. Photon absorption reduces the dark current and decreases the release of neurotransmitter to the bipolar cell. (Spotlight Figure 17–16)
34. During the process of **bleaching**, rhodopsin molecules are broken apart to regenerate retinal back to its photon-absorbing 11-*cis* form. (Spotlight Figure 17–16, Figure 17–17)
35. In the **dark-adapted state**, most visual pigments are fully receptive to stimulation. In the **light-adapted state**, the pupil constricts and bleaching of the visual pigments takes place.
36. The ganglion cells that monitor rods, called **M cells** (*magnocellular neurons*), are relatively large. The ganglion cells that monitor cones, called **P cells** (*parvocellular neurons*), are smaller and more numerous. (Figure 17–19)
37. Visual data from the left half of the combined field of vision arrive at the visual cortex of the right occipital lobe. Data from the right half of the combined field of vision arrive at the visual cortex of the left occipital lobe. (Figure 17–20)
38. **Depth perception** is resolved by comparing relative positions of objects between the left- and right-eye images. (Figure 17–20)
39. Visual inputs to the suprachiasmatic nucleus of the hypothalamus affect the function of other brainstem nuclei. This nucleus establishes a visceral **circadian rhythm**, which is tied to the day–night cycle and affects other metabolic processes.
40. The receptors of the internal ear provide the senses of equilibrium and hearing.
41. The ear is subdivided into the **external ear**, the **middle ear**, and the **internal ear**. (Figure 17–21)
42. The external ear includes the **auricle**, or **pinna**, which surrounds the entrance to the **external acoustic meatus**, which ends at the **tympanic membrane** (*eardrum*). (Figure 17–21)
43. The middle ear communicates with the nasopharynx by the **auditory** (*pharyngotympanic*) **tube**. The middle ear encloses and protects the **auditory ossicles**. (Figures 17–21, 17–22)
44. The **membranous labyrinth** (the chambers and tubes) of the internal ear contains the fluid **endolymph**. The **bony labyrinth** surrounds and protects the membranous labyrinth and can be subdivided into the **vestibule**, the **semicircular canals**, and the **cochlea**. (Figures 17–21, 17–23)
45. The vestibule of the internal ear encloses the **saccul** and **utricle**. The semicircular canals contain the **semicircular ducts**. The cochlea contains the **cochlear duct**, an elongated portion of the membranous labyrinth. (Figure 17–23)
46. The **round window** separates the **perilymph** from the air spaces of the middle ear. The **oval window** is connected to the base of the stapes. (Figure 17–21)
47. The basic sensory receptors of the internal ear are **hair cells**, which provide information about the direction and strength of mechanical stimuli. (Figure 17–24)
48. The **anterior**, **posterior**, and **lateral semicircular ducts** are continuous with the utricle. Each duct contains an **ampullary crest** with a gelatinous **ampullary cupula** and associated sensory receptors. (Figures 17–23, 17–24)
49. The saccul and utricle are connected by a passageway that is continuous with the **endolymphatic duct**. This duct terminates in the **endolymphatic sac**. In the saccul and utricle, hair cells cluster within **maculae**, where their hair cells contact the gelatinous **otolithic membrane**. The surface of the membrane contains calcium carbonate crystals called **otoliths**. (Figures 17–24, 17–25)
50. The vestibular receptors activate sensory neurons of the **vestibular ganglia**. The axons form the **vestibular nerve**, synapsing within the **vestibular nuclei**. (Figure 17–26)
51. The energy content of a sound determines its **intensity**, or loudness, measured in **decibels**. Sound waves travel toward the tympanic membrane, which vibrates, and the auditory ossicles then conduct these vibrations to the internal ear. Movement at the oval window applies pressure to the perilymph of the scala vestibuli. (Figures 17–27, 17–30; Table 17–1)
52. The **cochlear duct** (**scala media**) lies between the **scala vestibuli** (*vestibular duct*) and the **scala tympani** (*tympanic duct*). The hair cells of the cochlear duct lie within the **spiral organ** (**organ of Corti**). (Figures 17–28, 17–29)
53. Pressure waves distort the **basilar membrane** and push the hair cells of the spiral organ against the **tectorial membrane**. Two muscles, the **tensor tympani** and **stapedius**, contract to reduce the amount of motion when very loud sounds arrive. (Figures 17–30, 17–31)
54. The sensory neurons are in the **spiral ganglion** of the cochlea. The afferent fibers of these neurons form the **cochlear nerve**, synapsing at their respective left or right **cochlear nucleus**. Ascending auditory information from each ear reaches the auditory cortex on both sides of the brain. (Figure 17–32)

17-6 Equilibrium sensations monitor head position and movement, while hearing involves the detection and interpretation of sound waves

Review Questions

See the blue Answers tab at the back of the book.

LEVEL 1 Reviewing Facts and Terms

1. Identify the structures in the following horizontal section of the eye.

- | | |
|-----------|-----------|
| (a) _____ | (b) _____ |
| (c) _____ | (d) _____ |
| (e) _____ | (f) _____ |
| (g) _____ | (h) _____ |
| (i) _____ | (j) _____ |

- A reduction in sensitivity in the presence of a constant stimulus is (a) transduction, (b) sensory coding, (c) line labeling, (d) adaptation.
- A blind spot occurs in the retina where (a) the fovea centralis is located, (b) ganglion cells synapse with bipolar cells, (c) the optic nerve attaches to the retina, (d) rod cells are clustered to form the macula, (e) amacrine cells are located.
- Which components of the olfactory organ can replace its worn-out sensory neurons? (a) supporting cells, (b) olfactory glands, (c) olfactory dendrites, (d) basal epithelial cells, (e) lamina propria cells.
- The basic receptors in the internal ear are the (a) utricle, (b) saccule, (c) hair cells, (d) supporting cells, (e) ampullae.
- Which of the following is a part of the eyelid? (a) sclera, (b) orbicularis oculi, (c) cornea, (d) ciliary body.
- Which muscle(s) is/are responsible for constriction of the pupil? (a) dilator pupillae, (b) ciliary muscle, (c) sphincter pupillae, (d) ciliary process.
- A better-than-average visual acuity rating is (a) 20/20, (b) 20/30, (c) 15/20, (d) 20/15.
- Vibrations of the _____ membrane cause hair cells to vibrate against the tectorial membrane in the ear. (a) tympanic, (b) otolithic, (c) basilar, (d) vestibular.
- Identify the structures of the external, middle, and internal ear in the following figure.

- | | |
|-----------|-----------|
| (a) _____ | (b) _____ |
| (c) _____ | (d) _____ |
| (e) _____ | (f) _____ |
| (g) _____ | (h) _____ |
| (i) _____ | |

- Structures *not* controlled by the vestibular nuclei in the brain are the (a) maculae and ampullae, (b) cranial motor nerves, (c) cranial mixed nerves, (d) vestibulo-spinal tracts.
- Pressure waves passing through the cochlea terminate on the _____. (a) basilar membrane, (b) tympanic membrane, (c) round window, (d) oval window, (e) vestibular membrane.
- The typical decibel level of a "heavy metal" rock concert is (a) 30 dB, (b) 80 dB, (c) 120 dB, (d) 160 dB.
- Where on the human tongue are the vallate papillae located?
- (a) What structures make up the fibrous layer of the eye? (b) What are the functions of the fibrous layer?
- What structures make up the vascular layer of the eye?
- What are the two muscles found in the middle ear, and what is their function?

LEVEL 2 Reviewing Concepts

- Trace the olfactory pathway from the time an odor reaches the olfactory epithelium until nerve impulses reach their destination in the brain.
- Why are dogs good at detecting drugs and explosives?
- What effect does the contraction of the ciliary muscle have on the lens?
- Displacement of stereocilia toward the kinocilium of a hair cell (a) produces a depolarization of the membrane, (b) produces a hyperpolarization of the membrane, (c) decreases the membrane permeability to sodium ions, (d) increases the membrane permeability to potassium ions, (e) does not affect the membrane potential of the cell.
- Damage to the ampullary cupula of the lateral semicircular duct would interfere with the perception of (a) the direction of gravitational pull, (b) linear acceleration, (c) horizontal rotation of the head, (d) vertical rotation of the head, (e) angular rotation of the head.
- Cataract surgery involves the removal of the (a) cornea, (b) vitreous body, (c) lens, (d) anterior chamber, (e) posterior chamber.

LEVEL 3 Critical Thinking and Clinical Applications

- Alexei and Genadi are having a meal in a popular diner. They choose a vegetable dish containing broccoli and Brussels sprouts. Alexei enjoys the dish very much but Genadi thinks it tastes quite bitter. Why is there this difference in perception?
- Your friend Alina has myopia (nearsightedness). You remember from your physics class that concave lenses cause light waves to spread or diverge and that convex lenses cause light waves to converge. What type of corrective lenses would you suggest to your friend? (a) concave lenses, (b) convex lenses.
- Vlad has surgery to remove polyps (growths) from his sinuses. After he heals from the surgery, he notices that his sense of smell is not as keen as it was before the surgery. What is the reason for this?
- Like many children, Jessica often suffers from a throat infection. Her mother wonders why this infection is frequently followed by middle ear infection. Explain to her why this is understandable.
- Juan tells his physician that he has been feeling dizzy, especially when he closes his eyes. He is asked to stand with his feet together and arms extended forward. As long as he keeps his eyes open, he exhibits very little movement. But when he closes his eyes, his body begins to sway a great deal, and his arms tend to drift together toward the left side of his body. Why does this occur?

CLINICAL CASE Wrap-Up A Chance to See

Makena was diagnosed with *myopia*, which is also called nearsightedness. Due to the elongated shape of Makena's eyeballs, distant images are projected in front of her retina and appear blurry and out of focus to her. Glasses can correct this easily, but nobody in Makena's village has ever met an eye doctor. The closest optical shop is far out of this family's reach, both in distance and cost.

Makena's teacher sets up a makeshift eye clinic with the help of volunteers from the Centre for Vision in the Developing World, a group dedicated to correcting vision for poor children. To test her vision, Makena attempts to read from an eye chart taped to the wall of the school building 20 feet away. Makena's visual acuity tests at 20/200.

Next, Makena puts on a simple pair of universal glasses, made with a clear membrane filled with silicone oil, held between

two plastic discs on each side. A removable syringe filled with silicone oil is attached to each side. With her right eye covered, Makena uses the syringe to inject more silicone into the left lens until her left eye can read the eye chart perfectly. Then she repeats the process for her right eye. The final step is to remove the syringes. Now she can see things she never knew she had been missing—and she gets to keep the glasses.

1. What does Makena's initial eye test result of 20/200 mean?
2. If Makena's vision is corrected to a state of emmetropia, what does this mean?

See the blue Answers tab at the back of the book.

Related Clinical Terms

age-related macular degeneration: A disease associated with aging that gradually destroys sharp, central vision by affecting the macula, the part of the eye that allows a person to see fine detail. It is painless and, in some cases, can slowly worsen over time, causing little concern to the person, or it can rapidly progress and may cause blindness in both eyes. It is the leading cause of blindness in persons over the age of 60. It has two forms, wet and dry.

ageusia: A rare inability to taste. More common is hypogeusia, a disorder in which the person affected has trouble distinguishing between tastes.

anosmia: The complete loss of smell, which can be temporary (caused by an obstruction such as a polyp) or permanent (perhaps due to aging or a brain tumor).

blepharitis: Common and persistent inflammation of the eyelid caused by poor hygiene, excessive oil production by the glands of the eyelid, or a bacterial infection. Signs and symptoms include itching, flakes on the eyelashes, and a gritty, sandy feeling.

conductive hearing loss: Deafness resulting from conditions in the external or middle ear that block the transfer of vibrations from the tympanic membrane to the oval window.

hyposmia: A lessened sensitivity to odors.

mydriasis: Dilation of the pupils of the eye induced by medical eye drops or caused by disease.

ophthalmologist: A physician who specializes in ophthalmology, which is the branch of medicine dealing with the diseases and

surgery of the visual pathways, including the eye, brain, and areas surrounding the eye.

optometrist: A primary eye care doctor who diagnoses, manages, and treats disorders of the visual system and eye diseases and who also measures vision for the purpose of correcting one's vision problems with specifically prescribed lenses.

otalgia: Pain in the ear; an earache.

photophobia: An oversensitivity to light possibly leading to tearing, discomfort, or pain. Causes include abrasions to the corneal area, inflammation, disease, and some medications.

sensorineural hearing loss: Deafness resulting from problems within the cochlea or along the auditory nerve pathway.

Snellen chart: A printed chart of block letters in graduated type sizes used to measure visual acuity.

strabismus: The misalignment of one or both eyes that prevents the person from gazing on the same point with both eyes.

synesthesia: A condition in which sensory nerve messages connect to the wrong centers of the brain. For example, touching an object may produce the perception of a sound, while hearing a tone may produce the visualization of a color.

tinnitus: A buzzing, whistling, or ringing sound heard in the absence of an external stimulus. Causes include injury, disease, inflammation, or some drugs.

vertigo: A dizzy or spinning feeling or a feeling that things are dizzily turning about you. Vertigo is usually caused by a problem with the internal ear but can also be due to vision problems.

18

The Endocrine System

Learning Outcomes

These Learning Outcomes correspond by number to this chapter's sections and indicate what you should be able to do after completing this chapter.

- 18-1 ■ Explain the importance of intercellular communication, describe the mechanisms involved, and compare the modes of intercellular communication that occur in the endocrine and nervous systems.
- 18-2 ■ Compare the cellular components of the endocrine system with those of other systems, contrast the major structural classes of hormones, and explain the general mechanisms of hormonal action on target organs.
- 18-3 ■ Describe the location, hormones, and functions of the pituitary gland and discuss the effects of variation in pituitary hormone production.
- 18-4 ■ Describe the location, hormones, and functions of the thyroid gland and discuss the effects of variation in thyroid hormone production.
- 18-5 ■ Describe the location, hormone, and functions of the parathyroid glands and discuss the effects of variation in parathyroid hormone production.
- 18-6 ■ Describe the location, structure, hormones, and general functions of the adrenal glands and discuss the effects of variation in adrenal hormone production.
- 18-7 ■ Describe the location of the pineal gland and discuss the functions of the hormone it produces.
- 18-8 ■ Describe the location, structure, hormones, and functions of the pancreas and discuss the effects of variation in pancreatic hormone production.
- 18-9 ■ Describe the functions of the hormones produced by the kidneys, heart, thymus, testes, ovaries, and adipose tissue.
- 18-10 ■ Explain how hormones interact to produce coordinated physiological responses and influence behavior, describe the role of hormones in the general adaptation syndrome, and discuss how aging affects hormone production and give examples of interactions between the endocrine system and other organ systems.

CLINICAL CASE

Stones, Bones, and Groans

Monica is back in her doctor's office, following up on her lab results. She feels a little unsure about going to a new family practitioner with so many vague complaints. She has a history of hypertension (high blood pressure), heart palpitations (irregular heartbeats), and kidney stones. She has osteopenia along with nagging bone pain. Recently she experienced abdominal pain with loss of appetite and constipation. Furthermore, she has been feeling chronically fatigued, some of which she attributes to having trouble falling asleep and

regularly awakening in the middle of the night. Monica has also noticed that her memory is getting worse and that she feels increasingly depressed. Worst of all, her husband of 40 years has complained that she is getting irritable and cranky.

"Monica," says her doctor, "I think I know what is causing your symptoms. The answer is right here in your lab results." **What could be causing Monica's many complaints? To find out, turn to the Clinical Case Wrap-Up at the end of the chapter.**

An Introduction to the Endocrine System

Some 30 chemical messengers known as *hormones* regulate human activities such as sleep, body temperature, hunger, and stress management. These hormones are products of the *endocrine system*, which, along with the nervous system, controls and coordinates our body processes.

In this chapter we examine the structural and functional organization of the endocrine system and compare it to the nervous system. After an overview of the endocrine system and the characteristics of the hormones it produces, we consider the structure and function of the body's various *endocrine glands*. Finally, we introduce ways in which hormones modify metabolic operations and discuss the interactions between the endocrine system and other body systems. Let's begin by considering the role of intercellular communication in maintaining homeostasis.

18-1 Homeostasis is maintained through intercellular communication by the nervous and endocrine systems

Learning Outcome Explain the importance of intercellular communication, describe the mechanisms involved, and compare the modes of intercellular communication that occur in the endocrine and nervous systems.

To maintain homeostasis, cellular activities must be coordinated throughout the body. Cells coordinate their activities by sending and receiving chemical messages. Both the nervous system, which we have explored in Chapters 12–17, and the endocrine system accomplish this coordination. However, they provide different types of coordination because of how their cells communicate. To understand how cellular messages are generated and interpreted, let's take a closer look at how cells communicate with one another.

Mechanisms of Intercellular Communication

In a few specialized cases, adjacent cells coordinate cellular activities by exchanging ions and molecules across gap junctions.

This **direct communication** occurs between two cells of the same type, and the cells must be in extensive physical contact. The two cells communicate so closely that they function as a single entity. Gap junctions (1) coordinate ciliary movement among epithelial cells, (2) coordinate the contractions of cardiac muscle cells, and (3) facilitate the propagation of action potentials from one neuron to the next at electrical synapses.

Most communication between cells involves the release and receipt of chemical messages. When these messages occur between cells within a single tissue, it is called **paracrine communication**, and the chemicals involved are *paracrine*s. Each cell continuously "talks" to its neighbors by releasing chemicals into the extracellular fluid. These chemicals tell cells what their neighbors are doing at any moment. The result is the coordination of tissue function locally (within the same tissue). An example of a paracrine is somatostatin, which is released by some pancreatic cells to inhibit the release of insulin by other pancreatic cells. **Autocrine communication** occurs when the messages affect the same cells that secrete them, and the chemicals involved are *autocrine*s. Examples of autocrines include prostaglandins, which are secreted by smooth muscle cells to cause contraction of those cells.

Endocrine communication occurs when the endocrine system uses chemical messengers called **hormones** to relay information and instructions between cells in distant portions of the body. Endocrine cells release these hormones in one tissue, and they are then transported in the bloodstream and distributed throughout the body. Each hormone has **target cells**, specific cells in other tissues that have the *receptors* needed to bind and "read" the hormonal message when it arrives. These messages alter the operations of target cells by changing the types, quantities, or activities of important enzymes and structural proteins. A hormone can modify the physical structure or biochemical properties of its target cells. Because the target cells can be anywhere in the body, a single hormone can alter the metabolic activities of multiple tissues and organs at the same time.

Table 18–1 Mechanisms of Intercellular Communication

Mechanism	Transmission	Chemical Mediators	Distribution of Effects
Direct communication 	Via gap junctions	Ions, small solutes, lipid-soluble materials	Usually limited to adjacent cells of the same type that are interconnected by connexons
Paracrine communication 	Via extracellular fluid	Paracrine	Primarily limited to a local area, where paracrine concentrations are relatively high; target cells must have appropriate receptors
Autocrine communication 	Via extracellular fluid	Autocrine	Limited to the cell that secretes the hormone
Endocrine communication 	Via the bloodstream	Hormones	Target cells are primarily in other tissues and organs and must have appropriate receptors
Synaptic communication 	Across synapses	Neurotransmitters	Limited to very specific area; target cells must have appropriate receptors

Synaptic Communication

The nervous system, too, relies primarily on chemical communication, but it does not send messages through the bloodstream. With **synaptic communication**, neurons release a neurotransmitter at a synapse very close to target cells that have the appropriate receptors. The signal then travels rapidly from one location to another in the form of action potentials propagated along axons. The nervous system can thus carry high-speed “messages” to specific destinations throughout the body.

Table 18–1 summarizes the five ways cells and tissues communicate with one another.

Comparison of Endocrine and Nervous Communication

How are the cellular communication mechanisms of the endocrine and nervous systems similar and different? Viewed from a general perspective, the differences between these systems seem relatively clear. In the nervous system, neurons use action potentials and neurotransmitters to control specific cells or groups

of cells. This arrangement allows synaptic communication to provide crisis management in situations requiring split-second responses: If someone is in danger of being hit by a speeding bus, the nervous system can coordinate and direct their leap to safety. Only a small fraction of all the cells in the body are innervated, however, and the commands from the nervous system are very specific and relatively short-lived. However, in the endocrine system, the hormones produced by endocrine cells reach almost every cell in the body. The effects of hormones on their target cells may be slow to appear, but they typically last for days. Consequently, endocrine communication is effective in coordinating cell, tissue, and organ activities such as growth and development or affecting metabolic activities on a sustained, long-term basis. These broad organizational and functional distinctions are the basis for treating the nervous and endocrine systems as separate systems.

Yet when we consider these two systems in detail, we realize that they also have many similarities. For example:

- Both systems rely on the release of chemicals that bind to specific receptors on their target cells.

- The two systems share many chemical messengers. For example, norepinephrine and epinephrine are called hormones when released into the bloodstream, but neurotransmitters when released across synapses.
- Both systems are regulated mainly by negative feedback control mechanisms.
- The two systems share a common goal: to maintain homeostasis by coordinating and regulating the activities of other cells, tissues, organs, and systems.

The next section introduces the components and functions of the endocrine system.

Checkpoint

1. Define hormone.
2. Describe paracrine communication.
3. Identify five mechanisms of intercellular communication.

See the blue Answers tab at the back of the book.

18-2 The endocrine system regulates physiological processes by releasing bloodborne hormones that bind to receptors on remote target organs

Learning Outcome Compare the cellular components of the endocrine system with those of other systems, contrast the major structural classes of hormones, and explain the general mechanisms of hormonal action on target organs.

Because of their wide-reaching and long-term effects, the hormones of the endocrine system can produce complex changes in the body's physical structure and physiological capabilities. The major processes that are affected by hormone actions include:

- Growth and development
- Reproduction
- Regulation of cell metabolism and energy balance
- Regulation of body water content and levels of electrolytes and organic nutrients
- Mobilization of body defenses

Overview of Endocrine Organs and Tissues

The **endocrine system** includes all the endocrine cells and tissues of the body that produce hormones or paracrine factors with effects beyond their tissues of origin. As noted in Chapter 4, *endocrine cells* are glandular secretory cells that release their secretions into the extracellular fluid. This characteristic distinguishes them from *exocrine cells*, which secrete their products onto epithelial surfaces, generally by way of ducts.

Figure 18-1 introduces the tissues, organs, and hormones of the endocrine system. Notice that *endocrine organs* are scattered throughout the body rather than being clustered together like those of many systems. Some of these organs, such as the *pituitary gland*, have endocrine secretion as a primary function. Others, such as the *pancreas*, have many other functions in addition to endocrine secretion. We consider specific endocrine organs in later sections, and we cover them in more detail in chapters on other systems.

Classes of Hormones

We divide hormones into three classes based on their chemical structure: (1) *amino acid derivatives*, (2) *peptide hormones*, and (3) *lipid derivatives*.

Amino acid derivatives, sometimes known as *biogenic amines*, are relatively small molecules that are structurally related to amino acids, the building blocks of proteins. These hormones are synthesized from the amino acids tyrosine and tryptophan. Those made from tyrosine include (1) *thyroid hormones*, produced by the *thyroid gland*, and (2) the compounds epinephrine (E), norepinephrine (NE), and dopamine, which are sometimes called the *catecholamines* (kat-eh-KŌ-lah-mēnz). The primary hormone made from tryptophan is *melatonin* (mel-ah-TŌ-nin), produced by the *pineal gland*.

We can divide peptide hormones into two groups. One group consists of glycoproteins, while the other is made up of short polypeptides and small proteins.

There are two groups of lipid derivatives: (1) *eicosanoids* and (2) *steroid hormones*. Eicosanoids are signaling molecules and include leukotrienes, **prostaglandins**, thromboxanes, and prostacyclins. We consider eicosanoids in chapters that discuss individual tissues and organs, including Chapters 19 (the blood), 22 (the lymphatic system), and 28 (the reproductive system). Steroid hormones are lipids structurally similar to cholesterol (see **Figure 2-18**). The individual hormones differ in the side chains attached to a basic four-ring structure.

Spotlight Figure 18-2 summarizes the structural classification of hormones.

Transport and Inactivation of Hormones

Hormones are typically released where capillaries are abundant, and the hormones quickly enter the bloodstream for distribution throughout the body. Within the blood, hormones may circulate freely or travel bound to special carrier proteins. A freely circulating hormone remains functional for less than 1 hour, and sometimes for as little as 2 minutes. It is inactivated when (1) it diffuses out of the bloodstream and binds to receptors on target cells, (2) it is absorbed and broken down by cells of the liver or kidneys, or (3) it is broken down by enzymes in the blood or interstitial fluids.

Figure 18–1 Organs and Tissues of the Endocrine System.

Thyroid hormones and steroid hormones remain functional much longer, because when these hormones enter the bloodstream, more than 99% of them become attached to special transport proteins. For each hormone, an equilibrium state exists between its free and bound forms. As the free hormones are removed and inactivated, bound hormones are released to replace them. At any given time, the bloodstream contains a substantial reserve (several weeks' supply) of bound hormones.

Mechanisms of Hormone Action

The focus of this chapter is circulating hormones that function primarily to coordinate activities in many tissues and organs on a sustained basis. When such hormones bind to their specific

receptors, cellular activities are modified. Specifically, the binding of a hormone may:

- **Alter Genetic Activity.** The synthesis of an enzyme or a structural protein not already present in the cytoplasm may be stimulated by activating appropriate genes in the cell nucleus.
- **Alter the Rate of Protein Synthesis.** The rate of synthesis of a particular enzyme or other protein may be increased or decreased by changing the rate of transcription or translation.
- **Change Membrane Permeability.** An existing enzyme or membrane channel may be turned "on" or "off" by changing its shape or structure.

HORMONES

The hormones of the body can be divided into three classes on the basis of their chemical structure.

Amino Acid Derivatives

Amino acid derivatives are small molecules that are structurally related to amino acids, the building blocks of proteins.

Derivatives of Tyrosine

Thyroid Hormones

Thyroxine (T₄)

Catecholamines

Epinephrine

Sources of tyrosine include meat, dairy, and fish.

Derivative of Tryptophan

Melatonin

Turkey is a well-known source of tryptophan. Other sources include chocolate, oats, bananas, dried dates, milk, cottage cheese, and peanuts.

Peptide Hormones

Peptide hormones are chains of amino acids. Most peptide hormones are synthesized as **prohormones**—inactive molecules that are converted to active hormones before or after they are secreted.

Glycoproteins

These proteins are more than 200 amino acids long and have carbohydrate side chains. The glycoproteins include thyroid-stimulating hormone (TSH), luteinizing hormone (LH), and follicle-stimulating hormone (FSH) from the anterior lobe of the pituitary gland, as well as several hormones produced in other organs.

Short Polypeptides/ Small Proteins

This group of peptide hormones is large and diverse. It includes hormones that range from **short-chain polypeptides**, such as antidiuretic hormone (ADH) and oxytocin (OXT) (each 9 amino acids long), to **small proteins**, such as insulin (51 amino acids), growth hormone (GH; 191 amino acids), and prolactin (PRL; 198 amino acids). This group includes all the hormones secreted by the hypothalamus, heart, thymus, digestive tract, pancreas, and posterior lobe of the pituitary gland, as well as several hormones produced in other organs.

Structure of insulin

Lipid Derivatives

There are two classes of lipid derivatives: **eicosanoids**, derived from arachidonic acid, a 20-carbon fatty acid; and **steroid hormones**, derived from cholesterol.

Eicosanoids

Eicosanoids

(I-kō-sa-noydz) are important paracrine factors that coordinate cellular activities and affect enzymatic processes (such as blood clotting in extracellular fluids). Some eicosanoids, such as **leukotrienes** (lu-kō-TRĭ-ēns), have secondary roles as hormones. A second group of eicosanoids—**prostaglandins**—are involved primarily in coordinating local cellular activities. In some tissues, prostaglandins are converted to **thromboxanes** (throm-BOX-ānz) and **prostacyclins** (pros-ta-Sĭ-klinz), which also have strong paracrine effects.

Prostaglandin E

Aspirin suppresses the production of prostaglandins.

Steroid Hormones

Steroid hormones are released by the reproductive organs (androgens by the testes in males, estrogens and progesterone by the ovaries in females), by the cortex of the adrenal glands (corticosteroids), and by the kidneys (calcitriol). Because circulating steroid hormones are bound to specific transport proteins in the plasma, they remain in circulation longer than do secreted peptide hormones.

Estrogen

To affect a target cell, a hormone must first interact with an appropriate receptor. A **hormone receptor**, like a neurotransmitter receptor, is a protein molecule to which a particular molecule binds strongly. Each cell has receptors for several different hormones, but cells in different tissues have different combinations of receptors. This arrangement is one reason hormones have different effects on different tissues. For every cell, the presence or absence of a specific receptor determines the cell's hormonal sensitivities. Cells throughout the body are exposed to hormones whether or not they have the necessary receptors. If a cell has a receptor that can bind a particular hormone, that cell responds to the hormone. If a cell lacks that receptor, the hormone has no effect on that cell.

The presence or absence of a hormone can also affect the nature and number of hormone receptor proteins. **Down-regulation** is a process in which the presence of a hormone triggers a decrease in the number of hormone receptors. In down-regulation, cells become *less* sensitive to high levels of a particular hormone. In contrast, **up-regulation** is a process in which the absence of a hormone triggers an increase in the number of hormone receptors. In up-regulation, cells become *more* sensitive to low levels of a particular hormone.

Hormone receptors are located either on plasma membranes (*extracellular receptors*) or within target cells (*intracellular receptors*). These different types of receptors respond with different mechanisms. Using a few specific examples, let's consider the basic mechanisms involved.

Hormones and Extracellular Receptors: Second Messengers

The receptors for catecholamines (E, NE, and dopamine) and peptide hormones are extracellular receptors. Catecholamines and peptide hormones cannot penetrate a plasma membrane because they are not lipid soluble. Instead, these hormones bind to receptor proteins at the *outer* surface of the plasma membrane of their target cells.

Communication between the hormone and the cell uses a mechanism involving first and second messengers. A *first messenger* is a hormone that binds to an extracellular receptor. A **second messenger** is an intermediary molecule that appears due to a hormone–receptor interaction. Important second messengers are (1) *cyclic AMP* (cAMP), a derivative of ATP; (2) *cyclic GMP* (cGMP), a derivative of GTP (guanosine triphosphate), another high-energy compound; and (3) calcium ions (Ca^{2+}).

When a small number of hormone molecules binds to extracellular receptors, thousands of second messengers may appear in a cell. This process, called *amplification*, magnifies the effect of a hormone on the target cell. Moreover, the arrival of a single hormone may promote the release of more than one type of second messenger, or the production of a linked sequence of

enzymatic reactions known as a *receptor cascade*. Through such mechanisms, the hormone can alter many aspects of cell function at the same time.

The link between the first messenger and the second messenger generally involves a **G protein**, an enzyme complex coupled to a membrane receptor. (Roughly 80% of prescription drugs target receptors coupled to G proteins.) The name *G protein* refers to the fact that these proteins bind GTP. G proteins are activated when hormones bind to their receptors on the membrane surface. What happens next depends on the nature of the G protein and its effects on second messengers in the cytoplasm. **Spotlight Figure 18–3**, which focuses on the second messengers cyclic AMP (cAMP) and calcium ions (Ca^{2+}), diagrams three major patterns of response to G protein activation.

G Proteins and cAMP. **Spotlight Figure 18–3a** shows the steps involved in *increasing* the cAMP level:

1. The activated G protein activates the enzyme **adenylate cyclase**.
2. Adenylate cyclase converts ATP to the ring-shaped molecule *cyclic AMP*.
3. Cyclic AMP then functions as a second messenger, typically by activating a *kinase* ($\text{K}\bar{\text{I}}\text{-n}\bar{\text{a}}\text{s}$). A kinase is an enzyme that attaches a high-energy phosphate group ($-\text{PO}_4^{3-}$) to another molecule in a process called *phosphorylation*.
4. Generally, cyclic AMP activates kinases that phosphorylate proteins. The effect on the target cell depends on the nature of these proteins. The phosphorylation of plasma membrane proteins, for example, can open ion channels. In the cytoplasm, many important enzymes can be activated only by phosphorylation. One important example is the enzyme *glycogen phosphorylase*, which releases glucose from glycogen reserves in skeletal muscles and the liver.

Many hormones, including epinephrine, calcitonin, parathyroid hormone, ADH, ACTH, FSH, LH, TSH, and glucagon, produce their effects by this mechanism. The increase in cAMP level is usually short-lived because the cytoplasm contains another enzyme, **phosphodiesterase (PDE)**, which inactivates cyclic AMP by converting it to AMP (adenosine monophosphate).

Spotlight Figure 18–3a depicts one way the activation of a G protein can *decrease* the concentration of cAMP within the cell. In this case, the activated G protein stimulates PDE activity and inhibits adenylate cyclase activity. The cAMP level then decreases because cAMP breakdown accelerates while cAMP synthesis is prevented. The decline has an inhibitory effect on the cell, because without phosphorylation, key enzymes remain inactive.

G Proteins and Calcium Ions. An activated G protein can trigger either the opening of calcium ion channels in the

MECHANISM OF HORMONE ACTION

First and Second Messengers

A hormone that binds to receptors in the plasma membrane cannot directly affect the activities inside the target cell. For example, it cannot begin building a protein or catalyzing a specific reaction. Instead, the hormone uses an intracellular intermediary to bring about its effects. The hormone, or **first messenger**, does something that leads to the appearance of a **second messenger** in the cytoplasm. The second messenger may act as an enzyme activator, inhibitor, or cofactor. The net result is a change in the rates of various metabolic reactions. The two most important second messengers are cyclic AMP (cAMP), a derivative of ATP, and calcium ions (Ca^{2+}).

The first messenger (a peptide hormone, catecholamine, or eicosanoid) binds to a membrane receptor and activates a G protein.

A **G protein** is an enzyme complex coupled to a membrane receptor that serves as a link between the first and second messenger.

a Effects on cAMP Level

Many G proteins, once activated, exert their effects by changing the concentration of cyclic AMP, which acts as the second messenger within the cell.

If levels of cAMP increase, enzymes may be activated or ion channels may be opened, accelerating the metabolic activity of the cell.

In some instances, G protein activation results in decreased levels of cAMP in the cytoplasm. This decrease has an inhibitory effect on the cell.

First Messenger Examples

- Epinephrine and norepinephrine
- Calcitonin
- Parathyroid hormone
- ADH, ACTH, FSH, LH, TSH

First Messenger Examples

- Epinephrine and norepinephrine

b Effects on Ca^{2+} Level

Some G proteins use Ca^{2+} as a second messenger within the cell.

First Messenger Examples

- Epinephrine and norepinephrine
- Oxytocin
- Regulatory hormones of hypothalamus
- Several eicosanoids

plasma membrane or the release of calcium ions from intracellular compartments. **Spotlight Figure 18–3b** diagrams the steps involved:

1. The G protein first activates the enzyme **phospholipase C (PLC)**.
2. This enzyme triggers a receptor cascade that begins with the production of **diacylglycerol (DAG)** and **inositol triphosphate (IP₃)** from membrane phospholipids.
3. IP₃ diffuses into the cytoplasm and triggers the release of Ca²⁺ from intracellular reserves, such as those in the smooth endoplasmic reticulum of many cells.
4. The combination of DAG and intracellular calcium ions activates a cytosolic protein: **protein kinase C (PKC)**. The activation of PKC leads to the phosphorylation of calcium ion channel proteins, a process that opens the channels and permits extracellular Ca²⁺ to enter the cell. This sets up a positive feedback loop that rapidly elevates the intracellular calcium ion concentration.
5. The calcium ions themselves serve as messengers, generally in combination with an intracellular protein called **calmodulin**. Once it has bound calcium ions, calmodulin can activate specific cytoplasmic enzymes. Calmodulin activation is also involved in the responses to oxytocin and to several regulatory hormones secreted by the hypothalamus.

18

Hormones and Intracellular Receptors: Gene Activation

Most hormones that target intracellular receptors are steroid or thyroid hormones. Steroid hormones can diffuse across the lipid part of the plasma membrane and bind to receptors in the cytoplasm or nucleus. The hormone–receptor complexes then activate or deactivate specific genes (**Figure 18–4a**). By this mechanism, steroid hormones can alter the rate of DNA transcription in the nucleus and so change the pattern of protein synthesis. Alterations in the synthesis of enzymes or structural proteins directly affect both the metabolic activity and the structure of the target cell. For example, the sex hormone *testosterone* stimulates the production of enzymes and structural proteins in skeletal muscle fibers, causing increased muscle size and strength.

Thyroid hormones cross the plasma membrane primarily by a transport mechanism. Once in the cytoplasm, these hormones bind to receptors within the nucleus and on mitochondria (**Figure 18–4b**). The hormone–receptor complexes in the nucleus activate specific genes or change the rate of transcription. The change in transcription rate affects the metabolic activities of the cell by increasing or decreasing the concentration of specific enzymes. Thyroid hormones bound to mitochondria increase the mitochondrial rates of ATP production.

Control of Hormone Secretion

Hormone secretion, or endocrine activity, is mainly controlled by negative feedback. A stimulus triggers the production of a hormone whose direct or indirect effects reduce the intensity of the stimulus.

Hormone secretion can be triggered by (1) *humoral stimuli* (changes in the composition of the extracellular fluid), (2) *hormonal stimuli* (the arrival or removal of a specific hormone), or (3) *neural stimuli* (the arrival of neurotransmitters at neuroglandular junctions).

In the simplest case, only one hormone is involved. The endocrine cells involved respond directly to changes in the composition of the extracellular fluid by continuously releasing hormones. The secreted hormone adjusts the activities of target cells and restores homeostasis.

Hormone secretion by the heart, pancreas, parathyroid glands, and digestive tract is controlled by humoral stimuli. For example, when the blood glucose level increases, the pancreas increases its secretion of *insulin*, a hormone that stimulates glucose uptake and use. As the insulin level increases, the glucose level decreases, reducing the stimulation of the insulin-secreting cells. As the glucose level returns to normal, the rate of insulin secretion returns to resting levels. (This regulatory pattern, called *negative feedback*, was introduced in Chapter 1 when we considered the control of body temperature.)

Hormone secretion may also be controlled by hormonal stimuli, such as changes in the levels of circulating hormones. Such control may involve one or more intermediary steps and two or more hormones. However, the relationship between hormone concentration and target cell response is not always predictable. For instance, a hormone can have one effect at low concentrations and more exaggerated effects—or even different effects—at high concentrations. (We consider specific examples later in the chapter.)

Finally, hormone secretion can be triggered by neural stimuli when a neurotransmitter arrives at a neuroglandular junction. An important example of hormone secretion linked to neural stimuli involves the activity of the hypothalamus. It provides the highest level of endocrine control, as we discuss in the next section.

Checkpoint

4. What primary factor determines each cell's hormonal sensitivities?
5. How would a substance that inhibits the enzyme adenylate cyclase affect the activity of a hormone that produces its cellular effects by way of the second messenger cAMP?
6. Describe negative feedback as it relates to humoral stimuli.

See the blue Answers tab at the back of the book.

Figure 18-4 Effects of Intracellular Hormone Binding.

a Steroid hormones diffuse through the plasma membrane and bind to receptors in the cytoplasm or nucleus. The complex then binds to DNA in the nucleus, activating specific genes.

b Thyroid hormones enter the cytoplasm and bind to receptors in the nucleus to activate specific genes. They also bind to receptors on mitochondria and accelerate ATP production.

18-3 The anterior lobe of the pituitary gland produces and releases hormones under hypothalamic control, while the posterior lobe releases hypothalamic hormones

Learning Outcome Describe the location, hormones, and functions of the pituitary gland, and discuss the effects of variation in pituitary hormone production.

The *pituitary gland* has *anterior* and *posterior lobes* that differ in function and developmental anatomy. It releases nine

important peptide hormones; seven are from the anterior lobe and two are from the posterior lobe. The *hypothalamus* has a close anatomical and functional relationship with both lobes of the pituitary gland. We begin this section with the anatomy of these critical organs.

Anatomy of the Hypothalamus and Pituitary Gland

The **hypothalamus**, which contains both brain centers and endocrine tissue, is found inferior to the thalamus. The hypothalamus is superior to the pituitary gland, and

Figure 18-5 The Orientation and Anatomy of the Pituitary Gland.

is connected to it by the slender, funnel-shaped structure called the **infundibulum** (in-fun-DIB-ū-lum; funnel).

Figure 18-5a shows the anatomy of the **pituitary gland**, or **hypophysis** (hī-POF-ih-sis). This small, bilobed gland lies nestled within the *sella turcica*, a depression in the sphenoid bone. The pituitary gland is held in position by the *sellar diaphragm*, a sheet of dura mater that encircles the infundibulum. The sellar diaphragm isolates the pituitary gland from the cranial cavity.

Control of Pituitary Activity by the Hypothalamus

The hypothalamus regulates the functions of both the anterior and posterior lobes of the pituitary gland. It also integrates the activities of the nervous and endocrine systems in three ways (**Figure 18-6**):

- The hypothalamus itself acts as an endocrine organ. Hypothalamic neurons synthesize hormones and transport them along axons to the posterior lobe of the pituitary gland, where they are released into the circulation. We introduced these hormones, antidiuretic hormone (ADH) and oxytocin (ok-sih-TŌ-sin; OXT), in Chapter 14. These hormones then go on to cause effects in their target organs.
- The hypothalamus secretes **regulatory hormones**. The hypothalamic regulatory hormones control the secretory activities of endocrine cells in the anterior lobe of the

pituitary gland. In turn, the hormones from the anterior lobe control the activities of endocrine cells in target organs.

- The hypothalamus contains autonomic centers that exert direct neural control over the endocrine cells of the adrenal medulla. When the sympathetic division is activated, the adrenal medulla releases the hormones epinephrine (E) and norepinephrine (NE) into the bloodstream.

The hypothalamus secretes regulatory hormones and ADH in response to changes in the composition of the circulating blood. The secretion of OXT, E, and NE involves both neural and hormonal mechanisms. For example, the adrenal medulla secretes E and NE in response to action potentials rather than to circulating hormones. Such pathways are called *neuroendocrine responses* because they include both neural and endocrine components.

Several hypothalamic and pituitary hormones are released in sudden bursts called *pulses*, rather than continuously. When hormones arrive in pulses, target cells (such as the cells of the anterior lobe of the pituitary gland in response to hypothalamic regulatory hormones) may vary their response with the frequency of the pulses. For example, the target cell response to one pulse every 3 hours can differ from the response when pulses arrive every 30 minutes. The most complicated hormonal instructions from the hypothalamus involve changes in the frequency of pulses *and* in the amount secreted in each pulse.

Figure 18–6 Three Mechanisms of Hypothalamic Control over Endocrine Function.

The regulatory hormones from the hypothalamus control secretion from endocrine cells, which are located where?

The Anterior Lobe of the Pituitary Gland

Let's look at how the anatomy of the anterior lobe and its associated blood vessels facilitates its function. We then describe how the hypothalamus controls the secretion of anterior lobe hormones, and the actions of those secreted hormones.

Histology of the Anterior Lobe

The **anterior lobe** of the pituitary gland, also called the **adenohypophysis** (ad-eh-nō-hī-POF-ih-sis), contains a variety of endocrine cells. The anterior lobe has three regions: (1) the **pars distalis** (dis-TAL-is; distal part), the largest and most anterior portion of the pituitary gland; (2) an extension called the **pars tuberalis**, which wraps around the adjacent portion of the infundibulum; and (3) the slender **pars intermedia**, a narrow band bordering the posterior lobe (Figure 18–5b). An extensive capillary network radiates through these regions, giving every endocrine cell immediate access to the bloodstream.

Hormone Secretion and the Hypophyseal Portal System

The hypothalamus controls the production of hormones in the anterior lobe of the pituitary gland by secreting specific regulatory hormones. At the *median eminence*, a swelling near the attachment of the infundibulum, hypothalamic neurons release regulatory hormones into the surrounding interstitial fluids. Their secretions enter the bloodstream quite easily because the endothelial cells lining the capillaries in this region are unusually permeable. These **fenestrated** (FEN-es-trāted; *fenestra*, window) **capillaries** allow relatively large molecules to enter or leave the bloodstream.

The *superior hypophyseal artery* supplies the capillary networks in the median eminence (Figure 18–7). Before leaving the hypothalamus, the capillary networks unite to form a series of larger vessels that spiral around the infundibulum to reach the anterior lobe. In the anterior lobe, these vessels form a second capillary network that branches among the endocrine cells.

Figure 18-7 The Hypophyseal Portal System and the Blood Supply to the Pituitary Gland.

This vascular arrangement is unusual because it carries blood from one capillary network to another. In contrast, a typical artery conducts blood from the heart to a capillary network, and a typical vein carries blood from a capillary network back to the heart. Blood vessels that link two capillary networks are called **portal vessels**. In this case, they have the histological structure of veins, so they are also called *portal veins*. The entire complex is a **portal system**. Portal systems are named for their destinations. This network is the **hypophyseal (hi-pō-FIZ-ē-al) portal system**.

Portal systems provide an efficient means of chemical communication. This one ensures that all the hypothalamic hormones entering the portal vessels reach the target cells in the anterior lobe before being diluted through mixing with the general circulation. The communication is strictly one way, however. Any chemicals released by the cells “downstream” must do a complete circuit of the cardiovascular system before they reach the capillaries of the portal system.

Hypothalamic Control of the Anterior Lobe

Two classes of hypothalamic regulatory hormones exist: releasing hormones and inhibiting hormones. A **releasing hormone (RH)** stimulates the synthesis and secretion of one or more hormones at the anterior lobe. In contrast, an **inhibiting**

hormone (IH) prevents the synthesis and secretion of hormones from the anterior lobe. Releasing hormones, inhibiting hormones, or some combination of the two may control an endocrine cell in the anterior lobe.

Once secreted, the anterior pituitary hormones then stimulate the cells of their target organs. Many of these organs are endocrine glands themselves, which then secrete hormones in response. In fact, the hormones of the anterior lobe are sometimes called *tropic hormones* (*trope*, a turning), because they “turn on” endocrine glands or support the functions of other organs. Then negative feedback from these target organ hormones controls the rate at which the hypothalamus secretes regulatory hormones. The primary regulatory patterns are diagrammed in **Figure 18-8**, and we will refer to them as we examine specific pituitary hormones.

Hormones of the Anterior Lobe

The control mechanisms and functions of seven hormones from the anterior lobe are reasonably well understood. The regulation of *thyroid-stimulating hormone*, *adrenocorticotrophic hormone*, and two gonadotropins called *follicle-stimulating hormone* and *luteinizing hormone* follows the typical regulatory pattern shown in **Figure 18-8a**. Two others, *prolactin* and *growth hormone*, follow the atypical patterns shown in **Figure 18-8b** and **c**, respectively. Of these six hormones, which are all produced by

Figure 18–8 Feedback Control of Endocrine Secretion.**Typical pattern of regulation when multiple endocrine organs are involved**

- a** The hypothalamus produces a releasing hormone (RH) to stimulate hormone production by other glands. Homeostatic control occurs by negative feedback.

**Variations on the typical pattern of regulation of endocrine organs by the hypothalamus and anterior pituitary lobe**

- b** The regulation of prolactin (PRL) production by the anterior lobe. In this case, the hypothalamus produces both a releasing hormone (PRH) and an inhibiting hormone (PIH). When one is stimulated, the other is inhibited.

- c** The regulation of growth hormone (GH) production by the anterior lobe. When GH–RH release is inhibited, GH–IH release is stimulated.

In a typical regulation pattern of endocrine secretion, which hormone is responsible for negative feedback?

the pars distalis, four regulate the production of hormones by other endocrine glands such as the thyroid, adrenal cortex, and reproductive organs. A final hormone, *melanocyte-stimulating hormone*, is produced by the pars intermedia (Figure 18–5). All seven hormones bind to extracellular receptors, and all use cAMP as a second messenger.

Thyroid-Stimulating Hormone. **Thyroid-stimulating hormone (TSH)**, or *thyrotropin*, targets the thyroid gland and triggers the release of thyroid hormones. TSH is released in response to *thyrotropin-releasing hormone* (TRH) from the hypothalamus. Then as circulating concentrations of thyroid hormones (called T_3 and T_4) rise, the rates of TRH and TSH production decline.

Adrenocorticotrophic Hormone. **Adrenocorticotrophic hormone (ACTH)**, also known as *corticotropin*, stimulates the release of steroid hormones by the *adrenal cortex*, the outer portion of the adrenal gland. ACTH specifically targets cells that produce *glucocorticoids* (glū-kō-KOR-tih-koydz), hormones that affect glucose metabolism such as cortisol. ACTH release occurs under the stimulation of **corticotropin-releasing hormone (CRH)** from the hypothalamus. As glucocorticoid levels increase, the rates of CRH release and ACTH release decline.

Gonadotropins. The hormones called **gonadotropins** (gō-nad-ō-TRō-pinz) regulate the activities of the *gonads*. (These organs—the *testes* in males and the *ovaries* in females—produce reproductive cells as well as hormones.) **Gonadotropin-releasing hormone (GnRH)** from the hypothalamus stimulates production of gonadotropins. The two gonadotropins are follicle-stimulating hormone and luteinizing hormone:

- **Follicle-stimulating hormone (FSH)** promotes ovarian follicle development in females and, in combination with luteinizing hormone, stimulates the secretion of *estrogens* (ES-trō-jenz) by ovarian cells. Three major estrogens are *estrone*, *estradiol*, and *estriol*. Estrone is the primary estrogen made after menopause, estradiol is the primary estrogen made during reproductive years, and estriol is the primary estrogen made during pregnancy. *Estradiol* is the most potent estrogen. In males, FSH stimulates *nurse cells*, specialized cells in the seminiferous tubules where sperm differentiate. In response, the nurse cells promote the physical maturation of developing sperm. FSH production is inhibited by *inhibin*, a peptide hormone released by cells in the testes and ovaries. (The role of inhibin in suppressing the release of GnRH as well as FSH is under debate.)
- **Luteinizing (LŪ-tē-in-ī-zing) hormone (LH)** induces *ovulation*, the release of a reproductive cell in females. It also promotes ovarian secretion of estrogens and *progesterone*, which prepare the body for possible pregnancy. In males, this gonadotropin stimulates the production of sex hormones by the *interstitial endocrine cells* of the testes. These male sex hormones are called **androgens** (AN-drō-jenz; *andros*, man). The most important one is *testosterone*. LH production,

like FSH production, is stimulated by GnRH from the hypothalamus. Estrogens, progesterone, and androgens inhibit GnRH production.

Low production of gonadotropins results in **hypogonadism**. Children with this condition do not mature sexually, and adults with hypogonadism cannot produce functional sperm (males) or oocytes (females).

Prolactin. **Prolactin** (*pro-*, before + *lac*, milk) (**PRL**) helps stimulate mammary gland development in females. Although PRL exerts the dominant effect on the glandular cells, normal development of the mammary glands is regulated by the interaction of several hormones. (The functional development of the mammary glands is described in Chapter 28.) In pregnancy and during the nursing period that follows childbirth, PRL also stimulates milk production by the mammary glands. The functions of PRL in males are poorly understood, but evidence indicates that this hormone helps regulate androgen production by making interstitial endocrine cells more sensitive to LH.

Prolactin production is inhibited by the neurotransmitter dopamine, also known as **prolactin-inhibiting hormone (PIH)**. The hypothalamus also secretes **prolactin-releasing hormone (PRH)**. Circulating PRL stimulates PIH release and inhibits the secretion of PRH (Figure 18–8b).

Growth Hormone. **Growth hormone (GH)**, or **somatotropin**, stimulates cell growth and division by accelerating the rate of protein synthesis. Skeletal muscle cells and chondrocytes (cartilage cells) are particularly sensitive to GH, although virtually every tissue responds to some degree.

The stimulation of growth by GH involves two mechanisms, indirect and direct. The primary mechanism, which is indirect, is best understood. Liver cells respond to GH by synthesizing and releasing **somatomedins**, known also as *insulin-like growth factors* (IGFs). These peptide hormones stimulate tissue growth by binding to receptors on a variety of plasma membranes (Figure 18–8c). In skeletal muscle fibers, cartilage cells, and other target cells, somatomedins increase the uptake of amino acids and their incorporation into new proteins. These effects develop almost immediately after GH is released. They are particularly important after a meal, when the blood contains high concentrations of glucose and amino acids. In functional terms, cells can now obtain ATP easily through the aerobic metabolism of glucose, and amino acids are readily available for protein synthesis. Under these conditions, GH, acting through the somatomedins, stimulates protein synthesis and cell growth.

The direct actions of GH are more selective. They tend to appear after blood glucose and amino acid concentrations have returned to normal levels:

- In epithelia and connective tissues, GH stimulates stem cell divisions and the differentiation of daughter cells. (Somatomedins then stimulate the growth of these daughter cells.)

- In adipose tissue, GH stimulates the breakdown of stored triglycerides by adipocytes (fat cells), which then release fatty acids into the blood. As the level of circulating fatty acids rises, many tissues stop breaking down glucose to generate ATP and instead start breaking down fatty acids. This process is termed a **glucose-sparing effect**.
- In the liver, GH stimulates the breakdown of glycogen reserves by liver cells, which then release glucose into the bloodstream. Because most other tissues are now metabolizing fatty acids rather than glucose, the blood glucose concentration begins to climb to a level significantly higher than normal. This elevation of the blood glucose level by GH has been called a **diabetogenic effect** because *diabetes mellitus*, an endocrine disorder we consider later in the chapter, is characterized by high levels of blood glucose.

The production of GH is regulated by **growth hormone-releasing hormone (GH-RH)** and **growth hormone-inhibiting hormone (GH-IH)**, also called *somatostatin*, from the hypothalamus. Somatomedins inhibit GH-RH and stimulate GH-IH.

Melanocyte-Stimulating Hormone. The pars intermedia may secrete two forms of **melanocyte-stimulating hormone (MSH)**. As the name indicates, MSH stimulates the melanocytes of the skin, increasing their production of melanin, a brown, black, or yellow-brown pigment. Dopamine inhibits the release of MSH.

Melanocyte-stimulating hormone from the pituitary gland is important in the control of skin pigmentation in fishes, amphibians, reptiles, and many mammals other than primates. In humans, MSH is produced locally, within sun-exposed skin. The pars intermedia in adult humans is virtually nonfunctional, and the circulating blood usually does not contain MSH. However, the human pars intermedia secretes MSH (1) during fetal development, (2) in very young children, (3) in pregnant females, and (4) in the course of some diseases. The functional significance of MSH secretion under these circumstances is not known.

The Posterior Lobe of the Pituitary Gland

The **posterior lobe** of the pituitary gland, also called the **neurohypophysis** (nū-rō-hī-POF-ih-sis), contains the axons of hypothalamic neurons. Neurons of the **supra-optic** and **paraventricular nuclei** manufacture antidiuretic hormone (ADH) and oxytocin (OXT), respectively (**Figure 18-7**). Via axoplasmic transport, these hormones move within axons in the infundibulum to axon terminals, which end on the basement membranes of capillaries in the posterior lobe. The posterior lobe does not have a portal system. The *inferior hypophyseal artery* delivers blood to it, and the *hypophyseal veins* carry the blood and hormones away. At their target organs, both hormones bind to extracellular receptors, and both use cAMP as a second messenger.

Antidiuretic Hormone

Antidiuretic hormone (ADH), also known as *vasopressin* (VP), is released in response to a variety of stimuli, most notably an increase in the solute concentration in the blood or a decrease in blood volume or blood pressure. An increase in the solute concentration stimulates specialized neurons in the hypothalamus. These neurons are called *osmoreceptors* because they respond to a change in the osmotic concentration of body fluids. The osmoreceptors then stimulate the neurosecretory neurons that release ADH.

The primary function of ADH is to act on the kidneys to retain water and decrease urination. With losses minimized, any water absorbed from the digestive tract will be retained, reducing the concentrations of electrolytes in the extracellular fluid. At a high concentration, ADH also causes *vasoconstriction*, a narrowing of peripheral blood vessels that helps elevate blood pressure. Alcohol inhibits ADH release, which explains why people find themselves making frequent trips to the bathroom after consuming alcoholic beverages.

Oxytocin

In females, **oxytocin** (*oxy-*, quick + *tokos*, childbirth) (**OXT**) stimulates smooth muscle contraction in the wall of the uterus, promoting labor and delivery. After delivery, oxytocin promotes the ejection of milk by stimulating the contraction of myoepithelial cells around the secretory alveoli and the ducts of the mammary glands.

Until the last stages of pregnancy, the uterine smooth muscles are relatively insensitive to oxytocin, but they become

18

+ Clinical Note Diabetes Insipidus

Diabetes occurs in several forms. All are characterized by excessive urine production (*polyuria*; pol-ē-YŪR-ē-ah). Most forms result from endocrine abnormalities, but physical damage to the kidneys can also cause diabetes. The two most prevalent forms are *diabetes insipidus* and *diabetes mellitus*. (We describe diabetes mellitus in **Spotlight Figure 18-18**.) **Diabetes insipidus** generally develops because the posterior lobe of the pituitary gland no longer releases adequate amounts of antidiuretic hormone (ADH). Water conservation by the kidneys is impaired, and excessive amounts of water are lost in the urine. As a result, the person is constantly thirsty, but the body does not retain the fluids consumed.

Mild cases of diabetes insipidus may not require treatment if fluid and electrolyte intake keep pace with urinary losses. In severe cases, the fluid losses can reach 10 liters per day (normal urinary output is about 1–2 liters per day), and dehydration and electrolyte imbalances are fatal without treatment. This condition can be effectively treated with desmopressin, a synthetic form of ADH.

more sensitive as delivery approaches. The trigger for normal labor and delivery is probably a sudden rise in the oxytocin level at the uterus. There is good evidence, however, that the uterus and fetus secrete most of the oxytocin involved. Oxytocin from the posterior lobe plays only a supporting role.

Oxytocin secretion and milk ejection are part of a neuroendocrine response reflex called the *milk ejection reflex* (*milk let-down reflex*). Milk ejection occurs only in response to oxytocin release at the posterior lobe of the pituitary gland. The normal stimulus is an infant suckling at the breast, and sensory nerves innervating the nipples relay the information to the hypothalamus. Oxytocin is then released into the circulation at the posterior lobe, and the myoepithelial cells respond by squeezing milk from the secretory alveoli into large collecting ducts. Any factor that affects the hypothalamus can modify this reflex. For example, anxiety, stress, and other factors can prevent the flow of milk, even when the mammary glands are fully functional. In contrast, nursing individuals can become conditioned to associate a baby's crying with suckling. In these individuals, milk ejection may begin as soon as they hear a baby cry.

The functions of oxytocin in sexual activity remain uncertain, but it is known that the circulating concentration of oxytocin rises during sexual arousal and peaks at orgasm in both sexes. Evidence indicates that in males, oxytocin stimulates smooth muscle contractions in the walls of the *ductus deferens* (sperm duct) and prostate. These actions may be important in *emission*—the ejection of sperm, secretions of the prostate, and the secretions of other glands into the male reproductive tract before ejaculation. Studies suggest that the oxytocin released in females during intercourse may stimulate smooth muscle contractions in the uterus and vagina that promote the transport of sperm toward the uterine tubes.

Summary: The Hormones of the Pituitary Gland

Table 18–2 and Figure 18–9 summarize important information about the hormones of the pituitary gland. Review them carefully before considering the structure and function of other endocrine organs.

Table 18–2 The Pituitary Hormones

	Hormone	Target	Hormonal Effect	Hypothalamic Regulatory Hormone
ANTERIOR LOBE				
Pars distalis	Thyroid-stimulating hormone (TSH)	Thyroid gland	Secretion of thyroid hormones	Thyrotropin-releasing hormone (TRH)
	Adrenocorticotrophic hormone (ACTH)	Adrenal cortex (zona fasciculata)	Secretion of glucocorticoids (cortisol, corticosterone, and cortisone)	Corticotropin-releasing hormone (CRH)
	Gonadotropins:			
	Follicle-stimulating hormone (FSH)	Follicle cells of ovaries	Secretion of estrogen, follicle development	Gonadotropin-releasing hormone (GnRH)
		Nurse cells of testes	Stimulation of sperm maturation	Gonadotropin-releasing hormone (GnRH)
	Luteinizing hormone (LH)	Follicle cells of ovaries	Ovulation, formation of corpus luteum, secretion of progesterone	Gonadotropin-releasing hormone (GnRH)
		Interstitial endocrine cells of testes	Secretion of testosterone	Gonadotropin-releasing hormone (GnRH)
	Prolactin (PRL)	Mammary glands	Production of milk	Prolactin-releasing factor (PRF) Prolactin-inhibiting hormone (PIH)
	Growth hormone (GH)	All cells	Growth, protein synthesis, lipid mobilization and catabolism	Growth hormone–releasing hormone (GH–RH) Growth hormone–inhibiting hormone (GH–IH)
Pars intermedia (not active in adults)	Melanocyte-stimulating hormone (MSH)	Melanocytes	Increased melanin synthesis in epidermis	Melanocyte-stimulating hormone–inhibiting hormone (MSH–IH)
POSTERIOR LOBE				
	Antidiuretic hormone (ADH)	Kidneys	Reabsorption of water, elevation of blood volume and pressure	None; transported along axons from supra-optic nucleus to the posterior lobe of the pituitary gland
	Oxytocin (OXT)	Uterus, mammary glands (females)	Labor contractions, milk ejection	None; transported along axons from paraventricular nucleus to the posterior lobe of the pituitary gland
		Ductus deferens and prostate (males)	Contractions of ductus deferens and prostate	None; transported along axons from paraventricular nucleus to the posterior lobe of the pituitary gland

Figure 18–9 Pituitary Hormones and Their Targets.

What hormones are released from the posterior lobe of the pituitary gland and how does their release differ from hormones released by the anterior lobe of the pituitary gland?

Checkpoint

- Identify the two lobes of the pituitary gland.
- If a person were dehydrated, how would the amount of ADH released by the posterior pituitary lobe change?
- The release of which pituitary hormone would lead to an increased level of somatomedins in the blood?
- What effect would an elevated circulating level of cortisol, a steroid hormone from the adrenal cortex, have on the pituitary secretion of ACTH?

See the blue Answers tab at the back of the book.

18-4 The thyroid gland synthesizes thyroid hormones that affect the rate of metabolism

Learning Outcome Describe the location, hormones, and functions of the thyroid gland and discuss the effects of variation in thyroid hormone production.

The thyroid gland is a ductless gland in the neck that secretes hormones regulating growth, development, and metabolism. Cells of this gland extract iodine from the blood to synthesize thyroid hormones. Let's begin with the anatomy.

Anatomy of the Thyroid Gland

The **thyroid gland** curves across the anterior surface of the trachea just inferior to the *thyroid* (“shield-shaped”) *cartilage*, which forms most of the anterior surface of the larynx (**Figure 18–10a**). The two **lobes** of the thyroid gland are united by a slender connection, the **isthmus** (IS-mus). This gland is felt by applying pressure with the fingers to the anterior neck. The size of the gland varies, depending on heredity and environmental and nutritional factors, but its average weight is about 34 g (1.2 oz). When something goes wrong with this gland, it typically becomes visible as it enlarges and distorts the surface of the neck.

The thyroid gland contains large numbers of **thyroid follicles**, hollow spheres lined by a simple cuboidal epithelium (**Figure 18–10b,c**). The follicle cells encircle a **follicle cavity** that holds a viscous *colloid*, a fluid containing large quantities of dissolved proteins. A network of capillaries surrounds each follicle, delivering nutrients and regulatory hormones to the glandular cells and accepting their secretory products and metabolic wastes.

The thyroid also contains a second population of endocrine cells. These cells are the **C (clear) cells**, or *parafollicular cells* (**Figure 18–10c**). They lie sandwiched between the cuboidal follicle cells and their basement membrane. They are larger than the cells of the follicular epithelium and do not stain as clearly.

Tips

The structure of a thyroid follicle is similar to that of a gel capsule: The simple cuboidal epithelium is comparable to the capsule itself, and the colloid to the capsule’s viscous contents.

Synthesis and Regulation of Thyroid Hormones

The thyroid gland produces two types of **thyroid hormones**, called T_3 and T_4 . *Thyroid-stimulating hormone* (TSH) regulates both the synthesis and release of thyroid hormones. The synthesis of these hormones requires iodine, which we obtain from the food we eat.

Thyroid Hormone Synthesis

Follicle cells synthesize a globular protein called **thyroglobulin** (thī-rō-GLOB-yū-lin) and secrete it into the colloid of the thyroid follicles. Thyroglobulin molecules contain the amino acid tyrosine, the building block of thyroid hormones. The formation of thyroid hormones involves the following basic steps (**Figure 18–11a**):

① **Iodide ions** (I^-) are absorbed from the diet by the digestive tract, and the bloodstream delivers them to the thyroid gland. TSH-sensitive carrier proteins in the basement membrane of the follicle cells actively transport iodide ions into the cytoplasm.

② The iodide ions diffuse to the apical surface of each follicle cell, where they lose an electron and are converted to an atom of iodine (I^0) by the enzyme *thyroid peroxidase*. This reaction sequence, which occurs at the apical membrane surface, also attaches 1 or 2 iodine atoms to the tyrosine portions of a thyroglobulin molecule within the follicle cavity.

③ Tyrosine molecules with attached iodine atoms become linked by covalent bonds, forming molecules of thyroid hormones that remain incorporated into thyroglobulin. Thyroid peroxidase probably carries out the pairing process. The hormone **thyroxine** (thī-ROK-sēn), also known as *tetraiodothyronine*, or T_4 , contains 4 iodine atoms. A related molecule called **triiodothyronine**, or T_3 , contains 3 iodine atoms. Eventually, each molecule of thyroglobulin contains 4 to 8 molecules of T_3 , or T_4 , or both.

Hypothalamic Regulation of Thyroid Hormone Synthesis and Release

TSH plays a key role in both the synthesis and the release of thyroid hormones. TSH stimulates the active transport of iodide into the follicle cells. The resulting increase in the rate of iodide movement into the cytoplasm of these cells accelerates the formation of thyroglobulin and thyroid peroxidase, and so of thyroid hormones. TSH acts as a first messenger, binding to plasma membrane receptors and, by stimulating the second messenger adenylate cyclase, activates key enzymes involved in thyroid hormone production (**Spotlight Figure 18–3a**). Without TSH, the thyroid follicles become inactive, and neither synthesis nor secretion occurs.

The major factor controlling the rate of thyroid hormone release is the concentration of TSH in the circulating blood (**Figure 18–11b**). Under the influence of TSH, the following steps occur (**Figure 18–11a**):

④ Follicle cells remove thyroglobulin from the follicles by endocytosis.

⑤ Lysosomal enzymes break down the thyroglobulin, and the amino acids and thyroid hormones enter the cytoplasm. The amino acids are then recycled and used to synthesize more thyroglobulin.

⑥ The released molecules of T_3 and T_4 diffuse across the basement membrane and enter the bloodstream. About 90% of all thyroid secretions is T_4 , and T_3 is secreted in comparatively small amounts.

⑦ Thyroid hormones are distributed in blood by **thyroid-binding globulin** (TBG), one of three major transport proteins. The other two are **transthyretin** and albumin. Thyroid-binding globulin has a greater affinity to T_4 molecules.

Figure 18–10 Anatomy of the Thyroid Gland.

Figure 18–11 Synthesis and Regulation of Thyroid Hormones.**a** The synthesis, storage, and secretion of thyroid hormones.**b** The regulation of thyroid secretion.

Only the relatively small quantities of thyroid hormones that remain unbound—roughly 0.3% of the circulating T_3 and 0.03% of the circulating T_4 —are free to diffuse into peripheral tissues.

Equilibrium exists between the amount of bound and unbound thyroid hormones. At any moment, free thyroid hormones are being bound to transport proteins at the same rate at which bound hormones are being released. When unbound thyroid hormones diffuse out of the bloodstream and into other tissues, the equilibrium is disturbed. The transport proteins then release additional thyroid hormones until a new equilibrium is reached. The bound thyroid hormones make up a substantial reserve: The bloodstream normally has more than a week's supply of thyroid hormones.

Iodine and Thyroid Hormones

Each day the follicle cells in the thyroid gland absorb 120–150 μg of **iodine ions** (I^-), the minimum dietary amount needed to maintain normal thyroid function. As a result, the concentration of I^- inside thyroid follicle cells is generally about 30 times higher than that in the blood. If the blood I^- level rises, so does its level inside the follicle cells. The thyroid follicles contain most of the iodide reserves in the body.

The typical diet in the United States provides approximately 500 μg of iodide per day, about three times the minimum daily requirement. Much of the excess is due to the I^- added to table salt (iodized salt), which is consumed in large quantities in processed foods. For this reason, iodide deficiency is seldom responsible for limiting the rate of thyroid hormone production. (This is not necessarily the case in other countries.) The kidneys remove excess I^- from the blood and eliminate it in the urine. Each day the liver excretes a small amount of I^- (about 20 μg) into the bile, an exocrine product stored in the gallbladder. The I^- excreted in bile is then eliminated in the feces. Because the losses in the bile continue even if the diet contains less than the minimum iodide requirement, this process can gradually deplete the iodide reserves in the thyroid. Thyroid hormone production then declines, regardless of the circulating TSH level.

Functions of Thyroid Hormones

Thyroid hormones affect almost every cell in the body; they produce a strong, immediate, and short-lived increase in the rate of cellular metabolism. They enter target cells by means of an energy-dependent transport system. Inside a target cell, they bind to receptors in three locations: (1) in the cytoplasm, (2) on the surfaces of mitochondria, and (3) in the nucleus.

- Thyroid hormones bound to cytoplasmic receptors are essentially held in storage. If intracellular levels of thyroid hormones decline, the bound thyroid hormones are released into the cytoplasm.

- The thyroid hormones binding to mitochondria increase the rates of mitochondrial ATP production.
- The binding to receptors in the nucleus activates genes that control the synthesis of enzymes involved in energy transformation and use. One specific effect is the accelerated production of *sodium–potassium ATPase*. Recall that this membrane protein ejects intracellular sodium ions and recovers extracellular potassium ions. This exchange pump uses large amounts of ATP.

Thyroid hormones also activate genes that code for enzymes involved in glycolysis and ATP production. Coupled with the direct effect of thyroid hormones on mitochondria, this effect increases the metabolic rate of the cell. The effect is called the **calorigenic effect** (*calor*, heat) of thyroid hormones because the cell consumes more energy and generates more heat. In young children, TSH production increases in cold weather, and the calorigenic effect may help them adapt to cold climates. (This response does not occur in adults.) In growing children, thyroid hormones are also essential to normal development of the skeletal, muscular, and nervous systems.

The thyroid gland produces large amounts of T_4 , but T_3 is primarily responsible for the observed effects of thyroid hormones. At any moment, T_3 released from the thyroid gland accounts for only 10–15% of the T_3 in peripheral tissues. However, enzymes in the liver, kidneys, and other tissues convert T_4 to T_3 . Approximately 85–90% of the T_3 that reaches the target cells comes from the conversion of T_4 within peripheral tissues. **Table 18–3** summarizes the effects of thyroid hormones on major organs and systems.

Synthesis and Functions of Calcitonin

The C cells of the thyroid gland produce the hormone **calcitonin (CT)**, which helps to regulate the Ca^{2+} concentration in body fluids. We introduced the functions of this hormone in Chapter 6. Calcitonin stimulates Ca^{2+} excretion by the kidneys and prevents Ca^{2+} absorption by the digestive tract.

Calcitonin might be most important during childhood when it stimulates bone growth and skeletal mineral deposition.

Table 18–3 Effects of Thyroid Hormones on Major Organs and Systems

- Elevate rates of oxygen consumption and energy consumption; in children, may cause a rise in body temperature
- Increase heart rate and force of contraction; generally results in a rise in blood pressure
- Increase sensitivity to sympathetic stimulation
- Maintain normal sensitivity of respiratory centers to changes in oxygen and carbon dioxide concentrations
- Stimulate red blood cell formation and thus enhance oxygen delivery
- Stimulate activity in other endocrine tissues
- Accelerate turnover of minerals in bone

It also appears to be important in reducing the loss of bone mass (1) during prolonged starvation and (2) in the late stages of pregnancy. Late in pregnancy, the maternal skeleton competes with the developing fetus for calcium ions from the diet. The role of calcitonin on the bones of the skeleton in the healthy nonpregnant adult is unclear.

In several chapters you have read about the importance of Ca^{2+} in controlling muscle cell and neuron activities. The calcium ion concentration also affects the sodium ion permeabilities of excitable membranes. At a high Ca^{2+} concentration, sodium ion permeability decreases and membranes become less responsive. Such problems are relatively rare.

Lower-than-normal Ca^{2+} concentrations are dangerous. When the calcium ion concentration declines, sodium ion permeabilities increase. As a result, cells become extremely excitable. If the calcium ion level falls too far, convulsions or muscular spasms can result. The *parathyroid glands* and *parathyroid hormone* are largely responsible for maintaining an adequate blood calcium level.

✓ Checkpoint

11. Identify the hormones of the thyroid gland.
12. What signs and symptoms are expected in a person whose diet lacks iodine?
13. When a person's thyroid gland is removed, signs of decreased thyroid hormone concentration do not appear until about 1 week later. Why?

See the blue Answers tab at the back of the book.

18-5 The four parathyroid glands secrete parathyroid hormone, which increases the blood calcium ion level

Learning Outcome Describe the location, hormone, and functions of the parathyroid glands and discuss the effects of variation in parathyroid hormone production.

There are normally two pairs of **parathyroid glands** embedded in the posterior surfaces of the thyroid gland (**Figure 18-12a**). A dense capsule surrounding each parathyroid gland separates

18

Figure 18-12 Anatomy of the Parathyroid Glands.

it from the cells of the thyroid gland. Altogether, the four parathyroid glands weigh a mere 1.6 g (0.06 oz). The histology of a single parathyroid gland is shown in **Figure 18-12b,c**. The parathyroid glands have at least two cell populations. The **parathyroid principal cells** produce parathyroid hormone. The functions of the other cells, called *parathyroid oxyphil cells*, are unknown. They do not appear until after puberty, and then their numbers increase with age.

Like the C cells of the thyroid gland, the parathyroid cells monitor the circulating concentration of calcium ions. When the Ca^{2+} concentration of the blood falls below normal, the parathyroid cells secrete **parathyroid hormone (PTH)**, or *parathormone*. The net result of PTH secretion is an increase in Ca^{2+} concentration in body fluids. Parathyroid hormone has three major effects:

- It mobilizes calcium from bone by affecting osteoblast and osteoclast activity. PTH stimulates osteoblasts to secrete a growth factor known as RANKL (receptor activator of nuclear factor kappa beta ligand). Osteoclasts

have no PTH receptors, but both precursor and mature osteoclasts have RANKL receptors. This growth factor results in an increase in osteoclasts and osteoclast activity. With more active osteoclasts, the rates of mineral turnover and Ca^{2+} release accelerate. As bone matrix erodes, the blood Ca^{2+} level rises.

- It enhances the resorption of Ca^{2+} by the kidneys, reducing urinary losses.
- It stimulates the formation and secretion of *calcitriol* by the kidneys. In general, the effects of calcitriol complement or enhance those of PTH, but calcitriol also enhances Ca^{2+} and PO_4^{3-} absorption by the digestive tract.

Figure 18-13 illustrates the role of PTH in regulating the blood Ca^{2+} concentration. PTH, aided by calcitriol, is probably the primary regulator of the circulating calcium ion concentration in healthy adults.

Information about the hormones of the thyroid gland and parathyroid glands is summarized in **Table 18-4**.

Figure 18-13 Homeostatic Regulation of the Blood Calcium Ion Concentration.

Table 18–4 Hormones of the Thyroid Gland and Parathyroid Glands

Gland/Cells	Hormone	Target	Hormonal Effect	Regulatory Control
THYROID GLAND				
Follicular epithelium	Thyroxine (T_4) Triiodothyronine (T_3)	Most cells	Increases energy utilization, oxygen consumption, growth, and development	Stimulated by TSH from the anterior lobe of the pituitary gland
C cells	Calcitonin (CT)	Kidneys, bone (mechanism unclear)	Decreases Ca^{2+} concentration in body fluids	Stimulated by elevated blood Ca^{2+} level; actions opposed by PTH
PARATHYROID GLANDS				
Parathyroid principal cells	Parathyroid hormone (PTH)	Bone, kidneys	Increases Ca^{2+} concentration in body fluids	Stimulated by low blood Ca^{2+} level; PTH effects enhanced by calcitriol and opposed by calcitonin

✓ Checkpoint

14. Describe the location of the parathyroid glands.
15. Identify the hormone secreted by the parathyroid glands.
16. Removing the parathyroid glands would result in a decrease in the blood concentration of which important mineral?

18

See the blue Answers tab at the back of the book.

18-6 The paired adrenal glands secrete several hormones that affect electrolyte balance and stress responses

Learning Outcome Describe the location, structure, hormones, and general functions of the adrenal glands and discuss the effects of variation in adrenal hormone production.

The *adrenal glands* are found superior to each kidney. This section looks at the anatomy of the adrenal glands and then the hormones produced by each of its component parts, which have effects on both the electrolyte balance of body fluids and on our responses to stress.

Anatomy of the Adrenal Glands

A yellow, pyramid-shaped **adrenal** (ad-RE-nul) **gland** (*ad-*, near + *ren*, kidney), or *suprarenal gland*, sits on the superior border of each kidney (**Figure 18–14a**). Each adrenal gland lies near the level of the 12th rib. A dense fibrous capsule firmly attaches each adrenal gland to the superior portion of each kidney. The adrenal gland on each side nestles among the kidney, the diaphragm, and the major arteries and veins that run along the posterior wall of the abdominopelvic cavity. The adrenal glands project into the peritoneal cavity, and their anterior surfaces are covered by a layer of parietal peritoneum. Like other endocrine glands, the adrenal glands are highly vascularized.

A typical adrenal gland weighs about 5.0 g (0.18 oz), but its size can vary greatly as secretory demands change. The adrenal gland has two regions with separate endocrine functions: a superficial *adrenal cortex* and an inner *adrenal medulla* (**Figure 18–14b**).

Corticosteroids of the Adrenal Cortex

The yellowish color of the adrenal cortex is due to stored lipids, especially cholesterol and various fatty acids. The **adrenal cortex** produces more than two dozen steroid hormones that are collectively called **corticosteroids**. In the bloodstream, these hormones are bound to transport proteins called *transcortins*.

Corticosteroids are vital. If the adrenal glands are destroyed or removed, the person will die unless corticosteroids are administered. Like other steroid hormones, corticosteroids exert their effects by turning on transcription of certain genes in the nuclei of their target cells and determining their transcription rates. The resulting changes in the nature and concentration of enzymes in the cytoplasm affect cellular metabolism.

Deep to the adrenal capsule are three distinct zones in the adrenal cortex (**Figure 18–14c**): (1) an outer *zona glomerulosa*, (2) a middle *zona fasciculata*, and (3) an inner *zona reticularis*. Each zone synthesizes specific steroid hormones.

Mineralocorticoids of the Zona Glomerulosa

The **zona glomerulosa** (glō-mer-yū-LŌ-suh) is the outer region of the adrenal cortex. The zona glomerulosa accounts for about 15% of the volume of the adrenal cortex (**Figure 18–14c**). A *glomerulus* is a little ball, and as the term *zona glomerulosa* implies, the endocrine cells in this region form small, dense knots or clusters. This zone extends from the capsule to the radiating cords of the deeper zona fasciculata.

The zona glomerulosa produces **mineralocorticoids**, steroid hormones that affect the electrolyte composition of body fluids. **Aldosterone** is the main mineralocorticoid of the zona glomerulosa.

Aldosterone stimulates the conservation of sodium ions and the elimination of potassium ions. This hormone targets cells that regulate the ionic composition of excreted fluids. It causes the retention of sodium ions by the kidneys, sweat glands, salivary glands, and pancreas, preventing sodium ion loss in urine, sweat, saliva, and digestive secretions. A loss of K^+ accompanies this retention of Na^+ . As a secondary effect, the

Figure 18–14 The Adrenal Gland and Adrenal Hormones.

The Adrenal Hormones

Region/Zone	Hormones	Primary Target	Hormonal Effects	Regulatory Control
 Adrenal capsule Zona glomerulosa Zona fasciculata Zona reticularis Adrenal cortex Adrenal medulla Adrenal gland LM × 140	Mineralocorticoids, primarily aldosterone Glucocorticoids (cortisol, corticosterone, and cortisone) Androgens Epinephrine (E), norepinephrine (NE)	Kidneys Most cells Most cells Most cells	Increase renal reabsorption of Na⁺ and water (especially in the presence of ADH), and accelerate urinary loss of K⁺ Increase rates of glucose and glycogen formation by the liver; release of amino acids from skeletal muscles, and lipids from adipose tissues; promote peripheral utilization of lipids; anti-inflammatory effects Adrenal androgens stimulate the development of pubic hair in boys and girls before puberty. Increases cardiac activity, blood pressure, glycogen breakdown, blood glucose levels; releases lipids by adipose tissue	Stimulated by angiotensin II, elevated blood K⁺ or fall in blood Na⁺; inhibited by ANP and BNP Stimulated by ACTH from the anterior lobe of the pituitary gland Androgen secretion is stimulated by ACTH. Stimulated by sympathetic preganglionic fibers

c The major regions and zones of an adrenal gland and the hormones they produce

Which zone of the adrenal cortex produces mineralocorticoids and what is the primary mineralocorticoid?

retention of Na^+ enhances the osmotic reabsorption of water by the kidneys, sweat glands, salivary glands, and pancreas. The effect at the kidneys is most dramatic when a normal level of ADH is present. In addition, aldosterone increases the sensitivity of salt receptors in the taste buds of the tongue. As a result, a person's interest in (and consumption of) salty food increases.

Aldosterone secretion occurs in response to a drop in blood Na^+ content, blood volume, or blood pressure, or to a rise in blood K^+ concentration. Changes in either Na^+ or K^+ concentration have a direct effect on the zona glomerulosa, but the secretory cells are most sensitive to changes in the K^+ level. A rise in the K^+ level is very effective in stimulating the release of aldosterone. Aldosterone release also occurs in response to *angiotensin II*. We discuss this hormone, part of the *renin-angiotensin-aldosterone system*, later in this chapter.

Glucocorticoids of the Zona Fasciculata

The **zona fasciculata** (fah-sik-yū-LAH-tuh; *fasciculus*, little bundle) produces steroid hormones collectively known as **glucocorticoids**, due to their effects on glucose metabolism. This zone begins at the inner border of the zona glomerulosa and extends toward the adrenal medulla (**Figure 18–14c**). It contributes about 78% of the cortical volume. The endocrine cells are larger and contain more lipids than those of the zona glomerulosa, and the lipid droplets give the cytoplasm a pale, foamy appearance. The cells of the zona fasciculata form individual cords composed of stacks of cells. Adjacent cords are separated by flattened blood vessels (sinusoids) with fenestrated walls.

The Glucocorticoids. When stimulated by ACTH from the anterior lobe of the pituitary gland, the zona fasciculata secretes primarily **cortisol** (KOR-tih-sol) along with smaller amounts of the related steroid **corticosterone** (kor-tih-KOS-tehr-ōn) and **cortisone**. Negative feedback regulates glucocorticoid secretion: The glucocorticoids released have an inhibitory effect on the production of corticotropin-releasing hormone (CRH) in the hypothalamus and on ACTH in the anterior pituitary lobe (**Figure 18–8a**).

Effects of Glucocorticoids. Glucocorticoids speed up the rates of glucose synthesis and glycogen formation, especially in the liver. Adipose tissue responds by releasing fatty acids into the blood, and other tissues begin to break down fatty acids and proteins instead of glucose. This process is another example of a glucose-sparing effect.

Glucocorticoids also show **anti-inflammatory** effects. That is, they inhibit the activities of white blood cells and other components of the immune system. Steroid creams are commonly used to control irritating allergic rashes, such as poison ivy rash, and injections of glucocorticoids may be used to control more severe allergic reactions. How do these treatments work? Glucocorticoids slow the migration of phagocytic cells into an injury site and cause phagocytic cells already in

the area to become less active. In addition, mast cells exposed to these steroids are less likely to release histamine and other chemicals that promote inflammation. As a result, swelling and further irritation are dramatically reduced. On the negative side, the rate of wound healing decreases, and the weakening of the region's defenses makes it more susceptible to infectious organisms. For that reason, the topical steroids used to treat superficial rashes should never be applied to open wounds.

Androgens of the Zona Reticularis

The **zona reticularis** (re-tik-ū-LAR-is; *reticulum*, network) forms a narrow band bordering each adrenal medulla (**Figure 18–14c**). This zone accounts for only about 7% of the total volume of the adrenal cortex. The endocrine cells of the zona reticularis form a folded, branching network, and fenestrated blood vessels wind among the cells.

Under stimulation by ACTH, the zona reticularis normally produces small quantities of *androgens*, the sex hormones produced in large quantities by the testes in males. Once in the bloodstream, some of the androgens from the zona reticularis are converted to *estrogens*, the dominant sex hormones in females. Adrenal androgens stimulate the development of pubic hair in young males and young females before puberty. Adrenal androgens are not important in adult males, but in adult females they promote muscle mass and blood cell formation, and they support the sex drive.

Catecholamines of the Adrenal Medulla

The boundary between the adrenal cortex and the adrenal medulla is irregular, and the supporting connective tissues and blood vessels are extensively interconnected. The **adrenal medulla** is pale gray or pink, due in part to the many blood vessels in the area. It contains large, rounded cells—similar to cells in sympathetic ganglia that are innervated by preganglionic sympathetic fibers. The sympathetic division of the autonomic nervous system controls secretion by the adrenal medulla.

The adrenal medulla contains two populations of secretory cells: One produces epinephrine (E), the other norepinephrine (NE), both catecholamines. Evidence suggests that the two types of cells are distributed in different areas and that their secretory activities can be independently controlled. The secretions are packaged in vesicles that form dense clusters just inside plasma membranes. The hormones in these vesicles are continuously released at low levels by exocytosis. Sympathetic stimulation dramatically accelerates the rate of exocytosis and hormone release.

Epinephrine makes up 75–80% of the secretions from the adrenal medulla. The rest is norepinephrine. These hormones interact with alpha and beta receptors on plasma membranes, as described in Chapter 16. Stimulation of α_1 and β_1 receptors, the most common types, speeds up the use of cellular energy and the mobilization of energy reserves.

Activation of the adrenal medulla has the following effects:

- In skeletal muscles, E and NE trigger mobilization of glycogen reserves and accelerate the breakdown of glucose to provide ATP. This combination increases both muscular strength and endurance.
- In adipose tissue, stored fats are broken down into fatty acids, which are released into the bloodstream for other tissues to use for ATP production.
- In the liver, glycogen molecules are broken down. The resulting glucose molecules are released into the bloodstream, primarily for use by nervous tissue, which cannot shift to fatty acid metabolism.
- In the heart, the stimulation of β_1 receptors produces an increase in the rate and force of cardiac muscle contraction.

The metabolic changes that follow the release of E and NE reach their peak about 30 seconds after adrenal stimulation, and they persist for several minutes. As a result, the effects of stimulating the adrenal medulla outlast the other signs of sympathetic activation.

✓ Checkpoint

17. Identify the two regions of the adrenal gland and cite the hormones secreted by each.
18. List the three zones of the adrenal cortex.
19. What effect would elevated cortisol level have on blood glucose level?

See the blue Answers tab at the back of the book.

Clinical Note Sex and Gender

Who we are as human beings and how we self-identify as individuals is unique to each person. While Chapter 29 focuses on development and inheritance, it is important to recognize the role that hormones play in sex and gender. Sex refers to the anatomical differences between people as male, female, or intersex. Gender refers to how individuals perceive themselves. When referring to sex, this involves the sex chromosomes, X and Y. Assigning sex using XY for males and XX for females is called binary nomenclature, meaning we name (nomenclature) someone as male or female using two (binary) chromosomes. In the United States, sex is assigned at birth based on the appearance of the external genitalia and noted on the birth certificate. Gender cannot be known at birth.

Biology is a complicated science, and while textbooks in the field tend to focus on binary sex as the norm, differences in hormone production and/or hormone responses affect reproductive organ development. For these reasons, some people may be assigned XX or XY at birth, but their underlying anatomy does not match (**intersex**). For example, with the condition known as *congenital adrenal hyperplasia* (CAH), a genetic mutation causes a deficiency in the adrenal steroid 21-hydroxylase. Without this enzyme, the adrenal glands produce too much androgen and too little cortisol and/or aldosterone. With CAH, XX individuals are born with ambiguous genitalia. This means that the chromosomes indicate female, but the genitals are not clearly male or female. With this same condition, XY individuals are male, may have enlarged penises at birth, and experience rapid growth and early puberty.

Complete androgen insensitivity syndrome is another example. In this case, XY individuals may develop as females or underdeveloped males. This is because the Y chromosome has no functional receptors for testosterone, leading to a body that may appear more female.

A condition affecting male sexual development before birth and during puberty is *5-alpha reductase deficiency*. 5-alpha reductase is an enzyme that catalyzes the conversion of testosterone to dihydrotestosterone (DHT). Individuals with 5-alpha reductase deficiency are born XY, but they have external genitalia that may appear female or the genitalia may appear ambiguous. Increased DHT is responsible for the start of male puberty and development of typical male secondary sex characteristics, namely, increased muscle mass, deepening voice, and pubic hair. In terms of gender, some individuals will identify as females and others as males.

Gender identity is much more complicated than just identifying sex chromosomes, or the presence or absence of hormones and hormone receptors. A person's gender identity can be either the same as or different from their assigned sex at birth. For example, at birth, a person may be assigned XY male and identify as male, or as gender-expansive (person still is exploring possibilities), gender-fluid (person does not identify with a fixed gender), gender nonconforming (person does not identify into a specific category), or genderqueer (person identifies as being both male and female, neither male nor female, or something else outside of binary nomenclature).

Transgender individuals identify as something other than the sex they were assigned at birth, which does not necessarily imply sexual orientation. For many transgender people, transitioning from a gender norm to their true gender—the one they feel they are meant to be and enjoy a full life—takes many forms. People transitioning may change socially and/or physically, utilizing pronoun changes, gender-affirming surgeries, medical transitions, and/or hormone therapy. As we learn more and contemplate the breadth of who we are as humans, we will understand that our humanity is far more complex than indicated by one's sex chromosomes alone.

18-7 The pineal gland secretes melatonin, which affects the circadian rhythm

Learning Outcome Describe the location of the pineal gland and discuss the functions of the hormone it produces.

The **pineal gland**, the main part of the epithalamus, lies in the posterior portion of the roof of the third ventricle (**Figure 18-15**). The pineal gland contains neurons, neuroglia, and special secretory cells called **pinealocytes** (pin-Ē-al-ō-sīts). These cells synthesize the hormone **melatonin** from molecules of the neurotransmitter *serotonin*. Collaterals from the visual pathways enter the pineal gland and affect the rate of melatonin production. This rate is lowest during daylight hours and highest at night.

Among the functions suggested for melatonin in humans are the following:

- **Influencing Circadian Rhythms.** Because its activity is cyclical, the pineal gland may be involved in maintaining basic *circadian rhythms*—daily changes in physiological processes that follow a regular day–night pattern. Increased melatonin secretion in darkness has been suggested as a primary cause of *seasonal affective disorder* (SAD). This condition can develop during the winter in people who live at high latitudes, where sunlight is scarce or lacking. It is characterized by changes in mood, eating habits, and sleeping patterns.
- **Inhibiting Reproductive Functions.** In some mammals, melatonin slows the maturation of sperm, oocytes, and reproductive organs by reducing the rate of GnRH secretion. The significance of this effect in humans remains unclear. Circumstantial evidence suggests that melatonin may play a role in the timing of human sexual maturation. The melatonin level in the blood declines at puberty, and pineal tumors that eliminate melatonin production cause premature puberty in young children.

Figure 18-15 Anatomy of the Pineal Gland.

- **Protecting against Damage by Free Radicals.** Melatonin is a very effective *antioxidant*. It may protect CNS neurons from free radicals, such as nitric oxide (NO) or hydrogen peroxide (H_2O_2), that may form in active nervous tissue.

Checkpoint

20. Identify the hormone-secreting cells of the pineal gland.
21. Increased amounts of light would inhibit the production of which hormone?
22. List three possible functions of melatonin.

18-8 The pancreas is both an exocrine organ and an endocrine gland that produces hormones affecting the blood glucose level

Learning Outcome Describe the location, structure, hormones, and functions of the pancreas and discuss the effects of variation in pancreatic hormone production.

The pancreas is a large gland located within the first fold of the small intestine (duodenum), close to the stomach. As an exocrine organ, it secretes digestive enzymes into the duodenum. Embedded in the pancreas are endocrine cells that secrete two hormones, insulin and glucagon, into the bloodstream. Our discussion begins with the anatomy of the pancreas.

Anatomy of the Pancreas

The **pancreas** is mostly retroperitoneal and lies in the loop between the inferior border of the stomach and the proximal portion of the small intestine (**Figure 18-1**). It is a slender, pale organ with a nodular (lumpy) texture (**Figure 18-16a**). The pancreas is 20–25 cm (8–10 in.) long and weighs about 80 g (2.8 oz) in adults.

The pancreas is made up of both exocrine and endocrine cells. The **exocrine pancreas** consists of clusters of gland cells, called *pancreatic acini*, and their attached ducts. The exocrine pancreas takes up roughly 99% of the pancreatic volume. Together the gland and duct cells secrete large quantities of an alkaline, enzyme-rich fluid that reaches the lumen of the digestive tract through a network of secretory ducts. We consider its anatomy further in Chapter 24.

The **endocrine pancreas** consists of small groups of cells scattered among the exocrine cells. The endocrine clusters are known as **pancreatic islets**, or the *islets of Langerhans* (LAHNG-er-hanz) (**Figure 18-16b**). Pancreatic islets account for only about one percent of all cells in the pancreas. Nevertheless, a typical pancreas contains approximately 2 million pancreatic islets. The pancreatic islets are surrounded by an extensive, fenestrated capillary network.

Figure 18–16 Anatomy of the Pancreas.

Functions of Pancreatic Islets

The hormones secreted by the pancreatic islets into the bloodstream are vital to our survival. Each islet contains four types of cells:

- **Alpha (α) cells** produce the hormone *glucagon* (GLŪ-kah-gon). Glucagon raises the blood glucose level by increasing the rates of glycogen breakdown and glucose release by the liver.
- **Beta (β) cells** produce the hormone *insulin* (IN-suh-lin). Insulin lowers the blood glucose level by increasing the rate of glucose uptake and use by most body cells, and by increasing glycogen synthesis in skeletal muscles and the liver. Beta cells also secrete *amylin*, a peptide hormone whose level rises after a meal.
- **Delta (δ) cells** produce a peptide hormone identical to growth hormone–inhibiting hormone (GH-IH), a hypothalamic regulatory hormone. GH-IH suppresses the release of glucagon and insulin by other islet cells and slows the rates of food absorption and enzyme secretion along the digestive tract.
- **Pancreatic polypeptide cells (PP cells)** produce the hormone pancreatic polypeptide (PP). PP inhibits gallbladder contractions and regulates the production of some pancreatic enzymes. It may also help control the rate of nutrient absorption by the digestive tract.

Hormones That Regulate the Blood Glucose Level

The hormones that regulate the blood glucose level are insulin and glucagon (**Figure 18–17**). When the blood glucose level increases, beta cells secrete insulin, which then stimulates the

transport of glucose across plasma membranes and into target cells. When the blood glucose level decreases, alpha cells secrete glucagon, which stimulates glycogen breakdown and glucose release by the liver.

Tips

To help in differentiating between the polysaccharide storage molecule “glycogen” and the pancreatic hormone “glucagon,” remember that glycogen literally means “**generates** sugar,” and associate glucagon with the **Pentagon**, both of which “issue orders.”

Insulin

Insulin is a peptide hormone released by beta cells when the blood glucose concentration exceeds the normal range (70–110 mg/dL). Elevated levels of some amino acids, including arginine and leucine, also stimulate secretion of insulin. This hormone affects cellular metabolism in a series of steps that begins when insulin binds to receptor proteins on the plasma membrane of a target cell. Binding activates the receptor, which functions as a kinase, attaching phosphate groups to intracellular enzymes. These enzymes then produce primary and secondary effects in the cell. The biochemical details of these effects remain unresolved.

One of the most important effects of insulin is the enhancement of glucose absorption and use. Insulin receptors are present in most plasma membranes, and cells that have them are called *insulin dependent*. However, cells in the brain and kidneys, cells in the lining of the digestive tract, and red blood cells lack insulin receptors. These cells are called *insulin independent* because they can absorb and use glucose without insulin stimulation.

Figure 18–17 Homeostatic Regulation of the Blood Glucose Concentration.

Which pancreatic cells secrete glucagon? List the effects of glucagon.

These are the effects of insulin on its target cells:

- **Accelerating Glucose Uptake (All Target Cells).** This effect results from an increase in the number of glucose transport proteins in the plasma membrane. These proteins move glucose into the cell by facilitated diffusion, which follows the concentration gradient for glucose and does not require ATP.
- **Accelerating Glucose Use (All Target Cells) and Enhanced ATP Production.** This effect occurs for two reasons: (1) The rate of glucose use is proportional to its availability, so when more glucose enters the cell, more is used. (2) Second messengers activate a key enzyme involved in the initial steps of glycolysis.
- **Stimulating Glycogen Formation (Skeletal Muscle Fibers and Liver Cells).** When excess glucose enters these cells, it is stored as glycogen.

- **Stimulating Amino Acid Absorption and Protein Synthesis (All Target Cells).** This helps to maintain the glucose level by preventing the conversion of amino acids to glucose.
- **Stimulating Triglyceride Formation (Adipocytes).** Insulin stimulates the absorption of fatty acids and glycerol by adipocytes, which store these components as triglycerides. Adipocytes also increase their absorption of glucose, and excess glucose is used in the synthesis of additional triglycerides.

To summarize, the pancreas secretes insulin when glucose is abundant. The hormone stimulates glucose use to support growth and to build carbohydrate (glycogen) and lipid (triglyceride) reserves. The accelerated use of glucose soon brings the circulating glucose level within normal limits.

Tips

The function of **insulin** is to get glucose **into** cells.

Glucagon

When the glucose concentration decreases below the normal range, alpha cells release **glucagon** to mobilize energy reserves. When glucagon binds to a receptor in the target cell's plasma membrane, the hormone activates adenylate cyclase, which converts ATP to cAMP. As we have learned, cAMP acts as a second messenger that activates cytoplasmic enzymes (**Spotlight Figure 18–3**). The primary effects of glucagon are as follows:

- *Stimulating the Breakdown of Glycogen (Skeletal Muscle Fibers and Liver Cells).* The glucose molecules released are either metabolized for energy (in skeletal muscle fibers) or released into the bloodstream (by liver cells).
- *Stimulating the Breakdown of Triglycerides (Adipocytes).* The adipocytes then release the fatty acids into the bloodstream for use by other tissues.
- *Stimulating the Production and Release of Glucose (Liver Cells).* Liver cells absorb amino acids from the bloodstream, convert them to glucose, and release the glucose into the circulation. This process of glucose synthesis in the liver is called *gluconeogenesis* (glū-kō-nē-ō-JEN-eh-sis).

The results are a reduction in glucose use and the release of more glucose into the bloodstream. The blood glucose concentration soon increases toward the normal range.

Pancreatic alpha cells and beta cells monitor the blood glucose concentration, and they secrete glucagon and insulin without endocrine or nervous instructions. Yet because the alpha cells and beta cells are highly sensitive to changes in the blood glucose level, any hormone that affects the blood glucose concentration indirectly affects the production of both

insulin and glucagon. Autonomic activity also influences insulin production: Parasympathetic stimulation enhances insulin release, and sympathetic stimulation inhibits it. Information about insulin, glucagon, and other pancreatic hormones is summarized in **Table 18–5**.

Diabetes Mellitus

Whether glucose is absorbed by the digestive tract or manufactured and released by the liver, very little glucose leaves the body once it has entered the bloodstream. The kidneys reabsorb virtually all glucose, so glucose does not appear in the urine. However, in **diabetes mellitus**, glucose accumulates in the blood and urine because of faulty glucose metabolism.

Diabetes mellitus can be caused by genetic variation, and some of the genes responsible have been identified. Mutations that result in inadequate insulin production, the synthesis of abnormal insulin molecules, or the production of defective receptor proteins produce comparable symptoms. Under these conditions, obesity accelerates the onset and severity of the disease. Diabetes mellitus can also result from other pathological conditions, injuries, immune disorders, or hormonal imbalances.

The two major types of diabetes mellitus are type 1 diabetes (previously known as juvenile diabetes) and type 2 diabetes. This disorder is described in **Spotlight Figure 18–18**.

✓ Checkpoint

23. Identify the types of cells in the pancreatic islets and the hormones produced by each.
24. Why does a person with type 1 diabetes or type 2 diabetes urinate frequently and have increased thirst?
25. What effect would an increased blood glucagon level have on the amount of glycogen stored in the liver?

See the blue Answers tab at the back of the book.

Table 18–5 Hormones Produced by the Pancreatic Islets

Structure/Cells	Hormone	Primary Targets	Hormonal Effect	Regulatory Control
PANCREATIC ISLETS				
Alpha (α) cells	Glucagon	Liver, adipose tissue	Mobilizes lipid reserves; promotes glucose synthesis and glycogen breakdown in liver; elevates blood glucose concentration	Stimulated by low blood glucose concentrations; inhibited by GH-IH from delta cells
Beta (β) cells	Insulin	Most cells	Facilitates uptake of glucose by target cells; stimulates formation and storage of lipids and glycogen	Stimulated by high blood glucose concentrations, parasympathetic stimulation, and high levels of some amino acids; inhibited by GH-IH from delta cells and by sympathetic activation
Delta (δ) cells	Growth hormone-inhibiting hormone (GH-IH)	Other islet cells, digestive epithelium	Inhibits insulin and glucagon secretion; slows rates of nutrient absorption and enzyme secretion along digestive tract	Stimulated by protein-rich meal; mechanism unclear
Pancreatic polypeptide cells	Pancreatic polypeptide (PP)	Digestive organs	Inhibits gallbladder contraction; regulates production of pancreatic enzymes; influences rate of nutrient absorption by digestive tract	Stimulated by protein-rich meal and by parasympathetic stimulation

Untreated diabetes mellitus disrupts metabolic activities throughout the body. Clinical problems arise because the tissues involved are experiencing an energy crisis—in essence, most of the tissues are responding as they would during chronic starvation, breaking down lipids and even proteins because they are unable to absorb glucose from their surroundings. Problems involving abnormal changes in blood vessel structure are particularly dangerous.

Kidney Degeneration

Degenerative changes in the kidneys, a condition called **diabetic nephropathy**, can lead to kidney failure.

Retinal Damage

The proliferation of capillaries and hemorrhaging at the retina may cause partial or complete blindness. This condition is called **diabetic retinopathy**.

Early Heart Attacks

Degenerative blockages in cardiac circulation can lead to early heart attacks. Heart attacks are three to five times more likely in people with diabetes than in people without diabetes.

Peripheral Nerve Problems

Abnormal blood flow to neural tissues is probably responsible for a variety of neural problems with peripheral nerves, including abnormal autonomic function. These disorders are collectively termed **diabetic neuropathies**.

Diabetes Mellitus

Diabetes mellitus (mel-Ī-tus; *mellitum*, honey), is characterized by glucose concentrations that are high enough to overwhelm the reabsorption capabilities of the kidneys. (The presence of abnormally high glucose levels in the blood in general is called **hyperglycemia** [hī-per-glī-SĒ-mē-ah].) Glucose appears in the urine (**glycosuria**; glī-kō-SYŪ-rē-a), and urine volume generally becomes excessive (**polyuria**).

subdivided into

Type 1 Diabetes

Type 1 is characterized by inadequate insulin production by the pancreatic beta cells. Persons with type 1 diabetes require insulin to live and usually require multiple injections daily, or continuous infusion through an insulin pump or other device. This form of diabetes accounts for approximately 5% of cases. It usually develops in children and young adults.

Type 2 Diabetes

Type 2 is the most common form of diabetes mellitus. Most people with this form of diabetes produce normal amounts of insulin, at least initially, but their tissues do not respond properly, a condition known as insulin resistance. Type 2 diabetes is associated with obesity, and weight loss through diet and exercise can be an effective treatment, especially when coupled with oral medicines.

Peripheral Tissue Damage

Blood flow to the distal portions of the limbs is reduced, and peripheral tissues may suffer as a result. For example, a reduction in blood flow to the feet can lead to tissue death, ulceration, infection, and loss of toes or a major portion of one or both feet.

18-9 Many organs have secondary endocrine functions

Learning Outcome Describe the functions of the hormones produced by the kidneys, heart, thymus, testes, ovaries, and adipose tissue.

As we noted earlier, many organs of other body systems have secondary endocrine functions. Examples are the intestines (digestive system), the kidneys (urinary system), the heart (cardiovascular system), the thymus (lymphatic system), and the *gonads*—the testes in males and the ovaries in females (reproductive system).

Several new hormones from these endocrine tissues have been identified. In many cases, their structures and modes of action remain uncertain, and we have not described them in this chapter. However, in one instance, researchers traced a significant new hormone to an unexpected site of origin, leading to the realization that the body's adipose tissue has important endocrine functions. We include the endocrine functions of adipose tissue in this section, although all the details have yet to be worked out. **Table 18–6** provides an overview of some of the hormones those organs of other systems produce.

The Intestines

The intestines process and absorb nutrients. They release a variety of hormones that coordinate the activities of the digestive system. Most digestive processes are hormonally controlled locally, although the autonomic nervous system can affect the pace of digestive activities. We describe these hormones in Chapter 24.

The Kidneys

The kidneys release the steroid hormone *calcitriol*, the peptide hormone *erythropoietin*, and the enzyme *renin*. Calcitriol is important for calcium ion homeostasis. Erythropoietin and renin are involved in the regulation of blood volume and blood pressure.

Calcitriol

Calcitriol is a steroid hormone secreted by the kidneys in response to parathyroid hormone (PTH) (**Figure 18–19a**). *Cholecalciferol* (vitamin D₃) is a related steroid that is synthesized in the skin or absorbed from the diet. Cholecalciferol is converted to calcitriol, although not directly. The term *vitamin D* applies to the entire group of related steroids, including calcitriol, cholecalciferol, and various intermediate products.

The best-known function of calcitriol is to stimulate calcium and phosphate ion absorption along the digestive tract. The effects of PTH on Ca²⁺ absorption result primarily from stimulation of calcitriol release. Calcitriol's other effects on calcium metabolism include (1) stimulating the formation and differentiation of osteogenic cells and osteoclasts, (2) stimulating bone resorption by osteoclasts, (3) stimulating Ca²⁺ reabsorption by the kidneys, and (4) suppressing PTH production. Evidence indicates that calcitriol also affects lymphocytes and keratinocytes in the skin, but these effects have nothing to do with regulating calcium levels.

Erythropoietin

Erythropoietin (e-rith-rō-POY-e-tin; *erythros*, red + *poiesis*, making), or **EPO**, is a peptide hormone released by the kidneys in response to low oxygen levels in kidney tissues. EPO stimulates the red bone marrow to produce red blood cells. The increase in the number of red blood cells elevates blood volume. Because these cells transport oxygen, this increase also improves oxygen delivery to peripheral tissues. We consider EPO again in Chapter 19.

Renin

Specialized kidney cells called *juxtaglomerular cells* release **renin** (RĒ-nin) in response to (1) sympathetic stimulation or (2) a decline in renal blood flow. Once in the bloodstream, renin functions as an enzyme that starts an enzymatic cascade known as the *renin-angiotensin-aldosterone system* (RAAS) (**Figure 18–19b**). RAAS is involved with blood

Table 18–6 Representative Hormones Produced by Organs of Other Systems

Organ	Hormone	Primary Target	Hormonal Effect
Intestines	Many (secretin, gastrin, cholecystokinin)	Other regions and organs of the digestive system	Coordinate digestive activities
Kidneys	Erythropoietin (EPO) Calcitriol	Red bone marrow Intestinal lining, bone, kidneys	Stimulates red blood cell production Stimulates calcium and phosphate absorption; stimulates Ca ²⁺ release from bone; inhibits PTH secretion
Heart	Natriuretic peptides (ANP and BNP)	Kidneys, hypothalamus, adrenal gland	Increase water and salt loss at kidneys; decrease thirst; suppress secretion of ADH and aldosterone
Thymus	Thymosins (many)	Lymphocytes and other cells of the immune response	Coordinate and regulate immune response
Gonads	See Table 18–7		
Adipose tissue	Leptin	Hypothalamus	Suppression of appetite; permissive effects on GnRH and gonadotropin synthesis

Figure 18–19 Endocrine Functions of the Kidneys.

pressure regulation and electrolyte metabolism. First, renin converts **angiotensinogen**, a plasma protein produced by the liver, to angiotensin I. In the capillaries of the lungs,

angiotensin-converting enzyme (ACE) modifies **angiotensin I** to the hormone **angiotensin II**. This hormone, in turn, stimulates the secretion of aldosterone by the adrenal cortex and

ADH by the posterior lobe of the pituitary gland. The combination of aldosterone and ADH acts to retain salt and water by restricting their loss by the kidneys. Angiotensin II also stimulates thirst and elevates blood pressure. For these reasons, drugs known as *ACE inhibitors* are used to treat hypertension.

Because renin plays such a key role in the renin-angiotensin-aldosterone system, many physiological and endocrinological references consider renin to be a hormone. We look closer at the renin-angiotensin-aldosterone system when we examine the control of blood pressure and blood volume in Chapter 21.

The Heart

The endocrine cells in the heart are cardiac muscle cells in the walls of the *atria* (chambers that receive blood from the veins) and the *ventricles* (chambers that pump blood to the rest of the body). If blood volume becomes too great, these cells are stretched excessively, to the point at which they begin to secrete **natriuretic peptides** (nā-trē-ū-RET-ik; *natrium*, sodium + *ouresis*, urination). In general, the effects of natriuretic peptides oppose those of angiotensin II: In the kidneys, natriuretic peptides promote Na⁺ and water loss, inhibit renin release, and inhibit antidiuretic hormone and aldosterone secretion. They also suppress thirst and prevent angiotensin II and norepinephrine from elevating blood pressure. The net result is a reduction in both blood volume and blood pressure, thereby reducing the stretching of the cardiac muscle cells in the heart walls. We discuss two natriuretic peptides—*ANP* (atrial natriuretic peptide) and *BNP* (brain natriuretic peptide)—when we consider the control of blood pressure and volume in Chapters 21 and 26.

The Thymus

The **thymus** is in the mediastinum, generally just deep to the sternum. This gland produces several hormones that are important in developing and maintaining immune defenses.

Thymosin (THĭ-mō-sin) is the name originally given to an extract from the thymus that promotes the development and maturation of *lymphocytes*, the white blood cells responsible for immunity. The extract contains a blend of several complementary hormones. The term *thymosins* is sometimes used to refer to all thymic hormones. We consider the histological organization of the thymus and the functions of the thymosins in Chapter 22.

The Gonads

Information about reproductive hormones is presented in **Table 18–7**. In males, the **interstitial endocrine cells** of the testes produce male hormones called *androgens*. Testosterone (tes-TOS-ter-ōn) is an important androgen. During embryonic development, the production of testosterone affects the development of CNS structures, including hypothalamic nuclei, which will later influence sexual behaviors. **Nurse cells** (*Sertoli cells*) in the testes support the differentiation and physical maturation of sperm. Under FSH stimulation, these cells secrete the hormone **inhibin**. It inhibits the secretion of FSH at the anterior lobe of the pituitary gland and perhaps suppresses GnRH release at the hypothalamus.

In females, steroid hormones called **estrogens** are produced in the ovaries under FSH and LH stimulation. **Estradiol** is the main estrogen. Circulating FSH stimulates the secretion of inhibin by ovarian cells, and inhibin suppresses FSH release through a feedback mechanism comparable to that in males.

At ovulation, follicles in the ovary release an immature gamete, or oocyte. The remaining follicle cells then reorganize into a *corpus luteum* (LŪ-tē-um; “yellow body”) that releases a mixture of estrogens and **progesterone** (prō-JES-ter-ōn). During pregnancy, the placenta and uterus produce additional hormones that interact with those produced by the ovaries and the pituitary gland to promote normal fetal development and delivery. We consider the hormonal aspects of pregnancy in Chapter 29.

Table 18–7 Hormones of the Reproductive System

Structure/Cells	Hormone	Primary Target	Hormonal Effect	Regulatory Control
TESTES				
Interstitial endocrine cells	Androgens	Most cells	Support functional maturation of sperm, protein synthesis in skeletal muscles, male secondary sex characteristics, and associated behaviors	Stimulated by LH from the anterior lobe of the pituitary gland
Nurse cells	Inhibin	Pituitary gland	Inhibits secretion of FSH	Stimulated by FSH from the anterior lobe
OVARIES				
Follicular cells	Estrogens	Most cells	Support follicle maturation, female secondary sex characteristics, and associated behaviors	Stimulated by FSH and LH from the anterior lobe of the pituitary gland
	Inhibin	Pituitary gland	Inhibits secretion of FSH	Stimulated by FSH from anterior lobe
Corpus luteum	Progesterone	Uterus, mammary glands	Prepares uterus for implantation; prepares mammary glands for secretory activity	Stimulated by LH from the anterior lobe of the pituitary gland

+ Clinical Note Endocrine Disorders

Regulation of hormone levels often involves negative feedback control mechanisms. These mechanisms involve the endocrine organ, neural regulatory factors, and the target tissues. Hormone overproduction (*hypersecretion*) or underproduction (*hyposecretion*) may cause problems. Abnormal cellular sensitivity to the hormone can also lead to problems.

Primary disorders arise from problems within the endocrine organ. The underlying cause may be a metabolic factor. Hypothyroidism due to a lack of dietary iodine is an example. An endocrine organ may also malfunction due to physical damage that destroys cells or disrupts the normal blood supply. Congenital problems may also affect the regulation, production, or release of hormones by endocrine cells.

Secondary disorders are due to problems in other organs or target tissues. Such disorders often involve the hypothalamus or pituitary gland. For example, secondary hypothyroidism occurs when the hypothalamus or pituitary gland doesn't produce enough TRH and/or TSH.

Abnormalities in target cells can affect their sensitivity or responsiveness to a particular hormone. For example, type 2 diabetes is due to the target cells' decreased sensitivity to insulin.

Endocrine disorders often reflect either abnormal hormone production or abnormal cellular sensitivity to hormones. The signs and symptoms highlight the significance of normally "silent" hormonal contributions. The characteristics of these disorders are summarized in **Table 18–8**.

Table 18–8 Clinical Implications of Endocrine Malfunctions

Hormone	Underproduction or Tissue Insensitivity	Primary Signs and Symptoms	Overproduction or Tissue Hypersensitivity	Primary Signs and Symptoms
Growth hormone (GH)	Pituitary growth failure	Slow growth, abnormal fat distribution, low blood glucose hours after a meal	Gigantism, acromegaly	Excessive growth
Antidiuretic hormone (ADH) or vasopressin (VP)	Diabetes insipidus	Polyuria, dehydration, thirst	SIADH (syndrome of inappropriate ADH secretion)	Increased body weight and water content
Thyroxine (T₄), triiodothyronine (T₃)	Hypothyroidism, congenital hypothyroidism, myxedema	Low metabolic rate; low body temperature; impaired physical and mental development	Hyperthyroidism, Graves' disease	High metabolic rate and body temperature
Parathyroid hormone (PTH)	Hypoparathyroidism	Muscular weakness, neurological problems, formation of dense bones, tetany due to low blood Ca ²⁺ concentration	Hyperparathyroidism	Neurological, mental, muscular problems due to high blood Ca ²⁺ concentration; weak and brittle bones
Insulin	Diabetes mellitus (type 1)	High blood glucose, impaired glucose utilization, dependence on lipids for energy; glycosuria	Excess insulin production or administration	Low blood glucose levels, possibly causing coma
Mineralocorticoids	Hypoaldosteronism	Polyuria, low blood volume, high blood K ⁺ , low blood Na ⁺ concentration	Aldosteronism	Increased body weight due to Na ⁺ and water retention; low blood K ⁺ concentration
Glucocorticoids	Addison disease	Inability to tolerate stress, mobilize energy reserves, or maintain normal blood glucose concentration	Cushing disease	Excessive breakdown of tissue proteins and lipid reserves; impaired glucose metabolism
Epinephrine (E), norepinephrine (NE)	None identified		Pheochromocytoma	High metabolic rate, body temperature, and heart rate; elevated blood glucose level
Estrogens (females)	Hypogonadism	Sterility, lack of secondary sex characteristics	Adrenogenital syndrome	Increased androgen production from adrenal cortex leads to ambiguous or non-typical genitalia
			Precocious puberty	Premature sexual maturation and related behavioral changes
Androgens (males)	Hypogonadism	Sterility, lack of secondary sex characteristics	Gynecomastia	Reduced testosterone or increased estrogen production leads to breast tissue enlargement
			Precocious puberty	Premature sexual maturation and related behavioral changes

Adipose Tissue

Recall from Chapter 4 that adipose tissue is a type of loose connective tissue. Adipocytes that make up adipose tissue release chemical mediators called **adipokines**. Four major adipokines are adiponectin, apelin, chemerin, and leptin. Their physiological roles in inflammation, appetite and satiety, insulin sensitivity, glucose metabolism, and immunity are subjects of intense curiosity and research. We focus on **leptin**, a peptide hormone, with several functions. Its main role is feedback control of appetite. When we eat, adipose tissue absorbs glucose and lipids and synthesizes triglycerides for storage. At the same time, it releases leptin into the bloodstream. Leptin binds to hypothalamic neurons involved with emotion and appetite control. The result is a sense of fullness (satiation) and the suppression of appetite.

Leptin was first discovered in a strain of obese mice that had a defective leptin gene. When treated with leptin, these overweight mice quickly turned into slim, athletic animals. The initial hope that leptin could be used to treat human obesity was soon dashed, however. Most obese people appear to have defective leptin receptors (or leptin pathways) in the appetite centers of the CNS. Their circulating leptin levels are already several times higher than those in individuals of normal body weight. Additional leptin would have no effect. Researchers are now investigating the structure of the receptor protein and the biochemistry of the pathway triggered by leptin binding.

Leptin must be present for normal levels of GnRH and gonadotropin synthesis to take place. This explains why (1) young females with low body fat commonly enter puberty relatively late, (2) an increase in body fat can improve fertility, and (3) females stop menstruating when their body fat content becomes very low.

✓ Checkpoint

26. Identify two hormones secreted by the kidneys.
27. Identify a hormone released by adipose tissue.
28. Describe the action of renin in the bloodstream.

See the blue Answers tab at the back of the book.

18-10 Hormones interact over our lifetime to produce coordinated physiological responses

Learning Outcome Explain how hormones interact to produce coordinated physiological responses and influence behavior, describe the role of hormones in the general adaptation syndrome, and discuss how aging affects hormone production and give examples of interactions between the endocrine system and other organ systems.

We usually study hormones individually, but the extracellular fluids contain a mixture of hormones whose concentrations

change daily or even hourly. As a result, cells never respond to only one hormone. Instead, they respond to multiple hormones. When a cell receives instructions from two hormones at the same time, four outcomes are possible:

- The two hormones may have **antagonistic effects**, as in the opposing actions of insulin and glucagon. The net result depends on the balance between the two hormones. In general, when two antagonistic hormones are present, the observed effects are weaker than those produced by either hormone acting unopposed.
- The two hormones may have additive effects, so that the net result is greater than the effect that each would produce acting alone. In some cases, the net result is greater than the *sum* of the hormones' individual effects. This interaction is a **synergistic effect** (sin-er-JIS-tik; *sunergos*, working together). An example is the glucose-sparing action of GH and glucocorticoids.
- One hormone can have a **permissive effect** on another. In such cases, the first hormone is needed for the second to produce its effect. For example, epinephrine does not change energy consumption unless thyroid hormones are also present in normal concentrations.
- Finally, hormones may produce different, but complementary, results in specific tissues and organs. These **integrative effects** are important in coordinating the activities of diverse physiological systems. The differing effects of calcitriol and parathyroid hormone on tissues involved in calcium metabolism are an example.

When multiple hormones regulate a complex process, it is very difficult to determine whether a hormone has synergistic, permissive, or integrative effects. We now consider three examples of processes regulated by complex hormonal interactions: growth, the response to stress, and behavior.

Role of Hormones in Growth

Several endocrine organs work together to bring about normal growth. Several hormones—GH, thyroid hormones, insulin, PTH, calcitriol, and reproductive hormones—are especially important. Many others have secondary effects on growth. The circulating concentrations of these hormones are regulated independently. Every time the hormonal mixture changes, metabolic operations are modified to some degree. The modifications vary in duration and intensity, producing unique individual growth patterns.

- **Growth Hormone (GH).** The effects of GH on protein synthesis and cellular growth are most apparent in children. GH supports their muscular and skeletal

development. In adults, growth hormone helps to maintain normal blood glucose concentrations and to mobilize lipid reserves in adipose tissue. GH is not the primary hormone involved, however. An adult with a GH deficiency but normal levels of thyroxine (T_4), insulin, and glucocorticoids will have no physiological problems.

- **Thyroid Hormones.** Normal growth also requires appropriate levels of thyroid hormones. If these hormones are absent during fetal development or for the first year after birth, the nervous system fails to develop normally, and developmental delay results. If T_4 concentrations decline before the onset of puberty, normal skeletal development does not continue.
- **Insulin.** Growing cells need adequate supplies of energy and nutrients. Without insulin, the passage of glucose and amino acids across plasma membranes stops or is drastically reduced.
- **Parathyroid Hormone (PTH) and Calcitriol.** Parathyroid hormone and calcitriol promote the absorption of calcium from the bloodstream for deposition in bone. Without adequate levels of both hormones, bones can still enlarge, but are poorly mineralized, weak, and flexible. For example, *rickets* is a condition typically caused by inadequate calcitriol production due to vitamin D deficiency in growing children. As a result, the lower limb bones are so weak that they bend under the body's weight.
- **Reproductive Hormones.** The presence or absence of reproductive hormones (androgens in males, estrogens in females) affects the activity of osteoblasts in key locations and the growth of specific cell populations. Androgens and estrogens stimulate cell growth and differentiation in their target tissues, but their targets differ. The differential growth induced by each accounts for sex-related differences in skeletal proportions and secondary sex characteristics.

The Hormonal Responses to Stress

Any condition—physical or emotional—that threatens homeostasis is a form of **stress**. Specific homeostatic adjustments oppose many stresses. For example, a decrease in body temperature leads to shivering or changes in the pattern of blood flow, which can restore normal body temperature.

In addition, the body has a *general* response to stress that can occur while other, more specific responses are under way. A wide variety of stress-causing factors produce the same general pattern of hormonal and physiological adjustments. These responses are part of the **general adaptation syndrome**

(**GAS**), also known as the **stress response**. GAS has three phases: the *alarm phase*, the *resistance phase*, and the *exhaustion phase* (**Spotlight Figure 18–20**).

The Effects of Hormones on Behavior

As we have learned, the hypothalamus regulates many endocrine functions, and hypothalamic neurons monitor the levels of many circulating hormones. Other portions of the central nervous system are also quite sensitive to hormonal stimulation.

The behavioral effects of specific hormones are most evident in individuals whose endocrine glands are oversecreting or undersecreting. But even normal changes in circulating hormone levels can cause behavioral changes. For example, in *precocious* (premature) *puberty*, sex hormones are produced at an inappropriate time, perhaps as early as age 5 or 6. Not only does an affected child begin to develop adult secondary sex characteristics, but the child's behavior also changes. The “nice little kid” disappears, and the child becomes aggressive and assertive because of the effects of sex hormones on central nervous system function. In teenagers, these behaviors are usually attributed to environmental stimuli, such as peer pressure, but here they have a physiological basis as well. In adults, changes in the mixture of hormones reaching the CNS can affect intellectual capabilities, memory, learning, and emotional states.

Aging and Hormone Production

The endocrine system undergoes few functional changes with age. An exception is the decline in the concentrations of reproductive hormones. We noted the effects of these hormonal changes on the skeletal system in Chapter 6, and we continue the discussion in Chapter 29.

Blood and tissue concentrations of many other hormones, including TSH, thyroid hormones, ADH, PTH, prolactin, and glucocorticoids, do not change with advancing age. Circulating hormone levels may remain within normal limits, but some endocrine tissues become less responsive to stimulation. For example, in older people, smaller amounts of growth hormone and insulin are secreted after a carbohydrate-rich meal. The reduced levels of GH and other tropic hormones affect tissues throughout the body. These hormonal effects involve the reductions in bone density and muscle mass noted in earlier chapters.

Finally, age-related changes in peripheral tissues may make them less responsive to some hormones. This loss of sensitivity has been documented in the case of glucocorticoids and ADH.

ALARM

Alarm Phase (“Fight or Flight”)

During the **alarm phase**, an immediate response to the stress occurs. The sympathetic division of the autonomic nervous system directs this response. In the alarm phase, (1) energy reserves are mobilized, mainly in the form of glucose, and (2) the body prepares to deal with the stress-causing factor by “fight or flight” responses. Epinephrine is the dominant hormone of the alarm phase. Its secretion is part of a generalized sympathetic activation.

Immediate Short-Term Responses to Crises

- Increased mental alertness
- Increased energy use by all cells
- Mobilization of glycogen and lipid reserves
- Changes in circulation
- Decreased digestive activity and urine production
- Increased sweat gland secretion
- Increased heart rate and respiratory rate

Resistance Phase

If a stress lasts longer than a few hours, the person enters the **resistance phase** of GAS. Glucocorticoids are the dominant hormones of the resistance phase. Epinephrine, GH, and thyroid hormones are also involved. Energy demands in the resistance phase remain higher than normal, due to the combined effects of these hormones. Nervous tissue has a high demand for energy, and requires a reliable supply of glucose. If blood glucose level falls too low, neural function deteriorates. Glycogen reserves can meet neural demand during the alarm phase, but become depleted after several hours. Hormones of the resistance phase mobilize lipids and amino acids as energy sources to conserve glucose for use by nervous tissue.

Long-Term Metabolic Adjustments

- Mobilization of remaining energy reserves: Lipids are released by adipose tissue; amino acids are released by skeletal muscle
- Conservation of glucose: Peripheral tissues (except nervous) break down lipids to obtain energy
- Elevation of blood glucose concentration: Liver synthesizes glucose from other carbohydrates, amino acids, and lipids
- Conservation of salts and water, loss of K^+ and H^+

Exhaustion Phase

The body's lipid reserves are sufficient to maintain the resistance phase for weeks or even months. But when the resistance phase ends, homeostatic regulation breaks down and the **exhaustion phase** begins. Unless corrective actions are taken almost immediately, the failure of one or more organ systems will prove fatal. The production of aldosterone throughout the resistance phase results in a conservation of Na^+ at the expense of K^+ . As the body's K^+ content decreases, a variety of cells begin to malfunction. The underlying problem of the exhaustion phase is the body's inability to sustain the endocrine and metabolic adjustments of the resistance phase.

Collapse of Vital Systems

- Exhaustion of lipid reserves
- Cumulative structural or functional damage to vital organs
- Inability to produce glucocorticoids
- Failure of electrolyte balance

EXHAUSTION

Clinical Note Hormones and Athletic Performance

The use of hormones to improve athletic performance is widely banned. The International Olympic Committee, the U.S. Olympic Committee, the National Collegiate Athletic Association, Major League Baseball, and the National Football League all ban it. The American Medical Association and the American College of Sports Medicine condemn the practice. Performance-enhancing chemicals include anabolic steroids, growth hormone, erythropoietin, and a variety of synthetic hormones.

Androgen Abuse

Anabolic steroids (synthetic androgens) are used to increase muscle mass, endurance, and “competitive spirit.” One supposed justification for steroid use is the unfounded opinion that compounds made in the body not only are safe, but also are good for the body. In reality, administering natural or synthetic androgens in excessive amounts has considerable health risks. Androgens are known to produce several complications. These problems include (1) premature closure of epiphyseal cartilages, (2) various liver dysfunctions (such as jaundice and liver tumors), (3) prostate enlargement and urinary tract obstruction, and (4) testicular atrophy and infertility. Links to heart attacks, impaired cardiac function, and strokes have also been suggested.

The normal regulation of androgen production involves a feedback mechanism comparable to that described for adrenal steroids earlier in this chapter. GnRH stimulates the production of LH, and LH stimulates the secretion of testosterone and other androgens by the interstitial endocrine cells of the testes. Circulating androgens, in turn, inhibit the production of both GnRH and LH. For this reason, high doses of synthetic androgens can suppress the normal production of testosterone and depress the manufacture of GnRH by the hypothalamus. *This suppression of GnRH release can be permanent.*

The use of androgens as “bulking agents” by female bodybuilders may add muscle mass, but it can also alter muscular proportions and other sex characteristics. For

example, females taking steroids can develop irregular menstrual cycles and changes in body hair distribution (such as baldness). Finally, androgen abuse can depress the immune system.

Erythropoietin Abuse

Erythropoietin (EPO) is readily available because it is now synthesized by recombinant DNA techniques. Endurance athletes, such as cyclists and marathon runners, sometimes use it to boost the number of oxygen-carrying red blood cells in the bloodstream. This effect increases the oxygen content of the blood, but it also makes the blood more viscous. For this reason, the heart must work harder to push the “thicker” blood through the blood vessels. This effort can result in death due to heart failure or stroke in young and otherwise healthy individuals.

Androgens and EPO are hormones with reasonably well-understood effects. Drug testing is now widespread in amateur and professional sports, but athletes interested in “getting an edge” are experimenting with drugs not easily detected by standard tests. The long-term and short-term effects of these drugs are difficult to predict.

Gamma-Hydroxybutyric Acid Use

Another drug used by amateur athletes is *gamma-hydroxybutyrate* (GHB). It was tested for use as an anesthetic in the 1960s, but rejected in part because it was linked to seizures. In 1990, the drug appeared in health-food stores, sold as an anabolic agent and diet aid. The depressant drug, known also as the “date rape drug,” is prescribed as Xyrem (for a rare sleeping disorder), but has several “street names.” GHB and its analogues are abused and misused for their paradoxical calming and euphoric effects and because people believe they build muscle mass and cause weight loss. High doses lead to reduced heart rate, lowered body temperature, confusion, hallucinations, and seizures; overdose causes coma and death.

Extensive integration occurs between the endocrine system and other body systems. For all systems, the endocrine system adjusts metabolic rates and use of substrates such as glucose, triglycerides, and amino acids. It also regulates growth and development. Build Your Knowledge **Figure 18–21** shows the functional relationships between the endocrine system and other body systems we have studied so far.

Checkpoint

29. **Insulin decreases the blood glucose level and glucagon increases the blood glucose level. This is an example of which type of hormonal interaction?**
30. **The lack of which hormones would inhibit bone formation?**
31. **Why do levels of GH–RH and CRH rise during the resistance phase of the general adaptation syndrome?**
32. **Discuss the general role of the endocrine system in the functioning of other body systems.**
33. **Discuss the functional relationship between the endocrine system and the muscular system.**

Build Your Knowledge

Figure 18–21 Integration of the ENDOCRINE system with the other body systems presented so far.

Integumentary System

- The Integumentary System protects superficial endocrine organs; epidermis synthesizes vitamin D₃ (precursor to calcitriol production)
- The endocrine system secretes sex hormones that stimulate sebaceous gland activity, influence hair growth, fat distribution, and apocrine sweat gland activity; PRL that stimulates development of mammary glands; adrenal hormones that alter dermal blood flow; MSH that stimulates melanocyte activity

Skeletal System

- The Skeletal System protects endocrine organs, especially in the brain, chest, and pelvic cavity
- The endocrine system regulates skeletal growth with several hormones; calcium homeostasis regulated primarily by parathyroid hormone; sex hormones speed growth and closure of epiphyseal cartilages at puberty and help maintain bone mass in adults

Muscular System

- The Muscular System provides protection for some endocrine organs
- The endocrine system secretes hormones that adjust muscle metabolism, energy production, and growth; regulate calcium and phosphate levels in body fluids; speed skeletal muscle growth

Nervous System

- The Nervous System produces hypothalamic hormones that directly control pituitary secretions and indirectly control secretions of other endocrine organs; controls adrenal medulla; secretes ADH and oxytocin
- The endocrine system secretes several hormones that affect neural metabolism and brain development; hormones that help regulate fluid and electrolyte balance; reproductive hormones that influence CNS development and behaviors

Endocrine System

- The Endocrine System provides long-term regulation and adjustments of homeostatic mechanisms that affect many body functions. It:
- regulates fluid and electrolyte balance
 - regulates cell and tissue metabolism
 - regulates growth and development
 - regulates reproductive functions
 - responds to stressful stimuli through the general adaptation syndrome (GAS)

18 Chapter Review

Study Outline

An Introduction to the Endocrine System

1. Chemical messengers known as *hormones* regulate human activities such as sleep, body temperature, hunger, and stress management. They are products of the *endocrine system*, which, along with the nervous system, controls and coordinates our body processes.

18-1 Homeostasis is maintained through intercellular communication by the nervous and endocrine systems

2. In general, the nervous system performs short-term “crisis management,” whereas the endocrine system regulates longer-term, ongoing metabolic processes.
3. **Paracrine communication** involves the use of chemical signals to transfer information from cell to cell within a single tissue. **Autocrine communication** involves chemicals affecting the same cell that secreted them.
4. **Endocrine communication** results when chemicals, called **hormones**, are released into the circulation by *endocrine cells*. The hormones alter the metabolic activities of many tissues and organs simultaneously by modifying the activities of **target cells**. (Table 18-1)

18-2 The endocrine system regulates physiological processes by releasing bloodborne hormones that bind to receptors on remote target organs

5. The endocrine system includes all the cells and endocrine tissues of the body that produce hormones or paracrine factors. (Figure 18-1)
6. Hormones can be divided into three classes according to their chemical structure: *amino acid derivatives*, *peptide hormones*, and *lipid derivatives*, including **steroid hormones** and **eicosanoids**. (Spotlight Figure 18-2)
7. Hormones may circulate freely or bound to transport proteins. Free hormones are rapidly removed from the bloodstream.
8. Receptors for *catecholamines*, peptide hormones, and eicosanoids are in the plasma membranes of target cells. Thyroid and steroid hormones cross the plasma membrane and bind to receptors in the cytoplasm or nucleus, activating or inactivating specific genes. (Spotlight Figure 18-3, Figure 18-4)
9. Hormone secretion can be triggered by (1) *humoral stimuli* (changes in the composition of the extracellular fluid), (2) *hormonal stimuli* (the arrival or removal of a specific hormone), or (3) *neural stimuli* (the arrival of neurotransmitters at neuroglandular junctions).

18-3 The anterior lobe of the pituitary gland produces and releases hormones under hypothalamic control, while the posterior lobe releases hypothalamic hormones

10. The **hypothalamus** contains both brain centers and endocrine tissue. It is connected to the **pituitary gland**, or **hypophysis**, by the **infundibulum**. (Figure 18-5)

- PhysioEx
- SmartArt Video

11. The **anterior lobe** of the pituitary gland, or **adenohypophysis**, can be subdivided into the **pars distalis**, the **pars intermedia**, and the **pars tuberalis**. (Figure 18-5)
12. The hypothalamus regulates the activities of the nervous and endocrine systems. It acts as an endocrine organ by releasing hormones into the bloodstream at the posterior lobe of the pituitary gland; secreting **regulatory hormones**, which control the activities of endocrine cells in the anterior lobe of the pituitary gland; and exerting direct neural control over the endocrine cells of the adrenal medulla. (Figure 18-6)
13. At the median eminence of the hypothalamus, neurons release regulatory hormones (either **releasing hormones, RH**, or **inhibiting hormones, IH**) into the surrounding interstitial fluids through **fenestrated capillaries**. (Figure 18-7)
14. The **hypophyseal portal system** ensures that these regulatory hormones reach the intended target cells in the pituitary before they enter the general circulation. (Figure 18-7)
15. The pituitary gland releases nine important peptide hormones; seven come from the anterior lobe and two from the posterior lobe. The tropic hormones of the anterior lobe “turn on” endocrine glands or support the functions of other organs. (Figure 18-8; Table 18-2)
16. **Thyroid-stimulating hormone (TSH)** triggers the release of thyroid hormones. *Thyrotropin-releasing hormone (TRH)* from the hypothalamus promotes the pituitary’s secretion of TSH. (Figure 18-9)
17. **Adrenocorticotropic hormone (ACTH)** stimulates the release of *glucocorticoids* by the adrenal cortex. Corticotropin-releasing hormone (CRH) from the hypothalamus causes the pituitary to secrete ACTH. (Figure 18-9)
18. **Follicle-stimulating hormone (FSH)** stimulates follicle development and estrogen secretion in females and sperm production in males. **Luteinizing hormone (LH)** causes *ovulation* and *progesterone* production in females and androgen production in males. Gonadotropin-releasing hormone (GnRH) from the hypothalamus promotes the pituitary’s secretion of both FSH and LH. (Figure 18-9)
19. **Prolactin (PRL)** from the pituitary, together with other hormones, stimulates both the development of the mammary glands and milk production. (Figure 18-9)
20. **Growth hormone (GH, or somatotropin)** from the pituitary stimulates cell growth and replication through the release of **somatomedins**, also called **insulin-like growth factors (IGFs)**, from liver cells. The production of GH is regulated by **growth hormone-releasing hormone (GH-RH)** and **growth hormone-inhibiting hormone (GH-IH)** from the hypothalamus. (Figure 18-9)

21. **Melanocyte-stimulating hormone (MSH)** may be secreted by the pars intermedia of the pituitary during fetal development, early childhood, pregnancy, or certain diseases. This hormone stimulates melanocytes to produce melanin.
22. The **posterior lobe** of the pituitary gland, or **neurohypophysis**, contains the unmyelinated axons of hypothalamic neurons. Neurons of the **supra-optic** and **paraventricular nuclei** manufacture **antidiuretic hormone (ADH)** and **oxytocin (OXT)**, respectively. ADH decreases the amount of water lost at the kidneys and, in higher concentrations, elevates blood pressure. In females, oxytocin stimulates contractile cells in the mammary glands and has a stimulatory effect on smooth muscles in the uterus. (Figure 18-9; Table 18-2)

18-4 The thyroid gland synthesizes thyroid hormones that affect the rate of metabolism

23. The thyroid gland lies anterior to the *thyroid cartilage* of the larynx and consists of two **lobes** connected by a narrow **isthmus**. (Figure 18-10)
24. The thyroid gland contains numerous **thyroid follicles**. Thyroid follicles release several hormones, including **thyroxine** and **triiodothyronine**. (Figures 18-10, 18-11; Table 18-4)
25. Most of the thyroid hormones entering the bloodstream are attached to special **thyroid-binding globulins (TBGs)**; the rest are attached to either **transthyretin** or albumin. (Figure 18-11)
26. In target cells, thyroid hormones are held in storage in the cytoplasm, bound to mitochondria (where they increase ATP production), or bound to receptors activating genes that control energy utilization. They also exert a **calorigenic effect**. (Table 18-3)
27. The **C cells** of the thyroid follicles produce **calcitonin (CT)**, which possibly helps regulate Ca^{2+} concentrations in body fluids, especially during childhood and pregnancy. (Figure 18-10; Table 18-4)

18-5 The four parathyroid glands secrete parathyroid hormone, which increases the blood calcium ion level

28. Four **parathyroid glands** are embedded in the posterior surfaces of the thyroid gland. **Parathyroid principal cells** produce **parathyroid hormone (PTH)** in response to lower-than-normal concentrations of Ca^{2+} . The parathyroid glands, aided by *calcitriol*, are the primary regulators of blood calcium levels in healthy adults. (Figures 18-12, 18-13; Table 18-4)

18-6 The paired adrenal glands secrete several hormones that affect electrolyte balance and stress responses

29. One **adrenal (suprarenal) gland** lies along the superior border of each kidney. The gland is subdivided into the superficial **adrenal cortex** and the inner **adrenal medulla**. (Figure 18-14)
30. The adrenal cortex manufactures steroid hormones called **corticosteroids**. The cortex can be subdivided into three areas: (1) the **zona glomerulosa**, which releases **mineralocorticoids**, principally **aldosterone**; (2) the **zona fasciculata**, which produces **glucocorticoids**, notably **cortisol**, **corticosterone**, and **cortisone**; and (3) the **zona reticularis**, which produces androgens under ACTH stimulation. (Figure 18-14)

31. The adrenal medulla produces epinephrine (75–80% of medullary secretion) and norepinephrine (20–25%). (Figure 18-14)

18-7 The pineal gland secretes melatonin, which affects the circadian rhythm

32. The **pineal gland** contains **pinealocytes**, which synthesize **melatonin**. Suggested functions include inhibiting reproductive functions, protecting against damage by free radicals, and setting circadian rhythms. (Figure 18-15)

18-8 The pancreas is both an exocrine organ and an endocrine gland that produces hormones affecting the blood glucose level

33. The pancreas contains both exocrine and endocrine cells. Cells of the endocrine pancreas form clusters called **pancreatic islets (islets of Langerhans)**. These islets contain **alpha (α) cells**, which secrete the hormone **glucagon**; **beta (β) cells**, which secrete **insulin**; **delta (δ) cells**, which secrete **growth hormone-inhibiting hormone (GH-IH)**, also called *somatostatin*; and **pancreatic polypeptide (PP) cells**, which secrete **pancreatic polypeptide**. (Figure 18-16; Table 18-5)
34. Insulin lowers blood glucose by increasing the rate of glucose uptake and utilization by most body cells; glucagon raises blood glucose by increasing the rates of glycogen breakdown and glucose manufacture in the liver. (Figure 18-17; Table 18-5)
35. **Diabetes mellitus** is an endocrine disorder characterized by high blood glucose levels. (Spotlight Figure 18-18)

18-9 Many organs have secondary endocrine functions

36. The intestines produce hormones important in coordinating digestive activities. (Table 18-6)
37. Endocrine cells in the kidneys produce the hormones *calcitriol* and *erythropoietin* and the enzyme *renin*. (Table 18-6)
38. **Calcitriol** stimulates calcium and phosphate ion absorption along the digestive tract. (Figure 18-19)
39. **Erythropoietin (EPO)** stimulates red blood cell production by the red bone marrow. (Figure 18-19)
40. In the *renin-angiotensin-aldosterone system (RAAS)*, **renin** converts **angiotensinogen** to **angiotensin I**. In the capillaries of the lungs, angiotensin-converting enzyme (ACE) converts angiotensin I to **angiotensin II**, a hormone that (1) stimulates the adrenal production of aldosterone, (2) stimulates the pituitary release of ADH, (3) promotes thirst, and (4) elevates blood pressure. (Figure 18-19)
41. Specialized muscle cells in the heart produce **natriuretic peptides** (ANP and BNP) when blood volume becomes excessive. In general, their actions oppose those of angiotensin II. (Table 18-6)
42. The thymus produces several hormones, collectively known as **thymosins**, which play a role in developing and maintaining normal immune defenses. (Table 18-6)
43. The **interstitial endocrine cells** of the testes produce androgens. **Testosterone** is the most important sex hormone in males. (Table 18-7)
44. In females, *oocytes* develop in follicles, and follicle cells produce **estrogens**, especially **estradiol**. After ovulation, the remaining follicle cells reorganize into a *corpus luteum*. Those cells release a mixture of estrogens and **progesterone**. (Table 18-7)
45. Adipose tissue secretes **leptin** (a feedback control for appetite). (Table 18-6)

18-10 Hormones interact over our lifetime to produce coordinated physiological responses

46. Endocrine system hormones often interact, producing **antagonistic** (opposing) **effects**; **synergistic** (additive) **effects**; **permissive effects**, in which one hormone is necessary for another to produce its effect; or **integrative effects**, in which hormones produce different, but complementary, results.
47. Normal growth requires the cooperation of several endocrine organs. Several hormones are especially important: GH, thyroid hormones, insulin, PTH, calcitriol, and reproductive hormones.
48. Any condition that threatens homeostasis is a **stress**. Our bodies respond to a variety of stress-causing factors through the **general adaptation syndrome (GAS)**, or **stress response**.
49. The GAS can be divided into three phases: (1) the **alarm phase** (an immediate, “fight or flight” response, under the direction of the sympathetic division of the ANS); (2) the **resistance phase**, dominated by glucocorticoids; and (3) the **exhaustion phase**, the eventual breakdown of homeostatic regulation and failure of one or more organ systems. (*Spotlight Figure 18–20*)
50. Many hormones affect the CNS. Changes in the normal mixture of hormones can significantly alter intellectual capabilities, memory, learning, and emotional states.
51. The endocrine system undergoes few functional changes with advanced age. The major changes include a decline in the concentration of growth hormone and reproductive hormones.
52. The endocrine system provides long-term regulation and homeostatic adjustments that affect many body systems. (*Figure 18–21*)

Review Questions

See the blue Answers tab at the back of the book.

LEVEL 1 Reviewing Facts and Terms

1. When cell-to-cell communication occurs by the mechanism called endocrine communication, transmission happens _____. (a) through extracellular fluid, (b) across synapses, (c) through the blood stream, (d) through gap junctions.
2. Cyclic AMP functions as a second messenger to (a) build proteins and catalyze specific reactions, (b) activate adenylate cyclase, (c) open ion channels and activate key enzymes in the cytoplasm, (d) bind the hormone–receptor complex to DNA segments.
3. Adrenocorticotropic hormone (ACTH) stimulates the release of (a) thyroid hormones by the hypothalamus, (b) gonadotropins by the adrenal glands, (c) growth hormones by the hypothalamus, (d) steroid hormones by the adrenal glands.
4. In females, an LH surge (a) induces labor contractions, (b) decreases the release of progesterone, (c) induces ovulation, (d) results in reabsorption of water by the kidneys.
5. The hormones produced by the zona fasciculata of the adrenal cortex are (a) glucocorticoids, (b) mineralocorticoids, (c) epinephrine and norepinephrine, (d) androgens.
6. All of the following are true of the endocrine system *except* that it (a) releases chemicals into the bloodstream for distribution throughout the body, (b) releases hormones that simultaneously alter the metabolic activities of many different tissues and organs, (c) produces effects that can last for hours, days, and even longer, (d) produces rapid, local, brief-duration responses to specific stimuli, (e) functions to control ongoing metabolic processes.
7. A cell’s hormonal sensitivities are determined by the (a) chemical nature of the hormone, (b) quantity of circulating hormone, (c) shape of the hormone molecules, (d) presence or absence of appropriate receptors, (e) thickness of its plasma membrane.

8. Identify the endocrine glands and tissues in the following diagram.

9. In what three ways is the hypothalamus involved in integrating the activities of the nervous and endocrine systems?
10. Which seven hormones are released by the anterior lobe of the pituitary gland?
11. What is the site of production of the melanocyte-stimulating hormone, and what is the function of this hormone?

12. What five primary effects result from the action of thyroid hormones?
13. What are the two different cell types found in the parathyroid glands?
14. Which hormones are produced by the thymus, and what is the function of these hormones?
15. Which two hormones are released by the kidneys, and what is the importance of each hormone?
16. What are the four opposing effects of natriuretic peptides and angiotensin II?
17. What four cell populations make up the endocrine pancreas? Which hormone does each type of cell produce?

LEVEL 2 Reviewing Concepts

18. What is the primary difference in the way the nervous and endocrine systems communicate with their target cells?
19. In what ways can a hormone modify the activities of its target cells?
20. Why do steroid hormones stay in circulation longer than peptide hormones?
21. Compare the effects of oxytocin in men and women.
22. A researcher observes that stimulation by a particular hormone induces a marked increase in the activity of G proteins in the target plasma membrane. The hormone being studied is probably **(a)** a steroid, **(b)** a peptide, **(c)** testosterone, **(d)** estrogen, **(e)** aldosterone.
23. Leptin **(a)** increases appetite, **(b)** can be used to treat human obesity, **(c)** is a steroid, **(d)** is produced by adipose tissue, **(e)** is a polysaccharide.
24. In type 2 diabetes, insulin levels are frequently normal, yet the target cells are less sensitive to the effects of insulin. This suggests that the target cells **(a)** are impermeable to insulin, **(b)** may lack enough insulin receptors, **(c)** cannot convert insulin to an active form, **(d)** have adequate internal supplies of glucose, **(e)** both b and c.

LEVEL 3 Critical Thinking and Clinical Applications

25. Vladki has been extremely thirsty. He drinks numerous glasses of water every day and urinates a great deal. Name two disorders that could produce these signs and symptoms. What test could a clinician perform to determine which disorder Vladki has?
26. Sammy and his grandmother are both being treated for diabetes mellitus. Sammy wonders why it is necessary for him to get frequent insulin injections, whereas his grandmother is prescribed a combination of diet, exercise, and oral medication. Explain why this is the case.
27. Sakae tells her physician that she has been restless and irritable lately. She has a hard time sleeping and complains of diarrhea and weight loss. During the examination, her physician notices a higher-than-normal heart rate and a fine tremor in her outstretched fingers. What tests could the physician perform to make a positive diagnosis of Sakae's condition?
28. What are two benefits of having a portal system connect the median eminence of the hypothalamus with the anterior lobe of the pituitary gland?
29. Pamela and her teammates are considering taking anabolic steroids (synthetic hormones derived from testosterone) to enhance their competitive skills. What natural effects of testosterone are they hoping to gain? What additional side effects might these teammates expect if they begin an anabolic steroid regime?

CLINICAL CASE Wrap-Up Stones, Bones, and Groans

The doctor jokes with Monica that she has a case of “stones, bones, and groans.” He then shows her the lab results, which indicate an elevated blood calcium (Ca^{2+}) level—a pivotal key to diagnosing Monica's condition.

Calcium is critical in the control of many systems. It provides the means for cholinergic synapses to work, including those in the CNS, all neuron-to-neuron synapses in the PNS, and all neuromuscular junctions. Calcium also plays an essential role in the muscular contraction cycles of all skeletal, smooth, and cardiac muscles. In addition, it strengthens the skeleton, which acts as a Ca^{2+} reserve. Calcium is the most closely regulated element in our bodies.

The parathyroid glands function to increase the blood calcium ion concentration. Normally, the four small parathyroid glands produce parathyroid hormone (PTH). Their principal cells monitor the circulating concentration of Ca^{2+} and produce PTH in a negative feedback control system.

It turns out that one of Monica's parathyroid glands has a benign tumor that is producing PTH without feedback control. The excess PTH causes the elevated blood Ca^{2+} level, osteopenia, and bone pain. The elevated blood Ca^{2+} is responsible for Monica's heart palpitations, kidney stones, muscle fatigue, memory loss, depression, and irritability.

Outpatient surgery is performed to remove the tumor. The remaining three parathyroid glands take over normal Ca^{2+} regulation. Monica soon begins to feel like herself again.

1. In addition to mobilizing calcium from bone, how else does PTH increase the blood calcium ion level?
2. What hormone counteracts PTH and decreases the blood Ca^{2+} level?

See the blue Answers tab at the back of the book. Note also that calcium homeostasis was introduced in Chapter 6 and can be reviewed in Figure 6–16.

Related Clinical Terms

adrenalectomy: Surgical removal of an adrenal gland.

empty sella syndrome (ESS): Condition in which the pituitary gland becomes shrunken or flattened within an enlarged sella turcica.

exophthalmos: Protrusion of the eyeballs.

galactorrhea: A milky discharge from the nipple unrelated to normal breast feeding.

Hashimoto disease: Disorder that affects the thyroid gland, causing the immune system to attack the thyroid gland. It is the most common cause of hypothyroidism in the United States; also known as *chronic lymphocytic thyroiditis*.

hirsutism: Excessive growth of facial or body hair in a female. Hirsutism is a sign of hyperandrogenism, or the presence of excessively high levels of androgens. It may be a sign of polycystic ovarian syndrome, congenital adrenal hyperplasia (CAH), or androgen-secreting tumors, all of which may cause infertility in females.

hypocalcemic tetany: Muscle spasms affecting the face and upper extremities; caused by low Ca^{2+} concentrations in body fluids.

hypophysectomy: Surgical removal of the pituitary gland.

posttraumatic stress disorder (PTSD): A common anxiety disorder that develops after being exposed to a life-threatening situation or terrifying event.

prolactinoma: Noncancerous pituitary tumor that produces prolactin, resulting in too much prolactin in the blood.

psychosocial dwarfism: Growth disorder occurring between the ages of 2 and 15, caused by extreme emotional deprivation or stress; also called *deprivation dwarfism*.

thyroid function tests: Blood and radionuclide tests to determine thyroid gland activity.

thyroidectomy: Surgical removal of all or part of the thyroid gland.

thyrotoxicosis: A condition caused by the oversecretion of thyroid hormones (hyperthyroidism). Signs and symptoms include increases in metabolic rate, blood pressure, and heart rate; excitability and emotional instability; and lowered energy reserves.

virilism: A disorder of females caused by hormone irregularity characterized by hirsutism and lowered voice.

Learning Outcomes

These Learning Outcomes correspond by number to this chapter's sections and indicate what you should be able to do after completing the chapter.

- 19-1 ■ Describe the components and major functions of blood, identify blood collection sites, list the physical characteristics of blood, and specify the composition and functions of plasma.
- 19-2 ■ List the characteristics and functions of red blood cells, describe the structure and functions of hemoglobin, describe how red blood cell components are recycled, explain erythropoiesis, and discuss respiratory gas transport.
- 19-3 ■ Explain the importance of blood typing and the basis for ABO and Rh incompatibilities.
- 19-4 ■ Categorize white blood cell types based on their structures and functions and discuss the factors that regulate the production of each type.
- 19-5 ■ Describe the structure, function, and production of platelets.
- 19-6 ■ Discuss the mechanisms that control blood loss after an injury and describe the reaction sequences responsible for blood clotting.

CLINICAL CASE

Crisis in the Blood

She feels that same pain she had as a child: This time it comes from her legs, sharp and desperate. Clare has let things get out of control and she knows better. It was just hard to manage with the pressures of her classes in the pre-nursing program and her part-time job. She is exhausted, isn't eating well, and has badly neglected her fluid intake. Clare looks down at her legs and notices how red and swollen they look. Her feet feel icy. She winces as the bone-deep pain surges along her shins. Now that she is studying anatomy and physiology, Clare understands better than ever what is

happening in her own bloodstream. Clare knows she is in for another trip to the hospital.

Her roommate gives her a ride to the local emergency room (ER). The ER staff in her college town don't know her here like they did at home. The nurse practitioner listens carefully and learns about Clare's medical history. On physical examination, Clare is running a temperature, and her heart rate and blood pressure are elevated. Her sunken eyes and loss of skin elasticity reveal significant dehydration. The nurse practitioner sends a sample of blood to the lab to confirm Clare's blood condition. Clare's leg pain has become so severe that she is given a dose of morphine (an opioid painkiller) and is admitted for stabilization. **What crisis is occurring in Clare's blood? To find out, turn to the Clinical Case Wrap-Up at the end of the chapter.**

An Introduction to Blood and the Cardiovascular System

In this chapter we discuss the nature of *blood*, the fluid connective tissue of the **cardiovascular system**. This body system also includes a pump (the heart) that circulates the fluid and a series of conducting hoses (the blood vessels) that carry it throughout the body. In this chapter we take a close look at the components and functions of blood. We discuss the heart in Chapter 20 and the blood vessels in Chapter 21.

19

19-1 Blood, composed of plasma and formed elements, provides transport, regulation, and protective services to the body

Learning Outcome Describe the components and major functions of blood, identify blood collection sites, list the physical characteristics of blood, and specify the composition and functions of plasma.

Blood is a specialized connective tissue that contains cells suspended in a fluid matrix. In Chapter 4 we introduced the components and properties of this tissue. In this chapter we cover the components of blood and the processes of these components that allow this fluid tissue to perform its functions.

Functions of Blood

The blood of the cardiovascular system performs many vital roles. These services are essential to each of the body's roughly 75 trillion cells—so much so that any cell deprived of circulation may die in a matter of minutes. A summary of blood functions includes:

- *Transporting Dissolved Gases, Nutrients, Hormones, and Metabolic Wastes.* Circulating blood contains red blood cells that carry oxygen from the lungs to peripheral tissues, and carbon dioxide from those tissues back to the lungs. Blood distributes nutrients absorbed by the digestive tract or released from storage in adipose tissue or in the liver. It carries hormones from endocrine glands toward their target cells. It also absorbs the wastes produced by tissue cells and carries them to the kidneys for excretion.
- *Regulating the pH and Ion Composition of Interstitial Fluids.* Diffusion between interstitial fluids and blood eliminates local deficiencies or excesses of ions, such as calcium or potassium. Blood also absorbs and neutralizes acids, such as lactic acid, generated by active skeletal muscles.
- *Restricting Fluid Losses at Injury Sites.* Blood contains enzymes and other substances that respond to breaks in vessel walls by initiating the *clotting* process. A blood clot acts as a temporary patch that prevents further blood loss.
- *Defending against Toxins and Pathogens.* Blood transports *white blood cells*, specialized cells that migrate into other tissues to fight infections or remove debris. Blood also delivers *antibodies*, proteins that specifically attack invading pathogens.
- *Stabilizing Body Temperature.* Blood absorbs the heat generated by active skeletal muscles and redistributes it to other tissues. If body temperature is already high, that heat will be lost across the skin surface. If body temperature is too low, the warm blood is directed to the brain and to other temperature-sensitive organs.

Characteristics of Blood

Whole blood from any source—veins, capillaries, or arteries—has the same basic physical characteristics:

- Blood temperature is about 38°C (100.4°F), slightly above normal body temperature.
- Blood is five times as viscous as water—that is, five times as sticky, five times as cohesive, and five times as resistant to flow as water. The high viscosity results from interactions among dissolved proteins, formed elements, and water molecules in plasma.
- Blood is slightly alkaline, with a pH between 7.35 and 7.45.

We can estimate blood volume in liters for a person by calculating 7% of the body weight in kilograms. For example, a 75-kg (165-lb) person would have a blood volume of approximately 5.25 liters (5.4 quarts).

Components of Blood

Spotlight Figure 19–1 describes the composition of **whole blood**, which is made up of fluid *plasma* and *formed elements* (cells and cell fragments). The components of whole blood can be **fractionated**, or separated, for analytical or clinical purposes.

Plasma

As shown in the top half of **Spotlight Figure 19–1**, **plasma** makes up about 55% of the volume of whole blood. The components of plasma include plasma proteins, other solutes (primarily nutrients, electrolytes, and wastes), and water.

Plasma Proteins. Plasma contains significant quantities of dissolved proteins, namely *albumins*, *globulins*, and *fibrinogen*. These three types make up more than 99% of the plasma proteins. (The remaining 1% of plasma proteins is composed of enzymes and hormones whose levels vary widely.)

- **Albumins** (al-BYŪ-minz) make up most of the plasma proteins. Thus, they are the major contributors to plasma osmolarity and osmotic pressure. Albumins are also important for transporting fatty acids, thyroid hormones, some steroid hormones, and other substances.
- **Globulins** are the second most-abundant proteins in plasma. Examples of plasma globulins include antibodies (*immunoglobulins*) that aid in body defense and *transport globulins*. (We cover antibodies in depth with immunity in Chapter 22.) Transport globulins bind small ions, hormones, and substances that might otherwise be removed by the kidneys or that have very low water solubility. Transport globulins include *hormone-binding proteins*, which provide a reserve of hormones in the bloodstream. Examples include thyroid-binding globulin

and transthyretin, which transport thyroid hormones, and transcortin, which transports ACTH. There are also *metalloproteins* that transport metal ions. Transferrin, which transports iron ions (Fe^{2+}), is an example. In addition, *apolipoproteins* (ap-ō-lip-ō-PRŌ-tēnz) carry triglycerides and other lipids in blood. When bound to lipids, an apolipoprotein becomes a *lipoprotein* (LĪ-pō-prō-tēn). Finally, *steroid-binding proteins* transport steroid hormones in blood. For example, testosterone-binding globulin (TeBG) binds and transports testosterone.

- The third major type of plasma protein, **fibrinogen**, functions in clotting. If steps are not taken to prevent clotting in a blood sample, fibrinogen (a soluble protein) will be converted to *fibrin* (an insoluble protein). This conversion removes the clotting proteins, leaving a fluid known as **serum**. The clotting process also removes calcium ions and other materials from solution, so plasma and serum differ in several significant ways. Therefore, the results of a blood test indicate whether a sample was plasma or serum.

Origins of the Plasma Proteins. The liver synthesizes and releases more than 90% of the plasma proteins, including all albumins and fibrinogen, most globulins, and various proenzymes. Hence, liver disorders can alter the composition and functional properties of blood. For example, some forms of liver disease can lead to uncontrolled bleeding due to the inadequate synthesis of fibrinogen and other proteins involved in clotting.

Formed Elements

The **formed elements** of blood are made up primarily of red blood cells, white blood cells, and cell fragments known as *platelets*. Formed elements make up about 45% of whole blood volume. The percentage of a blood sample that consists of red blood cells is known as the **hematocrit** (hē-MAT-ō-krit). When referring to all the formed elements, it is called **packed cell volume (PCV)**.

Formed elements are produced in the process of **hemopoiesis** (hē-mō-POY-eh-sis). **Spotlight Figure 19–1** introduces these elements and hemopoiesis. Most of this chapter discusses the functions of formed elements, beginning with red blood cells.

✓ Checkpoint

1. List five major functions of blood.
2. Identify the three types of formed elements in blood.
3. List the three major types of plasma proteins.
4. What would be the effects of a decrease in the amount of plasma proteins in the blood?

See the blue Answers tab at the back of the book.

A Fluid Connective Tissue

Blood is a fluid connective tissue with a unique composition. It consists of a matrix called **plasma** (PLAZ-muh) and formed elements (cells and cell fragments). The term **whole blood** refers to the combination of plasma and the formed elements. The cardiovascular system of an adult male contains 5–6 liters (5.3–6.4 quarts) of whole blood. An adult female contains 4–5 liters (4.2–5.3 quarts). The sex differences in blood volume primarily reflect differences in average body size.

The **hematocrit** (he-MAT-ō-krit) is the percentage of red blood cells within a sample of whole blood. The **packed cell volume (PCV)** is the percentage of all formed elements within a sample of whole blood.

PLASMA

Plasma, the fluid matrix of blood, makes up 46–63% of the volume of whole blood. In many respects, the composition of plasma resembles that of interstitial fluid. This similarity exists because water, ions, and small solutes are continuously exchanged between plasma and interstitial fluids across the walls of capillaries. The primary differences between plasma and interstitial fluid involve (1) the levels of respiratory gases (oxygen and carbon dioxide, due to the respiratory activities of tissue cells), and (2) the concentrations and types of dissolved proteins (because plasma proteins cannot cross capillary walls).

Formed elements are blood cells and cell fragments that are suspended in plasma. These elements account for 37–54% of the volume of whole blood. Three types of formed elements exist: platelets, white blood cells, and red blood cells. Formed elements are produced through the process of **hemopoiesis** (hē-mō-poy-Ē-sis), also called **hematopoiesis**. Two populations of stem cells—myeloid stem cells and lymphoid stem cells—are responsible for the production of formed elements.

FORMED ELEMENTS

Plasma Proteins

Plasma proteins are in solution rather than forming insoluble fibers like those in other connective tissues, such as loose connective tissue or cartilage. On average, each 100 mL of plasma contains 7.6 g of protein, almost five times the concentration in interstitial fluid. The large size and globular shapes of most blood proteins prevent them from crossing capillary walls, so they remain trapped within the bloodstream. The liver synthesizes and releases more than 90% of the plasma proteins, including all albumins and fibrinogen, most globulins, and various proenzymes.

Albumins

(al-BŪ-minz) constitute about 60% of the plasma proteins. As the most abundant plasma proteins, they are major contributors to the osmotic pressure of plasma.

Globulins

(GLOB-ŭ-linz) account for approximately 35% of the proteins in plasma. Important plasma globulins include antibodies and transport globulins. **Antibodies**, also called **immunoglobulins** (i-mŭ-nŏ-GLOB-ŭ-linz), attack foreign proteins and pathogens. **Transport globulins** bind small ions, hormones, and other compounds.

Fibrinogen

(fi-BRIN-ŏ-jen) functions in clotting, and normally accounts for roughly 4% of plasma proteins. Under certain conditions, fibrinogen molecules interact, forming large, insoluble strands of **fibrin** (Fī-brin) that form the basic framework for a blood clot.

Plasma also contains enzymes and hormones whose concentrations vary widely.

Other Solutes

Other solutes are generally present in concentrations similar to those in the interstitial fluids. However, because blood is a transport medium there may be differences in nutrient and waste product concentrations between arterial blood and venous blood.

Organic Nutrients:

Organic nutrients are used for ATP production, growth, and cell maintenance. This category includes lipids (fatty acids, cholesterol, glycerides), carbohydrates (primarily glucose), and amino acids.

Electrolytes:

Normal extracellular ion composition is essential for vital cellular activities. The major plasma electrolytes are Na^+ , K^+ , Ca^{2+} , Mg^{2+} , Cl^- , HCO_3^- , HPO_4^- , and SO_4^{2-} .

Organic Wastes:

Wastes are carried to sites for breakdown or excretion. Examples of organic wastes include urea, uric acid, creatinine, bilirubin, and ammonium ions.

Platelets

Platelets (PLĀT-lets) are small, membrane-bound cell fragments that contain enzymes and other substances important for clotting.

White Blood Cells

White blood cells (WBCs), or **leukocytes** (LŪ-kŏ-sīts; *leukos*, white + -cyte, cell), play a role in the body's defense mechanisms. There are five classes of leukocytes, each with slightly different functions that will be explored later in the chapter.

Neutrophils

Eosinophils

Basophils

Lymphocytes

Monocytes

Red Blood Cells

Red blood cells (RBCs), or **erythrocytes** (e-RITH-rŏ-sīts; *erythros*, red + -cyte, cell), are the most abundant blood cells. These specialized cells are essential for the transport of oxygen in the blood.

+ Clinical Note Plasma Expanders

Plasma expanders can be used to increase blood volume temporarily, over a period of hours. They are often used to extend the time for lab work to determine a person's blood type. (Transfusion of the wrong blood type can kill the recipient.) Isotonic electrolyte solutions such as 0.9% saline can be used as plasma expanders, but their effects are short-lived due to diffusion into interstitial fluid and cells. This fluid loss is slowed by the addition of solutes that cannot freely diffuse across plasma membranes. One example is lactated *Ringer's solution*, an isotonic solution that contains dissolved sodium chloride, sodium lactate, potassium chloride, and calcium chloride. The effects of Ringer's solution fade gradually as the liver, skeletal muscles, and other tissues absorb and metabolize the lactate ions. Another option is isotonic saline solution containing purified human albumin.

However, the plasma expanders in clinical use often contain large carbohydrate molecules, rather than proteins, to maintain proper osmotic concentration. These carbohydrates are not metabolized, but phagocytes gradually remove them from the bloodstream, and blood volume slowly decreases. Plasma expanders are easily stored. Their sterile preparation avoids viral or bacterial contamination, which can be a problem with donated plasma. Note that plasma expanders provide a temporary solution to low blood volume, but they do not increase the amount of oxygen carried by the blood. Red blood cells are needed for that function.

19-2 Red blood cells, formed by erythropoiesis, contain hemoglobin that transports respiratory gases

Learning Outcome List the characteristics and functions of red blood cells, describe the structure and functions of hemoglobin, describe how red blood cell components are recycled, explain erythropoiesis, and discuss respiratory gas transport.

The most abundant blood cells are the **red blood cells (RBCs)**, also called **erythrocytes** (eh-RITH-rō-sitz), which account for 99.9% of the formed elements. These cells give whole blood its deep red color because they contain the red pigment *hemoglobin* (HĒ-mō-glō-bin), which binds and transports the respiratory gases oxygen and carbon dioxide.

Abundance of RBCs: The Hematocrit

RBCs make up roughly one-third of all cells in the human body. A standard blood test reports the number of RBCs per microliter (μL) of whole blood as the *red blood cell count*. In adult males, 1 microliter, or 1 *cubic millimeter* (mm^3), of whole blood contains 4.5–6.3 million RBCs. In adult females,

1 microliter contains 4.2–5.5 million. A single drop of whole blood contains approximately 260 million RBCs. The blood of an average adult has 25 trillion RBCs.

The **hematocrit** is the percentage of red blood cells within a sample of whole blood. To determine the hematocrit, a blood sample is spun in a centrifuge so that all the formed elements come out of suspension. Whole blood contains about 1000 red blood cells for each white blood cell. After centrifugation, the white blood cells and platelets form a very thin *buffy coat* above a thick layer of RBCs.

Many conditions can affect the hematocrit. For example, the hematocrit increases during dehydration, due to a decrease in plasma volume, or after stimulation with the hormone *erythropoietin* (eh-rith-rō-POY-eh-tin). The hematocrit decreases as a result of internal bleeding or problems with RBC formation. So the hematocrit alone does not provide specific diagnostic information. Still, an abnormal hematocrit is an indication that other, more specific tests are needed. (Examples of such tests are described in [Table 19-1](#).)

Relationship of RBC Structure to RBC Function

Red blood cells are among the most specialized cells of the body. A red blood cell is very different from the “typical cell” discussed in Chapter 3. Each RBC is a biconcave disc with a thin

+ Clinical Note Collecting Blood for Analysis

Fresh whole blood is generally collected from a superficial vein, such as the *median cubital vein* on the anterior surface of the elbow. The procedure is called **venipuncture** (VĒN-i-punk-chur; *vena*, vein *punctura*, a piercing). It is a common sampling technique because (1) superficial veins are easy to locate, (2) the walls of veins are thinner than those of comparably sized arteries, and (3) blood pressure in the venous system is relatively low, so the puncture wound seals quickly. The most common clinical procedures examine venous blood.

A small drop of blood can be used to prepare a *blood smear*, a thin film of blood on a microscope slide. The blood smear is then stained with special dyes to show each type of formed element. Blood from peripheral capillaries can be obtained by puncturing the tip of a finger, an earlobe, or (in infants) the great toe or heel. Small amounts of capillary blood can also be used to test glucose, cholesterol, and hemoglobin levels. This method is valuable when veins are difficult to access.

An **arterial puncture**, or “arterial stick,” can be used for blood gas analysis, an indicator of lung function. Samples are generally drawn from the *radial artery* at the wrist or the *brachial artery* at the elbow.

Figure 19-2 The Structure of Red Blood Cells.

a When viewed in a standard blood smear, RBCs appear as two-dimensional objects, because they are flattened against the surface of the slide.

b The three-dimensional shape of RBCs.

c A sectional view of a mature RBC, showing the normal ranges for its dimensions.

d When traveling through relatively narrow capillaries, RBCs may stack like dinner plates.

central region and a thicker outer margin (**Figure 19-2a,b,c**). An average RBC has a diameter of $7.8\ \mu\text{m}$ and a maximum thickness of $2.85\ \mu\text{m}$, although the center thins to about $0.8\ \mu\text{m}$. In addition, the cytoplasmic surface of an RBC plasma membrane is a meshwork of flexible proteins.

The biconcave shape and flexible plasma membrane have three important effects on RBC function:

- **Gives Each RBC a Large Surface-Area-to-Volume Ratio.** Each RBC carries oxygen bound to intracellular proteins. That oxygen must be absorbed or released quickly as the RBC passes through the capillaries of the lungs or peripheral tissues. The greater the surface area per unit volume, the faster the exchange between the RBC's interior and the surrounding plasma. The total surface area of all the RBCs in the blood of a typical adult is about 3800 square meters

(nearly 4600 square yards), some 2000 times the total surface area of the body.

- **Enables RBCs to Form Stacks That Smooth Blood Flow through Narrow Blood Vessels.** These stacks of RBCs are like stacks of dinner plates (**Figure 19-2d**). Known as *rouleaux* (rū-LŌ; singular, *rouleau*), the stacks form and dissociate repeatedly without affecting the cells involved. An entire stack can pass along a blood vessel that is only slightly larger than the diameter of a single RBC. In contrast, individual cells would bump the walls, bang together, and form logjams that could restrict or prevent blood flow.
- **Enables RBCs to Bend and Flex When Entering Small Capillaries.** Red blood cells are very flexible. By changing shape, individual RBCs can squeeze through capillaries as narrow as $4\ \mu\text{m}$.

When a developing red blood cell differentiates, it loses any organelles not directly associated with its primary function: the transport of respiratory gases. Mature RBCs are **anucleate**, without nuclei; they retain only the cytoskeleton. Without nuclei and ribosomes, circulating RBCs cannot divide or synthesize structural proteins or enzymes. As a result, the RBCs cannot repair themselves, so their life span is relatively short—normally less than 120 days. With few organelles and no ability to synthesize proteins, their energy demands are low. Without mitochondria, they obtain the energy they need through the anaerobic metabolism of glucose that is absorbed from the surrounding plasma. The lack of mitochondria ensures that absorbed oxygen will be carried to peripheral tissues, not “stolen” by mitochondria in the RBC.

Hemoglobin

Hemoglobin (Hb or Hgb) is responsible for the red blood cell's ability to transport oxygen and carbon dioxide. Molecules

of hemoglobin make up more than 95% of its intracellular proteins. The hemoglobin content of whole blood is reported in grams of Hb per deciliter (100 mL) of whole blood (g/dL). Hemoglobin values vary with age, sex, time of day, hydration status, and altitude.

Hemoglobin Structure

Hemoglobin molecules have a complex quaternary structure. Each Hb molecule has two *alpha* (α) chains and two *beta* (β) chains of polypeptides (Figure 19-3). Each chain is a globular protein subunit that resembles the myoglobin in skeletal and cardiac muscle cells. Like myoglobin, each Hb chain contains a single molecule of **heme**, a nonprotein pigment complex that forms a ring. Each heme unit holds an iron ion in such a way that the iron can interact with an oxygen molecule, forming **oxyhemoglobin**, HbO_2 . Blood that contains RBCs filled with oxyhemoglobin is bright red.

The binding of an oxygen molecule to the iron in a heme unit is reversible. The iron–oxygen interaction is very weak. The iron and oxygen can easily dissociate without damaging the heme unit or the oxygen molecule. A hemoglobin molecule whose iron is not bound to oxygen is called **deoxyhemoglobin**. Blood containing RBCs filled with deoxyhemoglobin is dark red.

The RBCs of an embryo or a fetus contain a different form of hemoglobin, known as *fetal hemoglobin* (HbF). It binds oxygen more readily than does adult hemoglobin. For this reason,

a developing fetus can “steal” oxygen from the maternal bloodstream at the placenta. The conversion from fetal hemoglobin to the adult form begins shortly before birth and continues over the next year. The production of fetal hemoglobin can be stimulated in adults by the administration of drugs such as *hydroxyurea* or *butyrate*. This is one method of treatment for *sickle cell disease* (SCD), a group of conditions that result from the production of abnormal forms of adult hemoglobin.

Hemoglobin Function: Binding and Releasing Oxygen and Carbon Dioxide

Each RBC contains about 280 million Hb molecules. Because 1 Hb molecule contains 4 heme units, each RBC can potentially carry more than a billion molecules of oxygen at a time. Roughly 98.5% of the oxygen carried by the blood is bound to Hb molecules inside RBCs.

The amount of oxygen bound to hemoglobin depends mostly on the oxygen content of the plasma. When the plasma oxygen level is low, hemoglobin releases oxygen. Under these conditions, typical of peripheral capillaries, the plasma carbon dioxide level is elevated. The α and β chains of hemoglobin then bind carbon dioxide, forming **carbaminohemoglobin**. In the lung capillaries, the plasma oxygen level is high and the carbon dioxide level is low. Upon reaching these capillaries, RBCs absorb oxygen (which is then bound to hemoglobin) and release carbon dioxide. We revisit these processes in Chapter 23.

Figure 19-3 The Structure of Hemoglobin. Hemoglobin consists of four globular protein subunits. Each subunit contains a single molecule of heme—a nonprotein ring surrounding a single ion of iron.

Each molecule of heme contains a single ion of what element?

Normal activity levels can be sustained only when the tissue oxygen level is kept within normal limits. If the hematocrit is low or the Hb content of the RBCs is reduced, a condition known as **anemia** results. Anemia interferes with oxygen delivery to peripheral tissues. Every system is affected as organ function deteriorates due to oxygen starvation. Anemic individuals become weak and lethargic. They may also become confused because the brain is affected as well.

RBC Formation and Turnover

An RBC is exposed to severe physical stresses. A single round-trip from the heart, through the peripheral tissues, and back to the heart usually takes less than a minute. In that time, the RBC gets pumped out of the heart and forced along vessels, where it bounces off the walls and collides with other RBCs. It forms stacks, contorts, and squeezes through tiny capillaries. Then it is rushed back to the heart to make another round trip.

With all this wear and tear and no repair mechanisms, a typical RBC has a short life span. After it travels about 700 miles in 120 days, either its plasma membrane ruptures or some other damage is detected by phagocytes of the spleen, liver, and red bone marrow, which engulf it. The continuous elimination of RBCs usually goes unnoticed because new ones enter the bloodstream at a comparable rate. About 1% of the circulating RBCs are replaced each day, and in the process approximately 3 million new RBCs enter the bloodstream *each second*!

RBC Production: Erythropoiesis

Erythropoiesis is the formation of RBCs and it occurs throughout life. Many factors stimulate this process, such as a decreased oxygen level or increased erythropoietin. Let's look at erythropoiesis in detail.

Erythropoiesis in the Fetal and Adult Periods. Embryonic blood cells appear in the bloodstream during the third week of development. These cells divide repeatedly, rapidly increasing in number. Blood forms primarily in the vessels of the embryonic *yolk sac* (an early membranous structure) during the first 8 weeks of development. As other organ systems appear, some of the embryonic blood cells move out of the bloodstream and into the liver, spleen, thymus, and bone marrow. These embryonic cells differentiate into **stem cells** that divide to produce blood cells. The liver and spleen are the primary sites of hemopoiesis from the second to fifth months of development, but as the skeleton enlarges, the bone marrow becomes increasingly important.

In adults, red blood cell formation, or **erythropoiesis** (e-rith-rō-poy-Ē-sis), takes place only in **red bone marrow**, or **myeloid** (MĪ-e-loyd; *myelos*, marrow) **tissue**. This tissue is in portions of the vertebrae, sternum, ribs, skull, scapulae, pelvis, and proximal limb bones. Other marrow areas contain a fatty tissue known as **yellow bone marrow**. Under extreme stimulation, such as severe and sustained blood loss, areas of yellow marrow can convert to red marrow, increasing the rate of RBC formation.

Stages of RBC Maturation. RBC production begins with the division of cells called **hemocytoblasts** (*hemo-*, blood + *cyte*, cell + *blastos*, precursor), or **hematopoietic stem cells (HSCs)**, in the red bone marrow. These stem cells produce two types of cells: (1) **myeloid stem cells**, which in turn divide to produce red blood cells and several classes of white blood cells, and (2) **lymphoid stem cells**, which divide to produce white blood cells called lymphocytes.

In the red bone marrow, a red blood cell matures in stages. Blood specialists, known as **hematologists** (hĒ-mah-TOL-ah-jists), have named six key developmental stages that occur over about a week (**Figure 19–4**). On day 1, cells destined to become RBCs first differentiate into **proerythroblasts**, and then on days 2 and 3 proceed through various **erythroblast** stages.

Figure 19–4 Stages of RBC Maturation: Erythropoiesis. Red blood cells are produced in the red bone marrow. The color density in the cytoplasm indicates the abundance of hemoglobin. Note the reductions in the sizes of the cell and nucleus leading up to the formation of a reticulocyte.

Erythroblasts, which actively synthesize hemoglobin, are named based on total size, amount of hemoglobin, and size and appearance of the nucleus.

After day 4, the erythroblast, now called a *normoblast*, sheds its nucleus and becomes a **reticulocyte** (re-TIK-yū-lō-sīt), which contains 80% of the Hb of a mature RBC. Hemoglobin synthesis then continues for days 5–7. During this period, while the cell is synthesizing Hb and other proteins, its cytoplasm still contains RNA, which can be seen under the microscope with certain stains. After 2 days in the red bone marrow, the reticulocyte enters the bloodstream. At this time, reticulocytes normally account for about 0.8% of the RBC population in the blood and can still be detected by staining. After a final day in circulation, the reticulocytes complete their maturation and become indistinguishable from other mature RBCs.

Regulation of Erythropoiesis

Erythropoiesis is stimulated directly by the hormone **erythropoietin (EPO)** and indirectly by several other hormones, including thyroxine, androgens, and growth hormone. As noted earlier in **Spotlight Figure 19–1**, estrogens do not stimulate erythropoiesis. This fact accounts for the differences in hematocrit values between males and females.

Erythropoietin is a glycoprotein formed by the kidneys and liver. EPO appears in the plasma when peripheral tissues, especially the kidneys, are exposed to a low concentration of oxygen. A low oxygen level in tissues is called **hypoxia** (hī-POKS-ē-uh; *hypo-*, below + *oxy-*, presence of oxygen). Erythropoietin is released (1) during anemia; (2) when blood flow to the kidneys decreases; (3) when the oxygen content of air in the lungs decreases, due to disease or high altitude; and (4) when the respiratory surfaces of the lungs are damaged.

Once in the bloodstream, EPO travels to the red bone marrow, where it stimulates stem cells and developing RBCs. Erythropoietin has two major effects: (1) It stimulates cell division rates in erythroblasts and in the stem cells that produce

erythroblasts, and (2) it speeds up the maturation of RBCs, mainly by accelerating Hb synthesis. Under maximum EPO stimulation, red bone marrow can increase RBC formation 10-fold, to about 30 million cells per second.

The ability to increase the rate of blood formation quickly and dramatically is important to a person recovering from a severe blood loss. But if EPO is administered to a healthy person, the hematocrit may rise to 65 or more. Such an increase can place an intolerable strain on the heart. Similar problems can occur after **blood doping**, a practice in which athletes elevate their hematocrits by re-infusing packed RBCs that were removed and stored at an earlier date. The goal is to improve oxygen delivery to muscles, thereby enhancing performance. The strategy can be dangerous, however, because it makes blood more viscous and increases the workload on the heart.

One more factor may limit red blood cell formation. For erythropoiesis to proceed normally, the red bone marrow needs adequate supplies of amino acids, iron, and vitamins (including B₁₂, B₆, and folic acid) for protein synthesis. We obtain **vitamin B₁₂** from dairy products and meat. To absorb vitamin B₁₂, we need *intrinsic factor*, which is produced in the stomach. Without vitamin B₁₂ from the diet, normal stem cell divisions cannot occur and *pernicious anemia* results. Thus, pernicious anemia may be caused by a vitamin B₁₂ deficiency, a problem with the production of intrinsic factor, or a problem with the absorption of vitamin B₁₂ bound to intrinsic factor.

Blood tests provide information about the general health of an individual, usually with a minimum of trouble and expense. Several common blood tests, called *RBC tests*, assess the number, size, shape, and maturity of circulating RBCs, indicating the erythropoietic activities under way. The tests can also be useful in detecting problems, such as internal bleeding, that may not produce other obvious signs or symptoms. **Table 19–1** lists examples of important red blood cell tests and related terms. (These tests are performed as part of a *complete blood count*, or CBC.)

Table 19–1 RBC Tests and Related Terminology

Test	Determines	Terms Associated with Abnormal Values	
		Elevated	Depressed
Hematocrit (Hct)	Percentage of red blood cells in whole blood Normal = 37–54%	Polycythemia (may reflect erythrocytosis)	Anemia
Reticulocyte (Retic) count	Percentage of circulating reticulocytes Normal = 0.8%	Reticulocytosis	Diminished erythropoiesis
Hemoglobin (Hb; Hgb) concentration	Concentration of hemoglobin in blood Normal = 12–18 g/dL	Polycythemia	Anemia
Red blood cell (RBC) count	Number of RBCs per μL of whole blood Normal = 4.2–6.3 million cells/ μL	Erythrocytosis/polycythemia	Anemia
Mean corpuscular volume (MCV)	Average volume of one RBC Normal = 82–101 μm^3 /cell (normocytic)	Macrocytic	Microcytic
Mean corpuscular hemoglobin (MCH)	Average weight of Hb in one RBC Normal = 27–34 pg/RBC (normochromic)	Hyperchromic	Hypochromic

Hemoglobin Recycling

Macrophages of the spleen, liver, and red bone marrow play a central role in recycling red blood cell components. These phagocytes engulf aged red blood cells and detect and remove Hb molecules from **hemolyzed** (ruptured) red blood cells (**Figure 19-5**). Hemoglobin remains intact only inside RBCs. If the Hb released by hemolysis is not phagocytized, its components will not be recycled.

Once a phagocytic cell has engulfed and broken down an RBC, each part of the Hb molecule has a different fate (**Figure 19-5**). The alpha and beta chains of Hb are filtered by the kidneys and eliminated in urine. The globular proteins are broken apart into their component amino acids, which are then either metabolized by the cell or released into the bloodstream for use by other cells. Only the iron of each heme unit is recycled. The remaining portion is processed separately.

When abnormally large numbers of red blood cells break down in the bloodstream, urine may turn red or brown. This condition is called **hemoglobinuria**. The presence of intact RBCs in urine—a sign called **hematuria** (hē-muh-TOO-rē-uh)—occurs only after kidney damage or damage to vessels along the urinary tract.

Fate of Heme. Each heme unit is stripped of its iron and converted to **biliverdin** (bil-ih-VER-din), an organic compound with a green color. (Bad bruises commonly develop a greenish tint when biliverdin forms in the blood-filled tissues.) Biliverdin is then converted to **bilirubin** (bil-ih-RŪ-bin), an orange-yellow pigment, and released into the bloodstream. There, the bilirubin binds to albumin and is transported to the liver for excretion in bile.

If the bile ducts are blocked or the liver cannot absorb or excrete bilirubin, the circulating level of the compound climbs rapidly. Bilirubin then diffuses into peripheral tissues, giving them a yellow color that is most apparent in the skin and over the sclera of the eyes. This combination of yellow skin and eyes is **jaundice** (JAWN-dis).

In the large intestine, bacteria convert bilirubin to related pigments called **urobilinogens** (yūr-ō-bĪ-LIN-ō-jens) and **stercobilinogens** (ster-kō-bĪ-LIN-ō-jens). Some of the urobilinogens are absorbed into the bloodstream and are then excreted into urine. When exposed to oxygen, some of the urobilinogens and stercobilinogens are converted to **urobilins** (ūr-ō-BĪ-lins) and **stercobilins** (ster-kō-BĪ-lins).

Iron Recycling. Large quantities of free iron are toxic to cells, so in the body iron is generally bound to transport or storage proteins. Iron ions (Fe^{2+}) extracted from heme molecules may be bound and stored in a phagocytic cell or released into the bloodstream, where they bind to **transferrin** (trans-FER-in), a plasma protein. Red blood cells developing in the red bone marrow absorb the amino acids and transferrins from the bloodstream and use them to synthesize new Hb molecules.

Excess transferrins are removed in the liver and spleen, and the iron is stored in two special iron-protein complexes: **ferritin** (FER-ih-tin) and **hemosiderin** (hē-mō-SID-eh-rin).

This recycling system is remarkably efficient. Although roughly 26 mg of iron is incorporated into new Hb molecules each day, a dietary supply of 1–2 mg can keep pace with the incidental losses that occur at the kidneys and digestive tract.

Any impairment in iron uptake or metabolism can cause serious clinical problems because RBC formation will be affected. For example, *iron-deficiency anemia* results from a lack of iron in the diet or from problems with iron absorption. Too much iron can also cause problems, due to excessive buildup in secondary storage sites, such as the liver and cardiac muscle tissue. Excessive iron deposition in cardiac muscle cells has been linked to heart disease.

19-3 The ABO and Rh blood groups are based on antigen-antibody responses

Learning Outcome Explain the importance of blood typing and the basis for ABO and Rh incompatibilities.

Antigens are substances that can trigger a protective defense mechanism called an *immune response*. Most antigens are proteins, but some other types of organic molecules are antigens as well. Plasma membranes contain **surface antigens**, substances that the immune system recognizes as “normal,” or “self.” In other words, the immune system ignores these substances rather than attacking them as “foreign.” Let's learn how surface antigens on red blood cells determine *blood type*. Blood type then determines how blood reacts during *transfusions*.

ABO and Rh Blood Groups

One's **blood type** is determined by the presence or absence of specific surface antigens in RBC plasma membranes. The surface antigens involved are integral membrane glycoproteins whose characteristics are genetically determined. Red blood cells have at least 50 kinds of surface antigens, but three surface antigens are of particular importance: **A**, **B**, and **Rh** (or **D**).

Figure 19–5 Recycling of Red Blood Cell Components.

Where are red blood cells produced?

The *ABO blood group* is based on the presence or absence of the A and B surface antigens. According to this group, there are four blood types (**Figure 19–6a**): **Type A** blood has RBCs with surface antigen A only, **type B** has surface antigen B only, **type AB** has both A and B, and **type O** has neither A nor B. Individuals with these blood types are not evenly distributed throughout the world.

The *Rh blood group* is based on the presence or absence of the Rh surface antigen. The term **Rh positive (Rh⁺)** indicates the presence of the Rh surface antigen, commonly called the *Rh factor*.

The absence of this antigen is indicated as **Rh negative (Rh⁻)**. When the complete blood type is recorded, the term *Rh* is usually omitted, and a positive or negative sign is used. For example, the types are reported as O negative (O⁻), A positive (A⁺), and so on. Type O⁺ is the most common blood type. As in the distribution of A and B surface antigens, Rh type differs by ethnic group and by region.

The immune system ignores these surface antigens—called **agglutinogens** (ah-glū-TIN-ō-jenz)—on your own red blood cells. However, the plasma contains antibodies, sometimes called

Figure 19–6 Blood Types and Cross-Reactions.

Type A	Type B	Type AB	Type O
Type A blood has RBCs with surface antigen A only.	Type B blood has RBCs with surface antigen B only.	Type AB blood has RBCs with both A and B surface antigens.	Type O blood has RBCs lacking both A and B surface antigens.
 Surface antigen A	 Surface antigen B		
 If you have Type A blood, your plasma contains anti-B antibodies, which will attack Type B surface antigens.	 If you have Type B blood, your plasma contains anti-A antibodies, which will attack Type A surface antigens.	If you have Type AB blood, your plasma has neither anti-A nor anti-B antibodies.	 If you have Type O blood, your plasma contains both anti-A and anti-B antibodies.

a Blood type depends on the presence of surface antigens (agglutinogens) on RBC surfaces. The plasma contains antibodies (agglutinins) that will react with foreign surface antigens.

b In a cross-reaction, antibodies react with their target antigens causing agglutination and hemolysis of the affected RBCs. In this example, anti-B antibodies encounter B surface antigens, which cause the RBCs bearing the B surface antigens to clump together and break up.

Type A blood has what type of RBC surface antigen and what type of opposing antibodies?

agglutinins (ah-GLŪ-tih-ninz), that will attack the antigens on “foreign” red blood cells. When these antibodies attack, the foreign cells *agglutinate*, or clump together; this process is called **agglutination**. If a person has type A blood, their plasma contains anti-B antibodies, which will attack type B surface antigens. If a person has type B blood, their plasma contains anti-A antibodies. The RBCs of an individual with type O blood have neither A nor B surface antigens, and that person’s plasma contains both anti-A and anti-B antibodies. A person with type AB blood has red blood cells with both A and B surface antigens, and the plasma does not contain anti-A or anti-B antibodies. The presence of anti-A and/or anti-B antibodies is genetically determined. These antibodies are present throughout life, regardless of whether the individual has ever been exposed to foreign RBCs.

In contrast, the plasma of an Rh-negative individual does not contain anti-Rh antibodies. These antibodies are present only if the individual has been **sensitized** by previous exposure to Rh⁺ RBCs. Such exposure can occur accidentally during a transfusion, but it can also accompany a seemingly normal pregnancy involving an Rh⁻ female and an Rh⁺ fetus. (This process is covered in more detail later in this section.)

Transfusions

A **transfusion** is the process of transferring whole blood or blood plasma from one person to another. If the donor’s cells and the recipient’s plasma are not compatible, a potentially life-threatening *cross-reaction* can occur. Such cross-reactions can be prevented by testing to make sure that the blood types of the donor and the recipient are **compatible**—that is, that the donor’s blood cells and the recipient’s plasma will not cross-react.

Cross-Reactions

During a transfusion, if an antibody meets its specific surface antigen, the RBCs agglutinate and may also hemolyze. This is called a **cross-reaction**, or *transfusion reaction* (Figure 19-6b). For instance, an anti-A antibody that encounters A surface antigens will cause the RBCs bearing the A surface antigens to clump or even break up. Clumps and fragments of RBCs under attack form drifting masses that can plug small blood vessels in the kidneys, lungs, heart, or brain, damaging or destroying affected tissues.

In practice, the surface antigens on the donor’s cells are more important in determining compatibility than are the antibodies in the donor’s plasma. Why? Unless large volumes of whole blood or plasma are transferred, cross-reactions between the donor’s plasma and the recipient’s blood cells will not produce significant agglutination. This is because the donated plasma is diluted quickly through mixing with the larger plasma volume of the recipient. (One unit of whole blood, 500 mL, contains roughly 275 mL of plasma, only about 10% of normal plasma volume.) When the goal is to increase the blood’s oxygen-carrying capacity rather than its plasma volume, packed

RBCs, with a minimal amount of plasma, are often transfused. This practice minimizes the risk of a cross-reaction.

Compatibility Testing

To avoid cross-reactions, a compatibility test is usually performed in advance of any transfusion. This process normally involves two steps: (1) determining blood type and (2) crossmatch testing.

The standard test for blood type considers only the three surface antigens most likely to produce dangerous cross-reactions: A, B, and Rh (Figure 19-7). The test involves taking drops of blood and mixing them separately with solutions containing anti-A, anti-B, and anti-Rh (anti-D) antibodies. Any cross-reactions are then recorded. For example, if an individual’s RBCs clump together when exposed to anti-A and to anti-B antibodies, the individual has type AB blood. If no reactions occur after exposure, that person must have type O blood. The presence or absence of the Rh surface antigen is also noted, and the individual is classified as Rh positive or Rh negative on that basis.

Standard blood typing of both donor and recipient can be completed in a matter of minutes. However, in an emergency, there may not be time for preliminary testing. For example, a person with a severe gunshot wound may require 5 liters or more of blood before the damage can be repaired. Under these circumstances, type O blood (preferably O⁻) will be administered. Because the donated RBCs lack both A and B surface antigens, the recipient’s blood can have anti-A antibodies, anti-B antibodies, or both and still not cross-react with the donor’s blood. Because cross-reactions with type O blood are very unlikely, type O individuals are sometimes called *universal donors*. Type AB individuals

Figure 19-7 Blood Type Testing. Test results for blood samples from four individuals. Drops of blood are mixed with solutions containing antibodies to the surface antigens A, B, AB, and Rh. Anti-A antibodies agglutinate A antigens. Anti-B antigens agglutinate B antigens. The tested person’s blood types are shown at right.

Anti-A	Anti-B	Anti-Rh	Blood type
 Clumping	 No clumping	 Clumping	A ⁺
 No clumping	 Clumping	 Clumping	B ⁺
 Clumping	 Clumping	 Clumping	AB ⁺
 No clumping	 No clumping	 No clumping	O ⁻

were once called *universal recipients* because they lack anti-A and anti-B antibodies that would attack donated RBCs, and so can safely receive blood of any type. However, now that blood supplies are usually adequate and compatibility testing is regularly done, the term has largely been dropped. If the recipient's blood type is known to be AB, type AB blood will be administered.

Enzymes can now be used to strip off the A or B surface antigens from RBCs and create type O blood in the laboratory. The procedure is expensive and time consuming and has limited use in emergency treatment. Still, cross-reactions can occur, even to type O⁻ blood, because at least 48 other surface antigens are present. For this reason, whenever time and facilities permit, further testing is performed to ensure complete compatibility between donor blood and recipient blood. **Crossmatch testing** involves exposing the donor's RBCs to a sample of the recipient's plasma under controlled conditions. This procedure reveals significant cross-reactions involving surface antigens other than A, B, or Rh. Another way to avoid compatibility problems is to replace lost blood with synthetic blood substitutes, which do not contain surface antigens that can trigger a cross-reaction.

Because blood groups are inherited, blood tests are also used as paternity tests and in crime detection. The blood collected cannot prove that a particular individual is a certain child's biological father or is guilty of a specific crime, but it can prove that the individual is *not* involved. For example, an adult with type AB blood cannot be the biological parent of an infant with type O blood. Testing for additional surface antigens, other than the standard ABO groups, can increase the accuracy of the conclusions. When available, DNA identity testing, which has nearly 100% accuracy, has replaced blood type identity testing.

Spotlight Figure 19–8 describes a serious condition known as *hemolytic disease of the newborn (HDN)*. Hemolytic disease of the newborn does not involve a transfusion; rather, it involves Rh incompatibility between a pregnant person and the developing fetus.

19-4 The various types of white blood cells contribute to the body's defenses

Learning Outcome Categorize white blood cell types based on their structures and functions and discuss the factors that regulate the production of each type.

Unlike red blood cells, **white blood cells (WBCs)**, or **leukocytes**, have nuclei and other organelles, and they lack hemoglobin. White

blood cells help defend the body against invasion by pathogens. They also remove toxins, wastes, and abnormal or damaged cells.

A typical microliter of blood contains 5000 to 10,000 WBCs, compared with 4.2 to 6.3 million RBCs. Most of the WBCs in the body at any moment are in connective tissue proper or in organs of the lymphatic system. Circulating WBCs are only a small fraction of the total WBC population.

WBC Characteristics and Functions

Unlike RBCs, WBCs circulate for only a short time during their life span. White blood cells migrate through the loose and dense connective tissues of the body. They use the bloodstream to travel from one organ to another and for rapid transportation to areas of infection or injury. As they travel along the miles of capillaries, WBCs can detect the chemical signs of damage to surrounding tissues. When these cells detect problems, they leave the bloodstream and enter the damaged area.

Circulating WBCs have the following functional characteristics:

- **All Can Migrate Out of the Bloodstream.** When WBCs in the bloodstream are activated, they contact and adhere to the vessel walls in a process called *margination*. After further interaction with endothelial cells, the activated WBCs squeeze between adjacent endothelial cells and enter the surrounding tissue. This process is called *emigration*, or *diapedesis* (dī-ah-peh-DEE-sis; *dia*, through + *pedesis*, a leaping).
- **All Are Capable of Amoeboid Movement.** Amoeboid movement is a gliding motion made possible by the flow of cytoplasm into slender cellular processes extended in the direction of movement. (The movement is so named because it is like that of an *amoeba*, a type of protozoan.) The mechanism is not fully understood, but it involves the continuous rearrangement of bonds between actin filaments in the cytoskeleton. It also requires calcium ions and ATP. This mobility allows WBCs to move through the endothelial lining and into peripheral tissues.
- **All Are Attracted to Specific Chemical Stimuli.** This characteristic, called **positive chemotaxis** (kē-mō-TAK-sis), guides WBCs to invading pathogens, damaged tissues, and other active WBCs.

In addition, keep in mind that some types of WBCs are capable of phagocytosis. These WBCs may engulf pathogens, cell debris, or other materials.

Types of WBCs

Several types of WBCs can be distinguished microscopically in a blood smear by using either of two standard stains: *Wright's stain* or *Giemsa (JEM-suh) stain*. Traditionally, WBCs have been divided into two groups based on their appearance after staining: (1) *granular leukocytes*, or *granulocytes* (with abundant stained granules)—the *neutrophils*, *eosinophils*, and *basophils*;

Hemolytic disease of the newborn is an RBC-related disorder caused by a cross-reaction between fetal and maternal blood types. Genes controlling the presence or absence of any surface antigen in the plasma membrane of a red blood cell are provided by both biological parents, so a child can have a blood type different from that of either parent. During pregnancy, when fetal and maternal vascular systems are closely intertwined, the female's antibodies may cross the placenta, attacking and destroying fetal RBCs. The resulting condition, called **hemolytic disease of the newborn (HDN)**, has many forms, some quite dangerous and others so mild they are undetected.

FIRST PREGNANCY

1

Problems seldom develop during a first pregnancy, because very few fetal cells enter the maternal bloodstream then, and thus the female's immune system is not stimulated to produce anti-Rh antibodies.

The most common form of hemolytic disease of the newborn develops after an Rh⁻ female has carried an Rh⁺ fetus.

2

Exposure to fetal red blood cell antigens generally occurs during delivery, when bleeding takes place at the placenta and uterus. Such mixing of fetal and maternal blood can stimulate the female's immune system to produce anti-Rh antibodies, leading to sensitization.

3

About 20% of Rh⁻ females who carried Rh⁺ children become sensitized within 6 months of delivery. Because the anti-Rh antibodies are not produced in significant amounts until after delivery, a female's first infant is not affected.

SECOND PREGNANCY

4

If a future pregnancy involves an Rh⁺ fetus, maternal anti-Rh antibodies produced after the first delivery cross the placenta and enter the fetal bloodstream. These antibodies destroy fetal RBCs, producing a dangerous anemia. The fetal demand for blood cells increases, and they leave the bone marrow and enter the bloodstream before completing their development. Because these immature RBCs are erythroblasts, HDN is also known as **erythroblastosis fetalis** (e-rith-rō-blas-TŌ-sis fē-TAL-is).

Without treatment, the fetus may die before delivery or shortly thereafter. A newborn with severe HDN is anemic, and the high concentration of circulating bilirubin produces jaundice. Because the maternal antibodies remain active in the newborn for 1 to 2 months after delivery, the infant's entire blood volume may require replacement to remove the maternal anti-Rh antibodies, as well as the damaged RBCs. Fortunately, the female's anti-Rh antibody production can be prevented if such antibodies (available under the name RhoGAM) are administered to the female in weeks 26–28 of pregnancy and during and after delivery. These antibodies destroy any fetal RBCs that cross the placenta before they can stimulate a maternal immune response. Because maternal sensitization does not occur, no anti-Rh antibodies are produced. In the United States, this relatively simple procedure has almost entirely eliminated HDN mortality caused by Rh incompatibilities.

and (2) *agranular leukocytes*, or *agranulocytes* (with few, if any, stained granules)—the *monocytes* and *lymphocytes*. This categorization is convenient but somewhat misleading. The granules in “granular leukocytes” are secretory vesicles and lysosomes, and the “agranular leukocytes” also contain vesicles and lysosomes, but they are just smaller and difficult to see with a light microscope.

Neutrophils, eosinophils, basophils, and monocytes are part of the body’s *nonspecific defenses*. A variety of stimuli activate such defenses, which do not discriminate between one type of threat and another. Neutrophils and eosinophils are sometimes called *microphages*, to distinguish them from the larger macrophages in connective tissues. Macrophages are monocytes that have moved out of the bloodstream and have become actively phagocytic. Lymphocytes, in contrast, are responsible for *specific defenses*, which mount a counter-attack against specific types of invading pathogens or foreign proteins. (The interactions among WBCs and the relationships between specific and nonspecific defenses are presented in Chapter 22.)

Neutrophils

Fifty to 70% of the circulating WBCs are **neutrophils** (NŪ-trō-filz). This name reflects the fact that the granules of these WBCs are chemically neutral and thus are difficult to stain with either acidic or basic (alkaline) dyes. A mature neutrophil has a very dense, segmented nucleus with two to five lobes resembling beads on a string (**Figure 19-9a**). This structure has given neutrophils another name: **polymorphonuclear** (pol-ē-mor-fō-NŪ-klē-ar) **leukocytes** (*poly*, many + *morphe*, form), or PMNs. “Polymorphs,” or “polys,” as they are often called, are roughly 12 μm in diameter. Their cytoplasm is packed with pale granules containing lysosomal enzymes and bactericidal (bacteria-killing) compounds.

Neutrophils are highly mobile. They are generally the first of the WBCs to arrive at the site of an injury. These very active phagocytic cells specialize in attacking and digesting bacteria that have been “marked” with antibodies or with *complement proteins*—plasma proteins involved in tissue defenses. (The complement system is presented in Chapter 22.)

When a neutrophil encounters a bacterium, it quickly engulfs the invader, and the metabolic rate of the neutrophil increases dramatically. Along with this *respiratory burst*, the neutrophil produces highly reactive, destructive chemical agents, including hydrogen peroxide (H₂O₂) and superoxide anions (O₂[−]), which can kill bacteria.

Meanwhile, the vesicle containing the engulfed pathogen fuses with lysosomes that contain digestive enzymes and small peptides called *defensins*. This process is called **degranulation** because it reduces the number of granules in the cytoplasm. Defensins kill a variety of pathogens, including bacteria, fungi, and enveloped viruses, by combining to form large channels

in their plasma membranes. The digestive enzymes then break down the bacterial remains.

While actively attacking bacteria, a neutrophil releases prostaglandins and leukotrienes. The prostaglandins increase capillary permeability in the affected region, contributing to local inflammation and restricting the spread of injury and infection. Leukotrienes are hormones that attract other phagocytes and help coordinate the immune response.

Most neutrophils have a short life span. They survive in the bloodstream for only about 10 hours. When actively engulfing debris or pathogens, they may last 30 minutes or less. A neutrophil decomposes after engulfing bacteria, but its breakdown releases chemicals that attract other neutrophils to the site. A mixture of dead neutrophils, cellular debris, and other wastes form the *pus* associated with infected wounds.

Tips

Remember that **neutrophils** are the most **numerous** of the white blood cells.

Eosinophils

Eosinophils (ē-ō-SIN-ō-filz) have granules that stain darkly with *eosin*, a red dye. The granules also stain with other acid dyes, so the name **acidophils** (ah-SID-ō-filz) applies as well. Eosinophils generally represent 2–4% of the circulating WBCs. They are similar in size to neutrophils. However, the combination of deep red granules and a typically bilobed (two-lobed) nucleus makes eosinophils easy to identify (**Figure 19-9b**).

Eosinophils attack objects that are coated with antibodies. These phagocytic cells will engulf antibody-marked bacteria, protozoa, or cellular debris, but their primary mode of attack is the exocytosis of toxic compounds, including nitric oxide and cytotoxic enzymes. This is particularly effective against multicellular parasites that are too big to engulf, such as flukes or parasitic roundworms. The number of circulating eosinophils increases dramatically during a parasitic infection.

Eosinophils increase in number during allergic reactions as well, because they are sensitive to circulating *allergens* (materials that trigger allergies). Eosinophils are also attracted to sites of injury, where they release enzymes that reduce inflammation produced by mast cells and neutrophils. This controls the spread of inflammation to adjacent tissues.

Basophils

Basophils (BĀ-sō-filz; *baso*-, base + *phileo*, to love) have numerous granules that stain darkly with basic dyes. In a standard blood smear, the inclusions are deep purple or blue (**Figure 19-9c**). Measuring 8–10 μm in diameter, basophils are smaller than neutrophils or eosinophils. They are also relatively rare, accounting for less than 1% of the circulating WBC population.

Figure 19–9 Types of White Blood Cells.

Basophils migrate to injury sites and cross the capillary **endothelium** to accumulate in the damaged tissues. There they discharge their granules into the interstitial fluids. The granules contain *histamine*, which dilates blood vessels, and *heparin*, a compound that prevents blood clotting. Stimulated basophils release these chemicals into the interstitial fluids to enhance the local inflammation initiated by mast cells. Although mast cells release the same compounds in damaged connective tissues, mast cells and basophils are distinct populations. Stimulated basophils also release other chemicals that attract eosinophils and other basophils to the area.

Monocytes

Monocytes (MON-ō-sīts) are spherical cells that may exceed 15 μm in diameter, nearly twice the diameter of a typical RBC. When flattened in a blood smear, they look even larger, so monocytes are easy to identify. The nucleus is large and tends to be oval or kidney bean-shaped rather than lobed (**Figure 19–9d**). Monocytes normally account for 2–8% of circulating WBCs.

An individual monocyte is transported in the bloodstream. It remains in circulation for only about 24 hours before entering peripheral tissues to become a tissue macrophage. Macrophages are aggressive phagocytes. They often attempt to engulf items as large as or larger than themselves. When active, they release chemicals that attract and stimulate neutrophils, monocytes, and other phagocytic cells. Active macrophages also secrete substances that draw fibroblasts into the region. The fibroblasts then begin producing scar tissue to wall off the injured area. Macrophages are discussed further in Chapter 22.

Tips

A **monocyte** is the **monster** cell that engulfs debris and pathogens.

Lymphocytes

Typical **lymphocytes** (LIM-fō-sīts) are slightly larger than RBCs and lack abundant, deeply staining granules. In blood smears, lymphocytes typically have a large, round nucleus surrounded by a thin halo of cytoplasm (**Figure 19–9e**).

Lymphocytes account for 20–40% of the circulating white blood cell population. Lymphocytes continuously migrate from the bloodstream, through peripheral tissues, and back to the bloodstream. Circulating lymphocytes represent only a small fraction of all lymphocytes. At any moment, most lymphocytes are in other connective tissues and in organs of the lymphatic system.

The circulating blood contains three functional classes of lymphocytes. These classes cannot be distinguished using just a light microscope. They are as follows:

- **T cells** (T lymphocytes) are responsible for *cell-mediated immunity*, a specific defense mechanism against invading foreign cells, and for the coordination of the immune response. T cells either enter peripheral tissues and attack foreign cells directly or control the activities of other lymphocytes.
- **B cells** (B lymphocytes) are responsible for *humoral immunity*, a specific defense mechanism that involves the production of antibodies. These antibodies are distributed by blood, lymph, and interstitial fluid and can attack foreign antigens throughout the body. Activated B cells differentiate into **plasma cells**, which are specialized to synthesize and secrete antibodies. The T cells responsible for cellular immunity must migrate to their targets, but the antibodies produced by plasma cells in one location can destroy antigens almost anywhere in the body.
- **Natural killer (NK) cells** carry out *immune surveillance*—the detection and subsequent destruction of abnormal cells. NK cells, sometimes known as *large granular lymphocytes*, are important in preventing cancer.

Tips

To remember the various white blood cell populations, think “Never let monkeys eat bananas” for neutrophils, lymphocytes, monocytes, eosinophils, and basophils.

The Differential Count and Changes in WBC Profiles

A variety of conditions, including infection, inflammation, and allergic reactions, cause characteristic changes in circulating populations of WBCs. By examining a stained blood smear, we can obtain a **differential count** of the white blood cell population. The values reported provide a *WBC profile* indicating

the number of each type of cell in a sample of 100 WBCs. The average and normal range of abundance (per μL) for each type of WBC is shown in **Table 19–2**.

The term **leukopenia** ($\text{l}\bar{\text{u}}\text{-k}\bar{\text{o}}\text{-P}\bar{\text{E}}\text{-n}\bar{\text{e}}\text{-uh}$; *penia*, poverty) indicates inadequate numbers of WBCs. **Leukocytosis** ($\text{l}\bar{\text{o}}\text{-k}\bar{\text{o}}\text{-s}\bar{\text{T}}\text{-T}\bar{\text{O}}\text{-sis}$) refers to excessive numbers of WBCs. A modest leukocytosis is normal during an infection. Extreme leukocytosis ($100,000/\mu\text{L}$ or more) generally indicates the presence of some form of **leukemia** ($\text{l}\bar{\text{u}}\text{-K}\bar{\text{E}}\text{-m}\bar{\text{e}}\text{-uh}$), a cancer of the WBCs.

WBC Production: Leukopoiesis

The process of WBC production is called **leukopoiesis** ($\text{l}\bar{\text{u}}\text{-k}\bar{\text{o}}\text{-POY}\text{-eh-sis}$). Stem cells that produce WBCs originate

Table 19–2 Formed Elements of the Blood

Cell	Abundance (average number per μL)	Appearance in a Stained Blood Smear	Functions	Remarks
RED BLOOD CELLS 	5.2 million (range: 4.2–6.3 million)	Flattened, circular cell; no nucleus, mitochondria, or ribosomes; red	Transport oxygen from lungs to tissues and carbon dioxide from tissues to lungs	Remain in bloodstream; 120-day life expectancy; amino acids and iron recycled; produced in red bone marrow
WHITE BLOOD CELLS	7000 (range: 5000–10,000)			
Neutrophils 	4150 (range: 1800–7300) Differential count: 50–70%	Round cell; nucleus lobed and may resemble a string of beads; cytoplasm contains large, pale inclusions	Phagocytic: Engulf pathogens or debris in tissues, release cytotoxic enzymes and chemicals	Move into tissues after several hours; may survive minutes to days, depending on tissue activity; produced in red bone marrow
Eosinophils 	165 (range: 0–700) Differential count: 2–4%	Round cell; nucleus generally in two lobes; cytoplasm contains large granules that generally stain bright red	Phagocytic: Engulf antibody-labeled materials, release cytotoxic enzymes, reduce inflammation; increase in allergic and parasitic situations	Move into tissues after several hours; survive minutes to days, depending on tissue activity; produced in red bone marrow
Basophils 	44 (range: 0–150) Differential count: <1%	Round cell; nucleus generally cannot be seen through dense, blue-stained granules in cytoplasm	Enter damaged tissues and release histamine and other chemicals that promote inflammation	Survival time unknown; assist mast cells of tissues in producing inflammation; produced in red bone marrow
Monocytes 	456 (range: 200–950) Differential count: 2–8%	Very large cell; kidney bean-shaped nucleus; abundant pale cytoplasm	Enter tissues to become macrophages; engulf pathogens or debris	Move into tissues after 1–2 days; survive for months or longer; produced primarily in red bone marrow
Lymphocytes 	2185 (range: 1500–4000) Differential count: 20–40%	Generally round cell, slightly larger than RBC; round nucleus; very little cytoplasm	Cells of lymphatic system, providing defense against specific pathogens or toxins	Survive for months to decades; circulate from blood to tissues and back; produced in red bone marrow and lymphatic tissues
PLATELETS 	350,000 (range: 150,000–500,000)	Round to disc-shaped cytoplasmic fragment; contain enzymes, proenzymes, actin, and myosin; no nucleus	Hemostasis: Clump together and stick to vessel wall (platelet phase); activate intrinsic pathway of coagulation phase	Remain in bloodstream or in vascular organs; remain intact for 7–12 days; produced by megakaryocytes in red bone marrow

in the red bone marrow, with the divisions of hemocytoblasts (**Figure 19-10**). As noted, hemocytoblast divisions produce myeloid stem cells and lymphoid stem cells. Myeloid stem cells divide to create **progenitor cells**, which give rise to all the formed elements except lymphocytes. One type of progenitor cell produces daughter cells that mature into RBCs. A second type produces cells that manufacture platelets. A third type produces daughter cells that develop into neutrophils, eosinophils, basophils, and monocytes.

Granulocytes (basophils, eosinophils, and neutrophils) complete their development in the red bone marrow. These WBCs go through a series of maturational stages, proceeding from *blast cells* to *myelocytes* to *band cells* before becoming mature WBCs. For example, a cell differentiating into a neutrophil goes from a *myeloblast* to a *neutrophilic myelocyte* and then becomes a *neutrophilic band cell*. Some band cells enter the bloodstream before completing their maturation. Normally, 3–5% of all circulating WBCs are band cells.

Monocytes begin to differentiate in the red bone marrow. Then they enter the bloodstream and complete development when they become free macrophages in peripheral tissues.

The process of lymphocyte production is called **lymphocytopoiesis**. Some lymphocytes are derived from lymphoid stem cells that remain in red bone marrow. These lymphocytes differentiate into either B cells or natural killer cells.

Many of the lymphoid stem cells that produce lymphocytes migrate from the red bone marrow to peripheral **lymphatic tissues**, including the thymus, spleen, and lymph nodes. As a result, lymphocytes are produced in these organs as well as in the red bone marrow. Lymphoid stem cells migrating to the thymus mature into T cells.

Regulation of WBC Production

Factors that regulate lymphocyte maturation are incompletely understood. Until adulthood, hormones produced by the thymus promote the differentiation and maintenance of T cell populations. The importance of the thymus in adults, especially with respect to aging, remains unclear. In adults, the production of B and T lymphocytes is regulated primarily by exposure to antigens (foreign proteins, cells, or toxins). When antigens appear, lymphocyte production escalates. (The control mechanisms are described in Chapter 22.)

Several hormones, called **colony-stimulating factors (CSFs)**, are involved in regulating other WBC populations. Each stimulates the formation of WBCs or both WBCs and RBCs. The designation for each factor indicates its target, as shown in the blue ovals in **Figure 19-10**:

- **Multi-CSF**, also known as *interleukin-3 (IL-3)*, accelerates the production of granulocytes, monocytes, platelets, and RBCs.
- **GM-CSF** stimulates the production of both granulocytes and monocytes. **G-CSF** stimulates the production of granulocytes (neutrophils, eosinophils, and basophils).
- **M-CSF** stimulates the production of monocytes.

Chemical communication between lymphocytes and other WBCs helps to coordinate the immune response. For example, active macrophages release chemicals that make lymphocytes more sensitive to antigens and that also accelerate the development of specific immunity. In turn, active lymphocytes release multi-CSF and GM-CSF, reinforcing non-specific defenses.

Immune system hormones are under intensive study because of their potential clinical importance. The molecular structures of many of the stimulating factors have been identified, and several are produced by genetic engineering.

12. Identify the five types of white blood cells.
13. Which type of white blood cell would be expected in the greatest numbers in an infected cut?
14. Which type of cell would be expected in elevated numbers in a person who is producing large amounts of circulating antibodies to combat a virus?
15. How do basophils respond to an injury?

See the blue Answers tab at the back of the book.

19-5 Platelets, disc-shaped cell fragments, function in the clotting process

Learning Outcome Describe the structure, function, and production of platelets.

In a blood smear, **platelets** appear as disc-shaped cell fragments (**Figure 19-10**). They average about 3 μm in diameter and are roughly 1 μm thick. Platelets, or *thrombocytes*, play a major role in a vascular *clotting system* that also includes plasma proteins and the cells and tissues of the blood vessels.

Platelets are continuously replaced. Each platelet circulates for 9–12 days before being removed by phagocytes, mainly in the spleen. Each microliter of circulating blood contains 150,000–500,000 platelets; the average concentration is 350,000/ μL . About one-third of the platelets in the body at any moment are in the spleen and other vascular organs, rather than in the bloodstream. These reserves are mobilized during a circulatory crisis, such as severe bleeding.

Platelet Functions

The functions of platelets include:

- **Releasing Chemicals Important to the Clotting Process.** By releasing enzymes and other factors at the appropriate times, platelets help initiate and control the clotting process.
- **Forming a Temporary Patch in the Walls of Damaged Blood Vessels.** Platelets clump together at an injury site, forming

Figure 19-10 The Origins and Differentiation of Formed Elements. Hemocytoblast divisions give rise to myeloid stem cells or lymphoid stem cells. Myeloid stem cells produce progenitor cells that divide to produce red blood cells, platelets, and white blood cells except for lymphocytes. The targets of erythropoietin (EPO) and the colony-stimulating factors (CSFs) are indicated. Lymphoid stem cells produce the various lymphocytes.

Granulocytes consist of what three types of mature cells and from what blast cell do granulocytes differentiate?

a *platelet plug*, which can slow blood loss while clotting takes place.

- **Reducing the Size of a Break in a Vessel Wall.** Platelets contain filaments of actin and myosin. After a blood clot has formed, platelet filaments contract to shrink the clot and reduce the size of the break in the vessel wall.

Platelet Production

Platelet production, or **thrombocytopoiesis** (throm-bō-sī-tō-POY-eh-sis), takes place in the red bone marrow. Normal red bone marrow contains **megakaryocytes** (meg-ah-KAR-ē-ō-sīts; *mega-*, big + *karyon*, nucleus + *-cyte*, cell), enormous cells (up to 160 μm in diameter) with large nuclei (**Figure 19-10**). During their development and growth, megakaryocytes manufacture structural proteins, enzymes, and membranes. They then begin shedding cytoplasm in small membrane-enclosed packets. These packets are the platelets that enter the bloodstream. A mature megakaryocyte gradually loses all its cytoplasm, producing about 4000 platelets before phagocytes engulf its nucleus for breakdown and recycling.

Three substances influence the rate of megakaryocyte activity and platelet formation. They are (1) *thrombopoietin (TPO)*, or *thrombocyte-stimulating factor*, a peptide hormone produced in the kidneys (and perhaps other sites) that accelerates platelet formation and stimulates the production of megakaryocytes; (2) *interleukin-6 (IL-6)*, a hormone that stimulates platelet formation; and (3) multi-CSF, which stimulates platelet production by promoting megakaryocyte formation and growth.

16. Define thrombocytopoiesis.
17. List the three primary functions of platelets.

See the blue Answers tab at the back of the book.

19-6 The process of blood clotting, or hemostasis, stops blood loss

Learning Outcome Discuss the mechanisms that control blood loss after an injury and describe the reaction sequences responsible for blood clotting.

The process of **hemostasis** (*haima*, blood + *stasis*, halt), the stopping of bleeding, halts the loss of blood through the walls of damaged vessels. At the same time, it establishes a framework for tissue repairs. Hemostasis has three phases: the *vascular phase*, the *platelet phase*, and the *coagulation phase* (**Figure 19-11**). The boundaries of these phases are somewhat arbitrary. Hemostasis is a complex *cascade*, or chain reaction, in which many things happen at once, and all of them interact to some degree. The end of the process is *clot retraction*.

The Vascular Phase

Cutting the wall of a blood vessel triggers a contraction in the smooth muscle fibers of the vessel wall (**Figure 19-11 1**). This local contraction of the vessel is a **vascular spasm**, which decreases the diameter of the vessel at the site of injury. Such a constriction can slow or even stop blood loss through the wall of a small vessel. The vascular spasm lasts about 30 minutes, a period called the **vascular phase** of hemostasis.

During the vascular phase, changes take place in the endothelium of the vessel at the injury site:

- *The Endothelial Cells Contract and Expose the Underlying Basement Membrane to the Bloodstream.*
- *The Endothelial Cells Begin Releasing Chemical Factors and Local Hormones.* Several of these factors, including ADP, *tissue factor*, and *prostacyclin*, are presented later in this section. Endothelial cells also release peptide hormones called **endothelins**. These local hormones (1) stimulate smooth muscle contraction and promote vascular spasms, and (2) stimulate the division of endothelial cells, smooth muscle cells, and fibroblasts to accelerate the repair process.
- *The Endothelial Plasma Membranes Become “Sticky.”* A tear in the wall of a small artery or vein may be partially sealed off by the attachment of endothelial cells on either side of the break. In small capillaries, endothelial cells on opposite sides of the vessel may stick together and prevent blood flow along the damaged vessel. The stickiness is also important because it helps platelets to attach as the platelet phase gets under way.

The Platelet Phase

Platelet attachment to sticky endothelial surfaces, the basement membrane, and exposed collagen fibers marks the start of the **platelet phase** of hemostasis (**Figure 19-11 2**). The attachment of platelets to exposed surfaces is called **platelet adhesion**. As more and more platelets arrive, they begin sticking to one another as well. This process, called **platelet aggregation**, forms a **platelet plug** that may close the break in the vessel wall if the damage is not severe or the vessel is relatively small. Platelet aggregation begins within 15 seconds after an injury occurs.

As platelets arrive at the injury site, they become activated. The first sign of this activation is that the platelets become more spherical and develop cytoplasmic processes that extend toward nearby platelets. At this time, the platelets begin releasing a wide variety of compounds. These compounds include (1) *adenosine diphosphate (ADP)*, which stimulates platelet aggregation and secretion; (2) *thromboxane A₂* and *serotonin*, which stimulate vascular spasms; (3) *clotting factors*, proteins that play a role in blood clotting; (4) *platelet-derived growth factor (PDGF)*, a peptide that promotes vessel repair; and

(5) calcium ions, which are required for platelet aggregation and in several steps in the clotting process.

The platelet phase proceeds quickly, as ADP, thromboxane, and calcium ions released from each arriving platelet stimulate further aggregation. This positive feedback loop ultimately produces a platelet plug that will be reinforced as clotting occurs. However, platelet aggregation must be controlled and restricted to the injury site.

Several key factors limit the growth of the platelet plug: (1) **prostacyclin**, a prostaglandin that inhibits platelet aggregation and is released by endothelial cells; (2) inhibitory compounds released by WBCs entering the area; (3) circulating plasma enzymes that break down ADP near the plug; (4) compounds that, when abundant, inhibit plug formation (for example, serotonin, which at a high concentration blocks the action of ADP); and (5) the development of a blood clot, which reinforces the platelet plug but isolates it from the general circulation.

The Coagulation Phase

The vascular and platelet phases begin within a few seconds after the injury. The **coagulation** (kō-ag-yū-LĀ-shun) **phase**, or **blood clotting**, does not start until 30 seconds or more after the vessel has been damaged. **Figure 19–11 3** shows the sequence of steps involved in the formation and structure of a blood clot.

Clotting Factors

Normal blood clotting depends on the presence of **clotting factors**, or **procoagulants**, in the plasma. Important clotting factors include Ca^{2+} and 11 different proteins (**Table 19–3**).

Many of the clotting proteins are **proenzymes**, or inactive enzymes. When converted to active enzymes, these proteins direct essential reactions in the **clotting response**. During the coagulation phase, enzymes and proenzymes interact successively. The activation of one proenzyme commonly creates an enzyme that activates a second proenzyme, and so on in a cascade.

Figure 19–11 The Phases of Hemostasis (Vascular, Platelet, and Coagulation) and Clot Retraction.

The Coagulation Process

The process of coagulation involves the chain reactions of the *extrinsic*, *intrinsic*, and *common pathways* (Figure 19-11 3). The extrinsic pathway begins outside the bloodstream, in the vessel wall. The intrinsic pathway begins inside the bloodstream, with the activation of a circulating proenzyme. These two pathways converge at the common pathway.

The Extrinsic Pathway. The **extrinsic pathway** begins when damaged endothelial cells or peripheral tissues release **Factor III**, also termed *tissue factor* or *thromboplastin*. The greater the damage, the more tissue factor is released, and the faster clotting takes place. Factor III then combines with Ca^{2+} and another clotting factor (Factor VII) to form an enzyme complex capable of activating Factor X, the first step in the common pathway.

The Intrinsic Pathway. The **intrinsic pathway** begins with the activation of proenzymes (usually Factor XII) ex-

posed to collagen fibers at the injury site (or to a glass surface of a slide or collection tube). This pathway proceeds with the assistance of **PF-3**, a platelet factor released by aggregating platelets. Platelets also release a variety of other factors that accelerate the reactions of the intrinsic pathway. After a series of linked reactions, activated Factors VIII and IX combine to form an enzyme complex capable of activating Factor X.

The Common Pathway. The **common pathway** begins when enzyme complexes from either pathway activate Factor X. Activated Factor X activates a complex called **prothrombin activator**. Prothrombin activator converts the proenzyme prothrombin into the enzyme **thrombin**. Thrombin then completes the clotting process by converting fibrinogen, a soluble plasma protein, to insoluble strands of **fibrin**, producing a **blood clot** (see the SEM in Figure 19-11 3).

3

Coagulation Phase

Coagulation, or blood clotting, involves a complex sequence of steps leading to the conversion of circulating fibrinogen (a soluble protein) into fibrin (an insoluble protein). As the fibrin network grows, blood cells and additional platelets are trapped in the fibrous tangle, forming a **blood clot** that seals off the damaged portion of the vessel.

4

Clot Retraction

Once the fibrin meshwork has formed, platelets and red blood cells stick to the fibrin strands. The platelets then contract, and the entire clot begins to undergo clot retraction, a process that continues over 30–60 minutes.

Table 19–3 Clotting Factors

Factor	Structure	Name	Source	Concentration in Plasma ($\mu\text{g/mL}$)	Pathway
I	Plasma protein	Fibrinogen	Liver	2500–3500	Common
II	Plasma protein	Prothrombin	Liver, requires vitamin K	100	Common
III	Glycoprotein	Tissue factor (TF)	Damaged tissue, activated platelets	0	Extrinsic
IV	Ion	Calcium ions (Ca^{2+})	Bone, diet, platelets	100	Entire process
V	Protein	Pro-accelerin	Liver, platelets	10	Extrinsic and intrinsic
VI	(No longer used)				
VII	Plasma protein	Proconvertin	Liver, requires vitamin K	0.5	Extrinsic
VIII	Plasma protein	Antihemophilic factor (AHF)	Liver, lung endothelial cells	15	Intrinsic
IX	Plasma protein	Plasma thromboplastin component (PTC), Christmas factor	Liver, requires vitamin K	3	Intrinsic
X	Plasma protein	Stuart–Prower factor	Liver, requires vitamin K	10	Extrinsic and intrinsic
XI	Plasma protein	Plasma thromboplastin antecedent (PTA)	Liver	<5	Intrinsic
XII	Plasma protein	Hageman factor	Liver	<5	Intrinsic; also activates plasmin
XIII	Plasma protein	Fibrin-stabilizing factor (FSF)	Liver, platelets	20	Stabilizes fibrin, slows fibrinolysis

Interactions among the Pathways

When a blood vessel is damaged, both the extrinsic and intrinsic pathways respond. The extrinsic pathway is shorter and faster than the intrinsic pathway, and it is usually the first to initiate clotting by the common pathway. In essence, the extrinsic pathway stimulates the common pathway to produce a small amount of thrombin very quickly. This quick patch is reinforced by the intrinsic pathway, which later stimulates the common pathway to produce more thrombin.

Then the activity of the common pathway in turn stimulates both the intrinsic and extrinsic pathways. Thrombin generated in the common pathway stimulates blood clotting by (1) stimulating the formation of tissue factor and (2) stimulating PF-3 release by platelets (**Figure 19–11 3**). This positive feedback loop accelerates the clotting process, and speed can be very important in reducing blood loss after a severe injury.

The time required to complete clot formation varies with the site and the nature of the injury. In tests of the clotting system, blood held in fine glass tubes normally clots in 8–18 minutes (the *coagulation time*). A small puncture wound typically stops bleeding in 1–4 minutes (the *bleeding time*).

Feedback Control of Blood Clotting

Blood clotting is restricted by substances that either deactivate or remove clotting factors and other stimulatory agents from the blood. Examples include the following:

- Normal plasma contains several **anticoagulants**—enzymes that inhibit clotting. One, **antithrombin-III**, inhibits several clotting factors, including thrombin.
- **Heparin**, a compound released by basophils and mast cells, is a cofactor that accelerates the activation of antithrombin-III. Heparin is also used clinically to impede or prevent clotting.
- **Thrombomodulin** is released by endothelial cells. This protein binds to thrombin and converts it to an enzyme that activates protein C. **Protein C** is a plasma protein that inactivates several clotting factors and stimulates the formation of *plasmin*, an enzyme that gradually breaks down fibrin strands.
- Prostacyclin released during the platelet phase inhibits platelet aggregation and opposes the stimulatory action of thrombin, ADP, and other factors.

The clotting process involves a complex chain of events, and disorders that affect any individual clotting factor can disrupt the entire process. For this reason, managing many clinical conditions involves controlling or manipulating the clotting response. Aspirin, for example, is a common drug that interferes with blood clotting and prolongs bleeding time. It inhibits platelets from producing prostaglandins and thromboxane A_2 , which stimulates new platelet activation and aggregation.

Calcium Ions, Vitamin K, and Blood Clotting

Calcium ions and **vitamin K** affect almost every aspect of the clotting process. All three pathways (intrinsic, extrinsic,

Clinical Note Bleeding and Clotting Extremes

In healthy circulation, blood moves relatively freely through smooth blood vessels. Both the composition of the blood and the structure of the vessels must be normal for ideal blood flow.

Bleeding problems occur when the blood lacks platelets, or when clotting proteins are deficient or defective. The most common reason for bleeding is **thrombocytopenia**, a condition in which the platelet count is too low. This may result from drug toxicity, from underlying bone marrow disease, or for unknown reasons. **Hemophilia** is an inherited bleeding disorder in which the blood does not clot properly. It affects more males than females and is characterized by a lack or deficiency of clotting factors. When hemostasis (blood clotting) is activated (for example, due to trauma), the coagulation pathway cannot proceed, and so the fibrin clot cannot form. The person experiences bleeding that may prove fatal depending on the severity of the injury.

Clotting problems are called **thrombophilia**. When clots form in the venous system, the serious condition **deep vein thrombosis (DVT)** can result. These clots can loosen, travel through the circulation, and end up wedged in blood vessels of the lungs, impeding blood oxygenation. This condition, called *pulmonary embolism*, is fatal in 30% of cases.

and common) require Ca^{2+} , so any disorder that lowers the plasma Ca^{2+} concentration will impair blood clotting.

Adequate amounts of vitamin K must be present for the liver to synthesize four of the clotting factors, including prothrombin. Vitamin K is a fat-soluble vitamin, present in green vegetables, grain, and organ meats, that is absorbed with dietary lipids. The diet provides about half of our daily requirements. Bacteria in the large intestine manufacture the other half. A vitamin K deficiency may arise from a diet inadequate in fats or in vitamin K, or a disorder that affects fat digestion and absorption (such as problems with bile production), or

prolonged use of antibiotics that kill normal intestinal bacteria. Vitamin K deficiency will cause the eventual breakdown of the common pathway due to a lack of clotting factors. Ultimately, the deficiency can deactivate the entire clotting system.

Clot Retraction

Clot retraction pulls the torn edges of the vessel closer together (**Figure 19-11 4**). This process reduces residual bleeding and stabilizes the injury site. The process also reduces the size of the damaged area, making it easier for fibroblasts, smooth muscle cells, and endothelial cells to complete repairs.

Fibrinolysis

As the repairs proceed, the clot gradually dissolves in a process called **fibrinolysis** (fī-brih-NOL-uh-sis). The process begins when two enzymes activate the proenzyme **plasminogen** (plaz-MIN-ō-jen). These enzymes are thrombin, produced by the common pathway, and **tissue plasminogen activator (t-PA)**, released by damaged tissues at the site of injury. The activation of plasminogen produces the enzyme **plasmin**, which begins digesting the fibrin strands and eroding the clot.

To perform its vital functions, blood must be kept in motion. On average, an RBC completes two circuits around the cardiovascular system each minute. Blood begins to circulate in the third week of embryonic development and continues throughout life. If the blood supply is cut off, dependent tissues may die in a matter of minutes. In Chapter 20, we examine the structure and function of the heart—the pump that maintains this vital blood flow.

Checkpoint

18. **Decreased megakaryocyte volume would interfere with what body process?**
19. **How could a fat-free diet affect blood clotting?**
20. **Unless chemically treated, whole blood will coagulate in a test tube. This clotting process begins when Factor XII is activated. Which clotting pathway is involved in this process?**

See the blue Answers tab at the back of the book.

19 Chapter Review

Study Outline

An Introduction to Blood and the Cardiovascular System

1. The **cardiovascular system** enables the rapid transport of nutrients, respiratory gases, waste products, and cells within the body.

19-1 Blood, composed of plasma and formed elements, provides transport, regulation, and protective services to the body

2. **Blood** is a specialized fluid connective tissue. Its functions include (1) transporting dissolved gases, nutrients, hormones, and metabolic wastes; (2) regulating the pH and ion composition of interstitial fluids; (3) restricting fluid losses at injury sites; (4) defending the body against toxins and pathogens; and (5) regulating body temperature by absorbing and redistributing heat.
3. Blood contains **plasma** and **formed elements—red blood cells (RBCs), white blood cells (WBCs), and platelets**. The plasma and formed elements make up **whole blood**, which can be **fractionated** for analytical or clinical purposes. (*Spotlight Figure 19-1*)
4. **Hemopoiesis** is the process of blood cell formation. Myeloid and lymphoid stem cells divide to form all types of blood cells. (*Spotlight Figure 19-1*)
5. Whole blood from any region of the body has roughly the same temperature, viscosity, and pH.
6. Plasma accounts for 55% of the volume of blood; roughly 92% of plasma is water. (*Spotlight Figure 19-1*)
7. Plasma differs from interstitial fluid in terms of its oxygen and carbon dioxide levels and the concentrations and types of dissolved proteins.
8. The three major types of plasma proteins are *albumins*, *globulins*, and *fibrinogen*.
9. **Albumins** make up about 60% of plasma proteins. **Globulins** constitute roughly 35% of plasma proteins; they include **antibodies (immunoglobulins)**, which attack foreign proteins and pathogens, and **transport globulins**, which bind ions, hormones, and other compounds. **Fibrinogen** molecules are converted to **fibrin** in the clotting process. **Serum** is plasma without fibrinogen.
10. The liver synthesizes and releases more than 90% of the plasma proteins.

19-2 Red blood cells, formed by erythropoiesis, contain hemoglobin that transports respiratory gases

11. Red blood cells make up slightly less than half of the blood volume and 99.9% of the formed elements. The **hematocrit** value indicates the percentage of red blood cells within whole blood. The percentage of all the formed elements within whole blood is commonly reported as the **packed cell volume (PCV)**. (*Spotlight Figure 19-1; Table 19-1*)
12. Each RBC is a biconcave disc, providing a large surface-to-volume ratio. This shape and a flexible plasma membrane allow RBCs to stack, bend, and flex. (*Figure 19-2*)

- PhysioEx

13. Red blood cells lack most organelles, including mitochondria and nuclei, retaining only the cytoskeleton. They typically degenerate after about 120 days in the bloodstream.
14. Molecules of **hemoglobin (Hb; Hgb)** make up more than 95% of the proteins in RBCs. Hemoglobin is a globular protein formed from two pairs of polypeptide subunits. Each subunit contains a single molecule of **heme**, which also has an iron atom that can reversibly bind an oxygen molecule.
15. **Erythropoiesis**, the formation of red blood cells, occurs only in *red bone marrow (myeloid tissue)*. The process speeds up under stimulation by erythropoietin (EPO or **erythropoiesis-stimulating hormone**). Stages in RBC development include **erythroblasts** and **reticulocytes**. (*Figure 19-4*)
16. Phagocytes recycle RBCs. Damaged RBCs are continuously replaced at a rate of approximately 3 million new RBCs entering the bloodstream per second. They are replaced before they **hemolyze**. (*Figure 19-5*)
17. The components of hemoglobin are individually recycled. The heme is stripped of its iron and converted to **biliverdin**, which is converted to **bilirubin**. If bile ducts of the liver are blocked, bilirubin builds up in skin and eyes, resulting in **jaundice**. (*Figure 19-5*)
18. Iron is recycled by being stored in phagocytic cells or transported through the bloodstream, bound to **transferrin**.

19-3 The ABO and Rh blood groups are based on antigen-antibody responses

19. **Blood type** is determined by the presence or absence of specific **surface antigens (agglutinogens)** in the RBC plasma membranes: antigens **A**, **B**, and **Rh** (or **D**). Antibodies (*agglutinins*) in the plasma will react with RBCs that have different surface antigens. When an antibody meets its specific surface antigen, a **cross-reaction** results. (*Figures 19-6 to Spotlight Figure 19-8*)

19-4 The various types of white blood cells contribute to the body's defenses

20. White blood cells, or **leukocytes**, have nuclei and other organelles. They defend the body against pathogens and remove toxins, wastes, and abnormal or damaged cells.
21. White blood cells are capable of *margination*, amoeboid movement, and **positive chemotaxis**. Some WBCs are also capable of *phagocytosis*.
22. *Granular leukocytes (granulocytes)* are subdivided into **neutrophils**, **eosinophils**, and **basophils**. Fifty to 70% of circulating

WBCs are neutrophils, which are highly mobile phagocytes. The much less common eosinophils are phagocytes attracted to foreign compounds that have reacted with circulating antibodies. The fairly rare basophils migrate to damaged tissues and release *histamine* and *heparin*, aiding the inflammatory response. (Figure 19–9)

23. **Agranular leukocytes (agranulocytes)** include **monocytes** and **lymphocytes**. Monocytes that migrate into peripheral tissues become tissue macrophages. Lymphocytes, the primary cells of the lymphatic system, include **T cells** (which enter peripheral tissues and attack foreign cells directly, or affect the activities of other lymphocytes); **B cells** (which produce antibodies); and **natural killer (NK) cells** (which destroy abnormal cells). (Figure 19–9; Table 19–2)
24. A **differential count** of the WBC population can indicate a variety of disorders. **Leukemia** is indicated by extreme **leukocytosis**—that is, excessive numbers of WBCs. (Table 19–2)
25. Granulocytes and monocytes are produced by myeloid stem cells in the red bone marrow that divide to create **progenitor cells**. Lymphoid stem cells also originate in the red bone marrow, but many migrate to peripheral **lymphatic tissues**. (Figure 19–10)
26. Factors that regulate lymphocyte maturation are not completely understood. Several **colony-stimulating factors (CSFs)** are involved in regulating other WBC populations and in coordinating RBC and WBC production. (Figure 19–10)

19-5 Platelets, disc-shaped cell fragments, function in the clotting process

27. Platelets are disc-shaped cell fragments. They circulate for 9–12 days before being removed by phagocytes. (Figure 19–11)

28. The functions of platelets include (1) releasing chemicals important to the clotting process, (2) forming a temporary patch in the walls of damaged blood vessels, and (3) reducing the size of a break in a vessel wall.
29. During **thrombocytopoiesis**, **megakaryocytes** in the red bone marrow release packets of cytoplasm (platelets) into the circulating blood. The rate of platelet formation is stimulated by thrombopoietin or thrombocyte-stimulating factor, interleukin-6, and multi-CSF.

19-6 The process of blood clotting, or hemostasis, stops blood loss

30. **Hemostasis** halts the loss of blood through the walls of damaged vessels. It consists of three phases: the *vascular phase*, the *platelet phase*, and the *coagulation phase*.
31. The **vascular phase** is a period of local blood vessel constriction, or **vascular spasm**, at the injury site. (Figure 19–11)
32. The **platelet phase** follows as platelets are activated, aggregate at the site, and adhere to the damaged surfaces. (Figure 19–11)
33. The **coagulation phase** occurs as factors released by platelets and endothelial cells interact with **clotting factors** (through the **extrinsic pathway**, the **intrinsic pathway**, or the **common pathway**) to form a **blood clot**. In this reaction sequence, soluble fibrinogen is converted to large, insoluble fibers of fibrin. (Figure 19–11; Table 19–3)
34. During **clot retraction**, platelets contract and pull the torn edges of the damaged vessel closer together. (Figure 19–11)
35. During **fibrinolysis**, the clot gradually dissolves through the action of **plasmin**, the activated form of circulating **plasminogen**.

Review Questions

See the blue Answers tab at the back of the book.

LEVEL 1 Reviewing Facts and Terms

1. Identify the five types of white blood cells in the following photographs,

- (a) _____ (b) _____
 (c) _____ (d) _____
 (e) _____

2. Which type(s) of blood cells is/are used to determine the hematocrit? (a) monocytes and lymphocytes, (b) erythrocytes, (c) neutrophils, (d) basophils and eosinophils.
3. In the blood of an average adult, the total number of RBCs is about _____, and the hemoglobin concentration is about _____. (a) 10 trillion, 0.15 g/dL, (b) 30 billion, 3 g/dL, (c) 5 trillion, 200 g/dL, (d) 25 trillion, 15 g/dL.
4. Plasma contributes approximately _____% of the volume of whole blood, and water accounts for _____% of the plasma volume. (a) 55; 92, (b) 25; 55, (c) 92; 55, (d) 35; 72.
5. Whole blood (a) is acidic, (b) is less cohesive than water, (c) is more resistant to flow than water, (d) has a temperature of about 35°C, (e) has different physical characteristics in veins and arteries.
6. The bright red color of blood is due to (a) oxyhemoglobin, (b) deoxyhemoglobin, (c) ferritin, (d) carbaminohemoglobin, (e) transferrin.
7. The following is a list of some of the stages involved in the process of erythropoiesis.
 (1) normoblast
 (2) red blood cell
 (3) reticulocyte
 (4) basophilic erythroblast
 (5) polychromatophilic erythroblast
 The correct sequence of these phases is
 (a) 4, 5, 1, 3, 2, (b) 1, 2, 3, 4, 5, (c) 5, 4, 3, 2, 1, (d) 3, 1, 4, 5, 2, (e) 2, 5, 3, 1, 4.

8. Stem cells responsible for lymphocytopoiesis are found in **(a)** the thymus and spleen, **(b)** the lymph nodes, **(c)** the red bone marrow, **(d)** all these structures.
9. _____ and _____ are also known as clotting factors I and II.
(a) Tissue factor, calcium ions, **(b)** Fibrinogen, prothrombin, **(c)** Prothrombin, proconvertin, **(d)** Tissue factor, pro-acclerlin.
10. What five major functions are performed by blood?
11. Name the three major types of plasma proteins and identify their functions.
12. Which of the following formed elements of blood are the most abundant of the four? **(a)** monocytes, **(b)** neutrophils, **(c)** lymphocytes, **(d)** basophils.
13. What four characteristics of WBCs are important to their response to tissue invasion or injury?
14. Which three substances influence the rate of platelet formation?
15. Name the three types of lymphocytes and identify their functions.
16. What is the difference between prothrombin and thrombin?
17. What four conditions cause the release of erythropoietin?
18. What contribution from the intrinsic and the extrinsic pathways is necessary for the common pathway to begin?

LEVEL 2 Reviewing Concepts

19. Dehydration would **(a)** cause an increase in the hematocrit, **(b)** cause a decrease in the hematocrit, **(c)** have no effect on the hematocrit, **(d)** cause an increase in plasma volume.
20. Erythropoietin directly stimulates RBC formation by **(a)** increasing rates of mitotic divisions in erythroblasts, **(b)** speeding up the maturation of red blood cells, **(c)** accelerating the rate of hemoglobin synthesis, **(d)** all of these.
21. Urine is yellow due to the presence of **(a)** hemoglobin, **(b)** biliverdin, **(c)** stercobilins, **(d)** bilirubin, **(e)** urobilins.
22. A difference between the A, B, and O blood types and the Rh factor is **(a)** Rh agglutinogens are not found on the surface of red blood cells, **(b)** Rh agglutinogens do not produce a cross-reaction, **(c)** individuals who are Rh⁻ do not carry agglutinins to Rh factor unless they have been previously sensitized, **(d)** Rh agglutinogens are found free in the plasma, **(e)** Rh agglutinogens are found bound to plasma proteins.
23. What factors determine whether myeloid stem cells develop into RBCs or WBCs?
24. How do elements of blood defend against toxins and pathogens in the body?
25. What is the reason that blood is more viscous than water?
26. What can be the consequences of having too little or too much iron in the body?
27. Name a method to prevent blood clotting in test tubes after blood sampling.

LEVEL 3 Critical Thinking and Clinical Applications

28. A test for prothrombin time is used to identify deficiencies in the extrinsic clotting pathway; prothrombin time is prolonged if any of the factors are deficient. A test for activated partial thromboplastin time is used in a similar fashion to detect deficiencies in the intrinsic clotting pathway. Which factor would be deficient if a person had a prolonged prothrombin time but a normal partial thromboplastin time?
29. In the disease mononucleosis ("mono"), the spleen enlarges because of increased numbers of phagocytes and other cells. Common signs and symptoms of this disease include pale complexion, a tired feeling, and a lack of energy sometimes to the point of not being able to get out of bed. What might cause these signs and symptoms?
30. Almost half of our vitamin K is synthesized by bacteria that inhabit the large intestine. Based on this information, how could taking a broad-spectrum antibiotic for a long time cause frequent nosebleeds?
31. Kolja often feels tired. He looks pale and is quite sensitive to cold. A blood test shows severe anemia, iron shortage, and low MCV. What is the relation between the two observations?

CLINICAL CASE Wrap-Up Crisis in the Blood

Clare knows what her blood test will show. Instead of looking like tiny, double-dimpled discs, many of her red blood cells look sharp and crescent shaped like the "sickles" for which they are named. Inside her red blood cells, the hemoglobin molecule has a malformation in the globular protein subunit called the beta chain. The quaternary structure of the molecule is disrupted and causes the distorted shape of the red blood cell. Clare has **sickle cell disease (SCD)**.

In **SCD**, two copies of a gene called hemoglobin-S are inherited, one from each parent. The gene mutation

Sickling in red blood cells

for SCD evolved in Africa, where the sickle shape prevented the malarial parasite from continuing its life cycle in the blood, and so conferred a survival advantage against malaria. Anemia frequently accompanies SCD because sickled red blood cells live only 10–20 days (as compared to 120 days for normal RBCs) and the red bone marrow is not able to keep up with their replacement.

Clare's trip to the hospital was brought on by a sickle cell crisis. The crisis occurred in the large bones of her leg, the tibia and fibula.

1. Why is Clare in such pain?
2. Why must she be careful to stay hydrated?

See the blue Answers tab at the back of the book.

Related Clinical Terms

arterial stick: The taking of a blood sample from an artery rather than a vein. It is usually more painful due to arteries being deeper, having more nerves, and having thicker walls.

blood bank: Place where blood is collected, typed, separated into components, stored, and prepared for transfusion to recipients.

bone marrow biopsy: The removal of a small piece of bone marrow for laboratory analysis, to diagnose and stage some forms of cancer, to diagnose other blood disorders, to find the source of unexplained fever, or to diagnose fibrosis of bone marrow or myeloma, a tumor composed of cells normally found in the bone marrow.

disseminated intravascular coagulation: A serious disorder in which the proteins that control blood clotting become abnormally active, causing small blood clots to form, which can prevent blood from reaching vital organs.

dyscrasia: An abnormal condition, especially of the blood.

ecchymosis: Skin discoloration caused by the escape of blood into tissues from ruptured blood vessels.

embolism: A condition in which a drifting blood clot (an embolus) becomes stuck in a blood vessel, blocking circulation to the area downstream.

hematology: The science concerned with the medical study of blood and blood-producing organs.

hemochromatosis: A rare metabolic disorder wherein the skin has a bronze coloration; accompanied by cirrhosis and severe diabetes mellitus; caused by the deposit of the iron-protein complex hemosiderin in tissues.

hemophilia: Inherited disorders characterized by the inadequate production of clotting factors.

hemopoietic growth factor: A group of proteins that cause blood cells to grow and mature.

hemosiderosis: An increase in tissue iron stores without any associated damage.

hypervolemic: Having an excessive blood volume.

hypovolemic: Having a low blood volume.

iron overload: Pathology in which iron accumulates in the tissues; characterized by bronzed skin, enlarged liver, diabetes mellitus, and abnormalities of the pancreas.

myeloproliferative disorder: A group of slow-growing blood cancers, including chronic myelogenous leukemia, characterized by large numbers of abnormal RBCs, WBCs, or platelets growing and spreading in the bone marrow and the peripheral blood.

normovolemic: Referring to a normal blood volume.

phlebotomist: Medical technician who extracts blood by venipuncture for treatment or for laboratory analysis.

plaque: An abnormal accumulation of large quantities of lipids within a blood vessel wall.

plasmapheresis: A procedure consisting of the removal of blood from a person, separating the blood cells from plasma, and returning these blood cells to the person's circulation, diluted with fresh plasma or a substitute. Used to treat autoimmune disorders.

Schilling test: The test to determine whether the body absorbs vitamin B₁₂ normally.

septicemia: Systemic toxic illness due to bacterial invasion of the bloodstream from a local infection. Signs and symptoms include chills, fever, and exhaustion. The disorder is treated with massive doses of antibiotics. Also known as *blood poisoning*.

thrombolytic: An agent that causes the breakup of a thrombus (clot).

thrombus: A blood clot attached to the luminal (inner) surface of a blood vessel.

20

The Heart

Learning Outcomes

These Learning Outcomes correspond by number to this chapter's sections and indicate what you should be able to do after completing the chapter.

- 20-1 ■ Describe the anatomy of the heart, including vascular supply and pericardium structure, and trace the flow of blood through the heart, identifying the major blood vessels, chambers, and heart valves.
- 20-2 ■ Explain the events of an action potential in cardiac muscle, indicate the importance of calcium ions to the contractile process, describe the conducting system of the heart, and identify the electrical events associated with a normal electrocardiogram.
- 20-3 ■ Explain the events of the cardiac cycle, including atrial and ventricular systole and diastole, and relate the heart sounds to specific events in the cycle.
- 20-4 ■ Define cardiac output, describe the factors that influence heart rate and stroke volume, and explain how adjustments in stroke volume and cardiac output are coordinated at different levels of physical activity.

CLINICAL CASE

A Needle to the Chest

It has been a slow night in the emergency room. Dr. Jim is reading an emergency medicine journal and nodding off. He perks up when he hears the speakerphone crackle.

“We have a male, mid-40s, driver of a vehicle involved in a head-on collision with a truck,” reports an EMT. “He was unconscious at the scene, but is now semi-alert, complaining of severe chest pain. His respirations are 30 and shallow. His blood pressure is 80/58. Pulse 130. Carotid pulses in the neck are present, but barely palpable (able to be felt). He has massive jugular venous distension (the veins in his neck are backed up with blood). The seat belt was broken and he has a steering wheel contusion on his anterior chest.”

Dr. Jim instructs the EMTs to take the victim directly into Trauma Room 1. The patient is loaded supine on the trauma cart, and Dr. Jim quickly introduces himself to the barely conscious man. A chest x-ray shows a fractured sternum and several fractured ribs, but the heart shadow (outline on the x-ray) appears normal. The heart sounds are distant and muffled through a stethoscope. After a rapid bedside ultra-

sound, Dr. Jim puts on sterile gloves, does a skin prep of the patient's anterior chest, and sticks a large-bore needle with a 100-mL syringe attached into the man's subxiphoid space, directing the needle toward his left shoulder. The syringe fills with dark blood twice. **What is Dr. Jim doing? To find out, turn to the Clinical Case Wrap-Up at the end of the chapter.**

An Introduction to the Heart as Part of the Cardiovascular System

The *heart*, along with the *blood* and *blood vessels*, is part of the cardiovascular system, as introduced in Chapter 19. This system functions to distribute oxygen and nutrients to the cells of the body, and to take away carbon dioxide and other wastes.

In this chapter we consider the structure and function of the heart, a small organ about the size of a person's clenched fist. This extraordinary organ beats approximately 100,000 times each day. Each day the heart pumps about 2000 gallons—or just over 9000 liters—of blood. Let's begin with the structure of this organ, and then move on to its function.

20-1 The heart is a four-chambered organ that pumps blood through the pulmonary and systemic circuits

Learning Outcome Describe the anatomy of the heart, including vascular supply and pericardium structure, and trace the flow of blood through the heart, identifying the major blood vessels, chambers, and heart valves.

The heart is a hollow muscular organ that pumps oxygen-poor blood to the lungs within the *pulmonary circuit* and oxygen-rich blood to the rest of the body within the *systemic circuit*. The pulmonary circuit carries oxygen-poor blood from the heart's lower right chamber (right ventricle), through the pulmonary arteries, to the lungs, and oxygen-rich blood back through the pulmonary veins to the heart's upper left chamber (left atrium). The systemic circuit carries oxygen-rich blood from the heart's lower left chamber (left ventricle), through the systemic arteries, and oxygen-poor blood through systemic veins back to the heart's upper right chamber (right atrium). Let's start with an overview of heart function.

Overview of Heart Function: The Pulmonary and Systemic Circuits

In the cardiovascular system, blood flows through a network of blood vessels that extend between the heart and peripheral tissues. Those blood vessels make up a **pulmonary circuit**, which carries blood to and from the gas exchange surfaces of the lungs, and a **systemic circuit**, which transports blood to and from the rest of the body (**Figure 20-1**). Each circuit begins and ends at the heart, and blood travels through these circuits in sequence. Thus, blood returning to the heart from the systemic circuit must complete the pulmonary circuit before reentering the systemic circuit.

The blood vessels of both circuits include arteries, capillaries, and veins. *Arteries* carry blood away from the heart, and *veins* return blood to the heart. The *great vessels* are the largest veins and arteries in the body, those connected to the heart. Microscopic thin-walled vessels called *capillaries* interconnect the smallest arteries and the smallest veins. Capillaries are called *exchange vessels*, because their thin walls permit the exchange of nutrients, dissolved gases (called *gas exchange*), and wastes between the blood and surrounding tissues.

The **heart** has four muscular chambers, two associated with each circuit—in essence, the heart is two side-by-side pumps. The *right atrium* (Ā-trē-um; entry chamber; plural, *atria*) receives blood from the systemic circuit and passes it to the *right ventricle* (VEN-tri-kul; little belly), which then pumps blood into the pulmonary circuit. The *left atrium* collects blood from the pulmonary circuit and empties it into the *left ventricle*, which pumps blood into the systemic circuit. When the heart beats, first the atria contract, and then the ventricles contract. The two ventricles contract at the same time and eject equal volumes of blood into the pulmonary and systemic circuits.

Figure 20-1 An Overview of the Cardiovascular System. Driven by the pumping of the heart, blood flows through the pulmonary and systemic circuits in sequence. Each circuit begins and ends at the heart and contains arteries, capillaries, and veins.

20

?

The _____ side of the heart supplies blood to the systemic circuit, while the _____ side of the heart supplies blood to the pulmonary circuit.

Heart Location and Position

The heart is in the thoracic cavity near the anterior chest wall, directly posterior to the sternum (**Figure 20-2**). The great vessels, both veins and arteries, are connected to the superior end of the heart at its base. The **base** sits posterior to the sternum at the level of the third costal cartilage, centered about 1.2 cm (0.5 in.) to the left side (**Figure 20-3**). The inferior pointed tip of the heart is the **apex** (Ā-peks). Standard measurements for determining heart size consider age, height, weight, and sex. A midsagittal section through the trunk does not divide the heart into two equal halves. Note that the center of the base lies slightly to the left of the midline.

The heart sits in the anterior portion of the **mediastinum**, the region between the two pleural cavities. The mediastinum contains the great vessels, which are attached at the base of the heart, as well as the thymus, esophagus, and trachea. **Figure 20-2b** is a superior view that shows the position of the heart relative to other structures in the mediastinum.

Heart Superficial Anatomy, Heart Wall, and Cardiac Skeleton

The walls of the heart, from deep to superficial, are the *endocardium* (inner layer whose simple squamous epithelium is continuous with the endothelial lining of blood vessels), *myocardium* (spiral bundles of cardiac muscle cells), and *pericardium* (fibrous pericardium and serous pericardium that protect, anchor, and prevent overfilling). The two-layered serous pericardium is made up of a parietal layer and a visceral layer (epicardium). These layers are separated by a fluid-filled pericardial cavity. Another structure, the *cardiac skeleton*, is a crisscrossing, interlacing layer of dense connective tissue that anchors muscle fibers, supports the great vessels and heart valves, and limits the spread of action potentials. Our discussion begins with the pericardium.

Outer Covering of the Heart: The Pericardium

The **pericardium** (pehr-ih-KAR-dē-um) surrounds the heart and consists of an outer *fibrous pericardium* and an inner *serous pericardium*. The fibrous pericardium contains a dense network of collagen fibers that stabilize the position of the heart and associated vessels within the mediastinum.

The inner **serous pericardium** is a two-layered membrane composed of an outer **parietal layer** and an inner **visceral layer**. The visceral layer is also known as the *epicardium*. The potential, fluid-filled space between these two serous layers is the **pericardial cavity**.

The pericardial cavity normally contains 15–50 mL of **pericardial fluid**, secreted by the pericardial membranes. This fluid acts as a lubricant, reducing friction between the opposing visceral and parietal surfaces as the heart beats. To visualize

Figure 20-2 The Location of the Heart in the Thoracic Cavity.

b A superior view of the organs in the mediastinum; portions of the lungs have been removed to reveal blood vessels and airways. The heart is located in the anterior part of the mediastinum, immediately posterior to the sternum.

c The relationship between the heart and the pericardial cavity; compare with the fist-and-balloon example.

Figure 20–3 The Position and Superficial Anatomy of the Heart.

the relationship between the heart and the pericardial cavity, imagine pushing your fist toward the center of a large, partially inflated balloon. The balloon represents the pericardium, and your fist is the heart. The base of the heart corresponds to your wrist area where the balloon folds back on itself (**Figure 20–2c**).

Pathogens can infect the pericardium, producing inflammation and the condition **pericarditis**. The inflamed pericardial surfaces rub against one another, making a distinctive

scratching sound (called a *friction rub*) that can be heard through an instrument called a *stethoscope* that is placed on the chest. The pericardial inflammation also commonly results in increased production of pericardial fluid. Fluid then collects in the pericardial cavity, restricting the movement of the heart. This condition, called **cardiac tamponade** (tam-pō-NĀD; *tampon*, plug), can also result from traumatic injuries (such as stab wounds) that produce bleeding into the pericardial cavity.

Superficial Anatomy of the Heart

The four chambers of the heart can be identified in a superficial view (**Figure 20-3**). The two atria have relatively thin muscular walls and are highly expandable. When not filled with blood, the outer portion of each atrium deflates and becomes a lumpy, wrinkled flap. This expandable extension of an atrium is called an **auricle** (AW-rih-kul; *auris*, ear), because it reminded early anatomists of the external ear (**Figure 20-3b**). Clinicians refer to it as an *atrial appendage*.

The **coronary sulcus**, a deep groove, marks the border between the atria and the ventricles. The **anterior interventricular sulcus** and the **posterior interventricular sulcus** are shallower depressions that mark the boundary between the left and right ventricles (**Figure 20-3b,c,d**). Substantial amounts of fat generally lie in the coronary and interventricular sulci. In fresh or preserved hearts, this fat must be stripped away to expose the underlying grooves. These sulci also contain the arteries and veins that carry blood to and from the cardiac muscle.

The Heart Wall

A section through the wall of the heart reveals three distinct layers: the outer epicardium, a middle myocardium, and an inner

endocardium (**Figure 20-4a**). The details of these three layers, from superficial to deep, are covered in the following list.

1. The **visceral layer of serous pericardium (epicardium)** covers the surface of the heart. This serous membrane consists of an exposed mesothelium and an underlying layer of areolar connective tissue that is attached to the myocardium. The **parietal layer of serous pericardium** consists of an outer dense fibrous layer, an areolar layer, and an inner mesothelium.
2. The **myocardium** is cardiac muscle tissue that forms the atria and ventricles. This muscular layer contains cardiac muscle cells, connective tissues, blood vessels, and nerves. The atrial myocardium contains muscle bundles that wrap around the atria and form figure eights that encircle the great vessels (**Figure 20-4b**). Superficial ventricular muscles wrap around both ventricles, and deeper muscle layers spiral around and between the ventricles toward the apex in a figure-eight pattern.
3. The **endocardium** covers the inner surfaces of the heart, including those of the heart valves. It is made up of a simple squamous epithelium and underlying areolar tissue. This simple squamous epithelium, or endothelium, is continuous with the endothelium of the attached great vessels.

Figure 20-4 The Heart Wall.

Connective Tissues and the Cardiac Skeleton

The connective tissues of the heart include large numbers of collagen and elastic fibers. Each cardiac muscle cell is wrapped in a strong, but elastic, sheath. Adjacent cells are tied together by fibrous cross-links, or “struts.” These fibers are, in turn, interwoven into sheets that separate the superficial and deep muscle layers. The connective tissue fibers (1) provide physical support for the cardiac muscle fibers, blood vessels, and nerves of the myocardium; (2) help distribute the forces of contraction; (3) add strength and prevent overexpansion of the heart; and (4) provide elasticity that helps return the heart to its original size and shape after a contraction.

The **cardiac skeleton** (sometimes called the *fibrous skeleton*) of the heart consists of four dense bands of tough elastic tissue that encircle the heart valves and the bases of the pulmonary trunk and aorta. These bands stabilize the positions of the heart valves and ventricular muscle cells. They also electrically insulate the ventricular cells from the atrial cells.

Heart Chambers, Valves, and Great Vessels

Next let’s examine the major landmarks and structures visible on the interior surface of the heart. In a sectional view, one can see that the right atrium communicates with the right ventricle, and the left atrium with the left ventricle (**Figure 20–5a,c**). The chambers of the heart are separated by muscular partitions called *septa* (singular *septum*, wall). The atria are separated by the **interatrial septum**, and the ventricles are separated by the much thicker **interventricular septum**. The heart also has *valves*, covered openings that direct the flow of blood between chambers and vessels. The cardiac skeleton stabilizes the positions of these valves. The two **atrioventricular (AV) valves** (tricuspid and mitral) are folds of fibrous tissue that extend into the openings between the atria and ventricles. These valves permit blood to flow only in one direction: from the atria to the ventricles. There are also two **semilunar valves** (pulmonary and aortic) between the ventricles and their great vessels, which ensure blood flows into these vessels.

The Vena Cavae, Right Atrium, and Tricuspid Valve

The **right atrium** receives blood from the systemic circuit through the two great veins: the **superior vena cava** (VĒ-nuh KĀ-vuh; *venae cavae*, plural) and the **inferior vena cava**. The superior vena cava opens into the posterior and superior portion of the right atrium. It delivers blood to the right atrium from the head, neck, upper limbs, and chest. The inferior vena cava opens into the posterior and inferior portion of the right atrium. It carries blood to the right atrium from the rest of the trunk, the viscera, and the lower limbs. Note there are no valves between the venae cavae and the right atrium.

From the fifth week of embryonic development until birth, an oval opening called the **foramen ovale** penetrates the interatrial septum and connects the two atria of the fetal heart. Before birth, the foramen ovale permits blood to flow from the right atrium to the left atrium while the lungs are developing. At birth, the foramen ovale closes, and the opening is permanently sealed off within 3 months of delivery. (If the foramen ovale does not close, serious cardiovascular problems may result. We consider these in Chapter 21.) A small, shallow depression called the **fossa ovalis** remains at this site in the adult heart (**Figure 20–5a**).

The posterior walls of the right atrium and the interatrial septum have smooth surfaces. In contrast, the anterior atrial wall and the inner surface of the auricle contain prominent muscular ridges called the **pectinate muscles** (*pectin*, comb) (**Figure 20–5a**).

Blood travels from the right atrium into the right ventricle through a broad opening bordered by three fibrous flaps. These flaps, called **cusps**, are part of the **tricuspid** (trĪ-KUS-pid; *tri*, three) **valve**, also known as the *right atrioventricular (AV) valve*. The free edge of each cusp is attached to connective tissue fibers called the **chordae tendineae** (KOR-dĒ TEN-dih-nĒ-Ē; *tendinous cords*). The fibers originate at the **papillary** (PAP-ih-lehr-Ē) **muscles**, conical muscular projections that arise from the inner surface of the right ventricle (**Figure 20–5b,c**).

Tips

The saying “To tug on your heartstrings” may help you remember the functions of the papillary muscles and the chordae tendineae: Contractions of the papillary muscles pull on the chordae tendineae, which “tug” on your heart’s valves.

The Right Ventricle, Pulmonary Valve, and Pulmonary Trunk

The internal surface of the **right ventricle** contains a series of muscular ridges: the **trabeculae carneae** (trah-BEK-yū-lĒ KAR-nĒ-Ē; *carneus*, fleshy). The *moderator band* is a muscular ridge that extends horizontally from the inferior portion of the interventricular septum and connects to the anterior papillary muscle. The moderator band delivers the stimulus for contraction to the papillary muscles. As a result, they begin tensing the chordae tendineae before the rest of the ventricle contracts.

The superior end of the right ventricle tapers to the **conus arteriosus**, a cone-shaped pouch that ends at the **pulmonary valve**, or *pulmonary semilunar valve*. The pulmonary valve consists of three semilunar (half-moon shaped) cusps of thick connective tissue. Blood flowing from the right ventricle passes through this valve into the **pulmonary trunk**, the start of the pulmonary circuit. Once in the pulmonary trunk, blood flows into the **left pulmonary arteries** and the **right pulmonary arteries**. These vessels branch repeatedly within the lungs before supplying the capillaries, where gas exchange occurs.

Figure 20–5 The Sectional Anatomy of the Heart.

Beginning with the right atrium, what is the order of the valves through which blood will pass?

The Pulmonary Veins, Left Atrium, and Mitral Valve

From the respiratory capillaries, blood collects into small veins that ultimately unite to form the four pulmonary veins. The posterior wall of the **left atrium** receives blood from two **left** and two **right pulmonary veins**. There is no valve between the pulmonary veins and the left atrium. Like the right atrium, however, the left atrium has an auricle.

The **mitral** (MĪ-tral) **valve** guards the entrance to the left ventricle (**Figure 20-5a,c**). This valve is also called the *left atrio-ventricular* (AV) *valve* and the *bicuspid valve*. As the name *bicuspid* implies, the left AV valve contains two cusps. The mitral valve allows blood to flow from the left atrium into the left ventricle.

Tips

To remember the locations of the tricuspid and bicuspid (mitral) valves, think “**try** to be **right**” for the **tricuspid**, and associate the **I** in mitral with the **I** in left.

The Left Ventricle, Aortic Valve, and Ascending Aorta

The internal organization of the **left ventricle** resembles that of the right ventricle, but it has no moderator band (**Figure 20-5a**). The trabeculae carneae are prominent. A pair of large papillary muscles tenses the chordae tendineae that anchor the cusps of the mitral valve and prevent blood from flowing back into the left atrium.

Blood leaves the left ventricle through the **aortic valve**, or *aortic semilunar valve*, and enters the **ascending aorta**. The arrangement of cusps in the aortic valve is the same as that in the pulmonary valve. Adjacent to each cusp of the aortic valve are saclike expansions of the base of the ascending aorta called **aortic sinuses**. From the ascending aorta, blood flows through the **aortic arch** and into the **descending aorta** (**Figure 20-5a**). The pulmonary trunk is attached to the aortic arch by the *ligamentum arteriosum*, a fibrous band left over from an important fetal blood vessel that once linked the pulmonary and systemic circuits.

Structural and Functional Differences between the Left and Right Ventricles

The function of the atria is to collect blood that is returning to the heart and to convey it to the ventricles. The demands on the right and left atria are similar, and the two chambers look almost identical. The demands on the right and left ventricles, however, are very different, and the two have significant structural differences. Even though the two ventricles hold and pump equal amounts of blood, the left ventricle is much larger than the right ventricle due to its thicker, muscular walls. Such muscular walls enable the left ventricle to push blood through the body's extensive systemic circuit. In contrast, the right ventricle pumps blood only about 15 cm (6 in.) to the lungs, which can occur at lower pressure.

Anatomical differences between the left and right ventricles are easiest to see in a three-dimensional view (**Figure 20-6a**). The lungs are close to the heart, and the pulmonary blood vessels are relatively short and wide. For these reasons, the right ventricle normally does not need to work very hard to push blood through the pulmonary circuit. Accordingly, the muscular wall of the right ventricle is relatively thin. In sectional view, it resembles a pouch attached to the massive wall of the left ventricle. When the right ventricle contracts, it acts like a bellows, squeezing the blood against the thick wall of the left ventricle. This action moves blood very efficiently with minimal effort, but it develops relatively low pressures.

A comparable pumping arrangement would not work well for the left ventricle. Four to six times as much pressure must be exerted to push through the systemic circuit as through the pulmonary circuit. The left ventricle has an extremely thick muscular wall

Figure 20-6 Structural Differences between the Left and Right Ventricles.

a A diagrammatic sectional view through the heart, showing the relative thicknesses of the two ventricular walls. Note the pouchlike shape of the right ventricle and the greater thickness of the left ventricular muscle.

b Diagrammatic views of the ventricles just before a contraction (dilated) and just after a contraction (contracted).

and is round in cross section (**Figure 20-6a**). When this ventricle contracts, it shortens and narrows. In other words, (1) the distance between the base and apex decreases, and (2) the diameter of the ventricular chamber decreases. The effect is like simultaneously squeezing and rolling up the end of a toothpaste tube. The pressure generated is more than enough to open the aortic valve and eject blood into the ascending aorta.

As the powerful left ventricle contracts, it bulges into the right ventricular cavity (**Figure 20-6b**). This action increases the pumping efficiency of the right ventricle. Individuals with severe damage to the right ventricle may survive because the contraction of the left ventricle helps push blood into the pulmonary circuit. We return to this topic in Chapter 21, where we consider the integrated functioning of the cardiovascular system.

Blood Flow through the Heart Valves

As previously noted, the heart has two pairs of one-way valves. These valves prevent the backflow of blood as the chambers contract. Let's look at the function of these heart valves, and the path of blood flow through each half of the heart.

The AV Valves: Atria to Ventricles

The atrioventricular (AV) valves prevent the backflow of blood from the ventricles to the atria when the ventricles are contracting. The chordae tendineae and papillary muscles play important roles in the normal function of the AV valves. When the ventricles are relaxed, the chordae tendineae are loose, and the AV valves offer no resistance as blood flows from the atria into the ventricles (**Figure 20-7a**). When the ventricles contract, blood moving back toward the atria swings the cusps together, closing the valves (**Figure 20-7b**). At the same time, the contraction of the papillary muscles tenses the chordae tendineae, stopping the cusps before they swing into the atria. If the chordae tendineae were cut or the papillary muscles were damaged, backflow, called **regurgitation**, of blood into the atria would occur each time the ventricles contracted.

Clinical Note Faulty Heart Valves

Each of the four heart valves must open and close crisply and precisely to permit the proper flow of blood through the heart.

The most common valve to falter is the mitral valve. One reason for mitral malfunction is an untreated bacterial or viral infection that infiltrates the valve cusps. The cusps become inflamed and later scar, resulting in a faulty valve.

A valve can malfunction in one of three ways: (1) It can become rigid (a *stenotic* valve) so that it does not open fully, (2) it can fail to close properly (a *regurgitant* valve), or (3) it can flop backwards (a *prolapsed* valve). Faulty valves are heard as *heart murmurs* with a stethoscope.

The Semilunar Valves: Ventricles to Great Vessels

The pulmonary and aortic semilunar valves prevent the backflow of blood from the pulmonary trunk and aorta into the right and left ventricles, respectively. Unlike the AV valves, the semilunar valves do not need muscular braces, because the arterial walls do not contract and the relative positions of the cusps are stable. When the semilunar valves close, the three symmetrical cusps support one another like the legs of a tripod (**Figure 20-7a**). When the aortic valve opens, the aortic sinuses prevent the individual cusps from sticking to the wall of the aorta (**Figure 20-7b**).

Serious valve problems can interfere with the working of the heart. If valve function deteriorates to the point at which the heart cannot maintain adequate circulatory flow, symptoms of **valvular heart disease (VHD)** appear. Congenital malformations may be responsible, but in many cases the condition develops after **carditis**, an inflammation of the heart, occurs. One important cause of carditis is **rheumatic** (rū-MAT-ik) **fever**, an inflammatory autoimmune response to an infection by streptococcal bacteria. It most often occurs in children.

The Blood Supply to the Heart

The heart works continuously, so cardiac muscle cells need reliable supplies of oxygen and nutrients. A great volume of blood flows through the chambers of the heart, but the myocardium has its own, separate blood supply. The **coronary circulation** supplies blood to the muscle tissue of the heart. During maximum exertion, the heart's demand for oxygen rises considerably. The blood flow to the myocardium may then increase to nine times that of the resting level. The coronary circulation includes an extensive network of coronary blood vessels, both arteries and veins (**Figure 20-8**).

The Coronary Arteries

The left and right **coronary arteries** originate at the base of the ascending aorta, at the aortic sinuses (**Figure 20-8a**). Blood pressure here is the highest in the systemic circuit. When the left ventricle contracts and forces blood into the aorta, the high pressure of this blood stretches the elastic walls of the aorta. When the left ventricle relaxes, blood no longer flows into the aorta, pressure declines, and the walls of the aorta recoil. This recoil, called *elastic rebound*, pushes blood both forward, into the systemic circuit, and backward, through the left and right aortic sinuses and then into the respective coronary arteries. In this way, the combination of elevated blood pressure and elastic rebound ensures a continuous flow of blood to meet the demands of active cardiac muscle tissue.

The *right* and *left coronary arteries*, which deliver blood to the myocardium, originate at the right and left aortic sinuses. The **right coronary artery** follows the coronary sulcus around the heart (**Figure 20-8**). It supplies blood to (1) the right atrium, (2) portions of both ventricles, and (3) portions of the electrical

Figure 20–7 Valves of the Heart and Blood Flow. Red (oxygenated) and blue (deoxygenated) arrows indicate blood flow into or out of a ventricle, smaller red arrows show blood flow into an atrium, and green arrows indicate contraction of the ventricles.

Figure 20–8 The Coronary Circulation.

conducting system of the heart. Inferior to the right atrium, the right coronary artery generally gives rise to one or more **marginal arteries**, which extend across the surface of the right ventricle. The right coronary artery then continues across the posterior surface of the heart. It supplies the **posterior interventricular artery**, or *posterior descending artery*, which runs toward the apex within the posterior interventricular sulcus. The posterior interventricular artery supplies blood to the interventricular septum and adjacent portions of the ventricles.

The **left coronary artery** supplies blood to the left ventricle, left atrium, and interventricular septum (**Figure 20–8**). As it reaches the anterior surface of the heart, it gives rise to a circumflex branch and an anterior interventricular branch. The **circumflex artery** curves to the left around the coronary sulcus. It eventually meets and fuses with small branches of the right coronary artery.

The much larger **anterior interventricular artery**, also called the *left anterior descending artery* (LAD), swings around the pulmonary trunk and runs along the surface within the anterior interventricular sulcus. The anterior interventricular artery supplies small tributaries continuous with those of the posterior interventricular artery. Such interconnections between arteries are called **arterial anastomoses** (ah-nas-tō-MŌ-sēz; *anastomosis*, outlet). Because the arteries are interconnected in this way, the blood supply to the cardiac muscle remains relatively constant despite pressure fluctuations in the left and right coronary arteries as the heart beats.

Coronary artery disease is characterized by interrupted blood flow to the myocardium. **Spotlight Figure 20–9** describes this condition, along with myocardial infarction.

The Cardiac Veins

The various cardiac veins are also shown in **Figure 20–8**. The **great cardiac vein** begins on the anterior surface of the

Coronary Artery Disease

HEART DISEASE

Coronary artery disease (CAD) is the buildup of plaque causing partial or complete blockage of the coronary circulation. Cardiac muscle cells need a constant supply of oxygen and nutrients, so any reduction in blood flow to the heart muscle produces a corresponding reduction in cardiac performance. Reduced blood flow leads to inadequate heart tissue perfusion, a condition called **coronary ischemia** (iss-KĒ-mē-uh). The usual cause is the formation of a fatty deposit, or *atherosclerotic plaque*, in the wall of a coronary vessel. The plaque, or an associated *thrombus* (clot), then narrows the passageway and reduces blood flow. Spasms in the smooth muscles of the vessel wall can further decrease or even stop blood flow. One of the first symptoms of CAD is commonly **angina pectoris** (an-JĪ-nuh PEK-tor-is; *angina*, pain + *pectoris*, of the chest). In its most common form, a temporary ischemia develops when the workload of the heart increases. Although the individual may feel comfortable at rest, exertion or emotional stress can produce a sensation of pressure, chest constriction, and pain that may radiate from the sternal area to the arms, back, and neck.

Normal Heart

A color-enhanced **digital subtraction angiography (DSA)** scan of a normal heart.

Advanced Coronary Artery Disease

A color-enhanced DSA scan showing advanced coronary artery disease. Blood flow to the ventricular myocardium is severely restricted.

Plaques may be visible by angiography or high-resolution ultrasound, and the effects on coronary blood flow can be detected in digital subtraction angiography (DSA) scans of the heart as shown above.

Normal Artery

Cross section

Narrowing of Artery

Cross section

Left: Chest pain or discomfort is a common symptom of angina pectoris. Although similar symptoms may accompany a heart attack, during a heart attack, pain often radiates down the left arm.

Below: The presence of any two of these coronary risk factors more than doubles the risk of heart attack.

Risk Factors for CAD and Myocardial Infarction

SMOKING • HIGH BLOOD PRESSURE • HIGH CHOLESTEROL •
 MALE OVER AGE 70 • SEVERE EMOTIONAL STRESS • OBESITY

In a **myocardial** (mī-ō-KAR-dē-al) **infarction (MI)**, or **heart attack**, part of the coronary circulation becomes blocked, and cardiac muscle cells die from lack of oxygen. The death of affected tissue creates a nonfunctional area known as an *infarct*. Heart attacks most commonly result from severe coronary artery disease (CAD). The consequences depend on the site and nature of the circulatory blockage. If it occurs near the start of one of the coronary arteries, the damage will be widespread and the heart may stop beating. If the blockage involves one of the smaller arterial branches, the individual may survive the immediate crisis but may have many complications such as reduced contractility and cardiac arrhythmias.

A crisis often develops as a result of thrombus formation at a plaque (the most common cause of an MI), a condition called **coronary thrombosis**. A vessel already narrowed by plaque formation may also become blocked by a sudden spasm in the smooth muscles of the vascular wall.

Individuals having an MI experience intense pain, similar to that felt in angina, but persisting even at rest. However, pain does not always accompany a heart attack, and silent heart attacks may be even more dangerous than more apparent attacks, because the condition may go undiagnosed and may not be treated before a fatal MI occurs. A myocardial infarction can usually be diagnosed with an electrocardiogram (ECG) and blood studies. Damaged myocardial cells release enzymes into the circulation, and these elevated enzymes can be measured in diagnostic blood tests. The enzymes include **cardiac troponin T**, **cardiac troponin I**, and a special form of creatinine phosphokinase, **CK-MB**.

Myocardial Infarction

HEART ATTACK

Treatment of CAD and Myocardial Infarction

About 25% of patients die before obtaining medical assistance, and 65% of MI deaths among those under age 50 occur within an hour after the initial infarction.

Risk Factor Modification

Stop smoking, treat high blood pressure, adjust diet to lower cholesterol and promote weight loss, reduce stress, and increase physical activity.

Drug Treatment

- Drugs that reduce coagulation and therefore the risk of thrombosis, such as aspirin and coumadin
- Drugs that block sympathetic stimulation (propranolol or metoprolol)
- Drugs that cause vasodilation, such as **nitroglycerin** (nī-trō-GLIS-er-in)
- Drugs that block calcium ion movement into the cardiac and vascular smooth muscle cells (calcium ion channel blockers)
- In a myocardial infarction, drugs to relieve pain, fibrinolytic agents to help dissolve clots, and oxygen

Noninvasive Surgery

- **Atherectomy**. Blockage by a single, soft plaque may be reduced with the aid of a long, slender **catheter** (KATH-e-ter) inserted into a coronary artery to the plaque. A variety of surgical tools can be slid into the catheter, and the plaque can then be removed.
- **Balloon angioplasty** (AN-jē-ō-plas-tē; *angeion*, vessel). In balloon angioplasty, the tip of the catheter contains an inflatable balloon. Once in position, the balloon is inflated, pressing the plaque against the vessel walls. Because plaques commonly redevelop after angioplasty, a fine tubular wire mesh called a **stent** may be inserted into the vessel, holding it open.

Coronary Artery Bypass Graft (CABG)

In a **coronary artery bypass graft**, a small section is removed from either a small artery or a peripheral vein and is used to create a detour around the obstructed portion of a coronary artery. As many as four coronary arteries can be rerouted this way during a single operation. The procedures are named according to the number of vessels repaired, so we speak of single, double, triple, or quadruple coronary bypasses.

DIABETES • HIGH CIRCULATING LOW-DENSITY LIPOPROTEIN
BITY • SEDENTARY LIFESTYLE • GENETIC PREDISPOSITION

+ Clinical Note Broken Heart Syndrome

The popular notion that grief can “break your heart” finds support in the novel diagnosis of *broken heart syndrome*, also called *stress-induced cardiomyopathy* or *takotsubo cardiomyopathy*. First noted in Japan in the early 2000s, older females were presenting with apparent heart attacks. The precipitating event was an acute emotional stress, such as the death of a loved one. The females’ ECGs were abnormal; their left ventricles were significantly dilated. But their coronary arteries—the site of the lesions responsible for heart attacks—were clear! All these changes reverted to normal within a month of supportive care.

ventricles, along the interventricular sulcus. This vein drains blood from the region supplied by the anterior interventricular artery, a branch of the left coronary artery. The great cardiac vein reaches the level of the atria and then curves around the left side of the heart within the coronary sulcus.

The cardiac veins draining the myocardium return blood to the **coronary sinus**, a large, thin-walled vein. The coronary sinus opens into the right atrium near the base of the inferior vena cava.

Other cardiac veins empty into the great cardiac vein or the coronary sinus. These veins include (1) the **posterior vein of left ventricle**, draining the area served by the circumflex artery; (2) the **middle cardiac vein**, draining the area supplied by the posterior interventricular artery; and (3) the **small cardiac vein**, which receives blood from the posterior surfaces of the right atrium and ventricle. The **anterior cardiac veins** (also called the *anterior veins of right ventricle*), which drain the anterior surface of the right ventricle, empty directly into the right atrium.

20-2 The cells of the conducting system distribute electrical impulses through the heart, causing cardiac contractile cells to contract

Learning Outcome Explain the events of an action potential in cardiac muscle, indicate the importance of calcium ions to the contractile process, describe the conducting system of the heart, and identify the electrical events associated with a normal electrocardiogram.

We now turn our attention to how the heart works—cardiac physiology. That requires understanding the structure and function of the different types of cardiac muscle cells. Some form the *conducting system*, an internal network that uses electrical signals to coordinate the contractions of cardiac muscle cells. The electrical events of the heart can then be recorded in an *electrocardiogram* (ECG). We then discuss heart contraction at the cellular level.

Cardiac Physiology: Electrical Impulses Leading to the Contractions Making Up a Heartbeat

In a single cardiac contraction, called the **heartbeat**, all heart chambers contract in series—first the atria and then the ventricles. Two types of cardiac muscle cells are involved in a normal heartbeat: (1) Specialized *autorhythmic cells* (pacemaker and conducting) of the conducting system control and coordinate the heartbeat, and (2) *contractile cells* produce the powerful contractions that propel blood. The electrical impulses of the conducting system initiate the contraction of the heart chambers.

Each heartbeat begins with an action potential generated by cells of the conducting system. Other cells of this system then propagate and distribute this electrical impulse to stimulate contractile cells at the proper time. The arrival of an electrical impulse at the plasma membrane of a cardiac contractile cell produces an action potential that is comparable to an action potential in a skeletal muscle fiber. As in a skeletal muscle fiber, this action potential triggers the contraction of the cardiac contractile cell. The actual contraction lags behind the beginning of the action potential. Because of the coordination provided by the conducting system, the atria contract first, driving blood into the ventricles through the AV valves, and the ventricles contract next, driving blood out of the heart through the semilunar valves.

A heartbeat lasts only about 370 milliseconds (msec). Let’s follow the steps in that brief time that produce a single heartbeat.

The Conducting System: Pacemaker and Conducting Cells

Unlike skeletal muscle, cardiac muscle tissue contracts on its own, without neural or hormonal stimulation; this property is called **autorhythmicity**. The cells that initiate and distribute the stimulus to contract are part of the heart’s **conducting system**. This system is a network of specialized cardiac muscle cells, called *pacemaker cells* and *conducting cells*. Let’s examine these types of cells, and how they function in the conducting system.

Figure 20–10 The Conducting System of the Heart and the Pacemaker Potential.

Components of the Conducting System

The network of specialized cardiac cells of the conducting system are grouped in various locations. This section introduces the components of this system (**Figure 20–10a**).

Pacemaker Cells in the Sinoatrial and Atrioventricular Nodes. **Pacemaker cells** are essential to establishing the normal *heart rate*. They are also called *nodal cells* because they are found in two nodes, or locations:

- The **sinoatrial** (sī-nō-ā-trē-al) (**SA**) **node** is embedded in the posterior wall of the right atrium, near the entrance of the superior vena cava. Because the SA node is the primary driver of the heart rate, it is also known as the *cardiac pacemaker*.
- The relatively large **atrioventricular (AV) node** is located at the junction between the atria and ventricles, near the opening of the coronary sinus. The pacemaker cells of this node send signals from the cells of the SA node and act as a backup to the SA node pacemaker cells.

Conducting Cells in the Internodal Pathways, AV Bundles, Bundle Branches, and Purkinje Fibers. **Conducting cells** interconnect the SA and AV nodes and distribute the contractile stimulus throughout the myocardium. These cells are found in two main locations:

- In the atria, conducting cells are found in **internodal pathways** in the atrial walls. These pathways distribute the contractile stimulus to surrounding atrial muscle cells as this electrical impulse travels from the SA node to the AV node.
- In the ventricles, conducting cells include those in the **atrioventricular (AV) bundle** (also called the *bundle of His*)

and the **bundle branches** that run between the ventricles, as well as the **Purkinje** (pur-KIN-jē) **fibers**, which distribute the stimulus to the ventricular myocardium.

Most of the cells of the conducting system are smaller than the contractile cells of the myocardium and contain very few myofibrils. Purkinje fibers, however, are much larger in diameter than the contractile cells.

Pacemaker Cells and Heart Rate

Pacemaker cells of the SA and AV nodes share a unique characteristic: Their excitable membranes do not have a stable resting membrane potential. Each time a pacemaker cell repolarizes, its membrane potential drifts toward threshold. This gradual depolarization is called a **pacemaker potential** (**Figure 20–10b**). The pacemaker potential results from a slow inflow of Na^+ without a compensating outflow of K^+ .

The rate of spontaneous depolarization differs in various parts of the conducting system. It is fastest at the SA node. Without neural or hormonal stimulation, the SA node generates action potentials at a rate of 60–100 per minute. Isolated cells of the AV node depolarize more slowly, generating 40–60 action potentials per minute. Because the SA node reaches threshold first, it establishes the basic *heart rhythm*, or **sinus rhythm**. (While heart rhythm is essential to heart rate, the heart rate is the number of beats per minute.) In other words, the impulse generated by the SA node brings the AV pacemaker cells to threshold faster than does the pacemaker potential of the AV pacemaker cells. The normal resting heart rate is somewhat slower than 80–100 beats per minute (bpm), however, because of parasympathetic innervation. (The influence of autonomic innervation on heart rate is described in Section 20–4.)

The pacemaker cells of the AV node can conduct impulses at a maximum rate of 230 per minute. Because each impulse results in a ventricular contraction, this value is the maximum normal heart rate. Even if the SA node generates impulses at a faster rate, the ventricles will still contract at 230 bpm. This limitation is important, because mechanical factors (discussed later) begin to decrease the pumping efficiency of the heart at rates above approximately 180 bpm. Rates above 230 bpm occur only when the heart or the conducting system has been damaged or stimulated by drugs. As ventricular rates increase toward their theoretical maximum limit of 300–400 bpm, pumping effectiveness becomes dangerously, if not fatally, reduced.

Impulse Conduction through the Heart

Now let's trace the path of an impulse from its initiation at the SA node, examining its effects on the surrounding myocardium as we proceed.

Functions of the Pacemaker Cells. An action potential produced by the pacemaker cells of the SA node (Figure 20-11 1) takes approximately 50 msec to travel to the AV node along the internodal pathways. Along the way, the conducting cells pass the stimulus to contractile cells of both atria. The action potential then spreads across the atrial surfaces by cell-to-cell contact (Figure 20-11 2). The stimulus affects only the atria, because the fibrous tissue of the cardiac skeleton (Figure 20-7) isolates the atrial myocardium from the ventricular myocardium.

The impulse slows as it leaves the internodal pathways and enters the AV node, because the nodal cells are smaller in diameter than the conducting cells. (Chapter 12 discussed the relationship between axon diameter

Figure 20-11 Impulse Conduction through the Heart and Accompanying ECG

Tracings. The ECG tracings are explained in the next section and in Figure 20-12. After reading about the electrocardiogram, come back to this figure to integrate the electrical activity of the heart and atrial and ventricular contractions.

What happens to the electrical impulse when it reaches the AV node?

and propagation speed.) In addition, the connections between pacemaker cells are less efficient than those between conducting cells at relaying the impulse from one cell to another. As a result, the impulse takes about 100 msec to pass through the AV node (**Figure 20-11 3**). This delay is important because it allows the atria to contract before the ventricles do. (The delay is a result of the time it takes for calcium ions to enter the sarcoplasm and activate the contraction process, as described in Chapter 10.) Otherwise, contraction of the powerful ventricles would close the AV valves and prevent blood flow from the atria into the ventricles.

Functions of the Conducting Cells. After the brief delay at the AV node, the impulse is conducted along the AV bundle and the bundle branches to the Purkinje fibers and the papillary muscles (**Figure 20-11 4**). The connection between the AV node and the AV bundle is normally the only electrical connection between the atria and the ventricles. Once an impulse enters the AV bundle, it travels to the interventricular septum and enters the **right** and **left bundle branches**. The left bundle branch, which supplies the massive left ventricle, is much larger than the right bundle branch. Both branches extend toward the apex of the heart, turn, and fan out deep to the endocardial surface.

As the bundle branches diverge, they conduct the impulse to both the Purkinje fibers and, through the moderator band, to the papillary muscles of the right ventricle. Because the impulse is delivered to the papillary muscles directly, these muscles begin contracting before the rest of the ventricular musculature does. Contraction of the papillary muscles applies tension to the chordae tendineae, bracing the AV valves. This tension limits the movement of the cusps, preventing the backflow of blood into the atria when the ventricles contract.

The Purkinje fibers then distribute the impulse to the ventricular myocardium (**Figure 20-11 5**). Purkinje fibers, which radiate from the apex toward the base of the heart, conduct action potentials very rapidly—as fast as small, myelinated axons. Within about 75 msec, the signal to begin a contraction has reached all the ventricular cardiac contractile cells, and ventricular contraction begins. By this time, the atria have completed their contractions and ventricular contraction can safely occur. Because of the location of the Purkinje fibers, the ventricles contract in a wave that begins at the apex of the heart and spreads toward the base. The contraction pushes blood toward the base, into the aorta and pulmonary trunk.

In summary, each time the heart beats, a wave of depolarization spreads through the atria, pauses at the AV node, then travels down the interventricular septum to the apex, turns, and spreads through the ventricular myocardium toward the base (**Figure 20-11**). The entire process, from the

generation of an impulse at the SA node to the complete depolarization of the ventricular myocardium, normally takes around 225 msec.

Disturbances in Heart Rhythm

Many clinical problems result from abnormal pacemaker function. **Bradycardia** (brād-ē-KAR-dē-uh; *bradys*, slow) is a condition in which the heart rate is slower than normal. **Tachycardia** (tak-ē-KAR-dē-uh; *tachys*, swift) is a faster-than-normal heart rate. These terms are relative, and in clinical practice the definitions vary with the normal resting heart rate of the individual.

Damage to the conducting pathways disturbs the normal rhythm of the heart. The resulting problems are called *conduction deficits*. If the SA node or any of the internodal pathways becomes damaged, the heart continues to beat, but at a slower rate, usually 40–60 bpm, as dictated by the AV node. Certain cells in the Purkinje fiber network depolarize spontaneously at an even slower rate. If the rest of the conducting system is damaged, these cells can stimulate a heart rate of 20–40 bpm. Under normal conditions, cells of the AV bundle, the bundle branches, and most Purkinje fibers do not depolarize spontaneously. If, due to damage or disease, these cells *do* begin depolarizing spontaneously, the heart may no longer pump blood effectively. Death can result if the problem persists.

If an abnormal conducting cell or ventricular contractile cell begins generating action potentials at a higher rate, the impulses can override those of the SA or AV node. The origin of these abnormal signals is called an **ectopic** (ek-TOP-ik; out of place) **pacemaker**. The activity of an ectopic pacemaker partially or completely bypasses the conducting system, disrupting the timing of ventricular contraction. The result may be a dangerous reduction in the pumping efficiency of the heart. Such conditions are commonly diagnosed with the aid of an electrocardiogram.

The Electrocardiogram (ECG)

The electrical events in the heart are powerful enough to be detected by electrodes on the body. A procedure known as *electrocardiography* can monitor the electrical events of the conducting system. A recording of these events is an **electrocardiogram** (ē-lek-trō-KAR-dē-ō-gram), also called an **ECG**, or **EKG**. Clinicians can use an ECG to assess the functions of specific pacemaker, conducting, and contractile cells. When a portion of the heart has been damaged by a heart attack, for example, the ECG reveals an abnormal pattern of impulse conduction.

The monitoring electrodes for an ECG are placed at different locations on the body surface. The appearance of the ECG varies with the placement of the monitoring electrodes, which are called *leads*. **Figure 20-12a** shows the leads in one of the standard configurations. **Figure 20-12b** depicts the important

Figure 20–12 An Electrocardiogram (ECG).**a** Electrode placement for recording a standard ECG.**b** An ECG printout is a strip of graph paper containing a record of the electrical events monitored by the electrodes. The placement of electrodes on the body surface affects the size and shape of the waves recorded. The example is a normal ECG; the enlarged section indicates the major components of the ECG and the measurements most often taken during clinical analysis.

features of an ECG recorded with that configuration. Note the following ECG features:

- The small **P wave**, which accompanies the depolarization of the atrial contractile cells. Depolarization of these cells causes atrial contraction. (Compare with **Figure 20–11 2**.)
- The **QRS complex**, which appears as the ventricle contractile cells depolarize. This electrical signal is relatively strong, because the ventricular muscle is much more massive than that of the atria. It is also a complex signal, largely because of the complex pathway that the spread of depolarization takes through the ventricles. The ventricles begin contracting shortly after the peak of the **R wave**. Atrial repolarization takes place while the ventricles are depolarizing and it is obscured by the more powerful QRS complex. (Compare with **Figure 20–11 4** and **5**.)
- The smaller **T wave**, which indicates repolarization of the ventricular contractile cells.

To analyze an ECG, one must measure the size of the voltage changes and determine the durations and temporal (time) relationships of the various components. The amount of depolarization during the P wave and the QRS complex is particularly important in making a diagnosis. For example, an excessively large QRS complex often indicates that the heart has become enlarged. A smaller-than-normal electrical signal may mean that the mass of the heart muscle has decreased (although monitoring problems are more often responsible). The size and shape of the T wave may also be affected by any condition that slows ventricular repolarization. For example, starvation and low cardiac energy reserves, coronary ischemia (inadequate blood flow to cardiac cells), or abnormal ion concentrations reduce the size of the T wave.

The times between waves are reported as *segments* and *intervals*. Segments generally extend from the end of one wave to the start of another. Intervals are more variable, but always include at least one entire wave. Commonly used segments

and intervals are labeled in **Figure 20-12b**. The names, however, can be somewhat misleading. For example:

- The **P–R interval** extends from the start of atrial depolarization to the start of the QRS complex (ventricular depolarization) rather than to R, because in abnormal ECGs the peak at R can be difficult to determine. Extension of the P–R interval to more than 200 msec can indicate damage to the AV node or conducting pathways.
- The **Q–T interval** indicates the time required for the ventricles to undergo a single cycle of depolarization and repolarization. It is usually measured from the end of the P–R interval rather than from the bottom of the Q wave. The Q–T interval can be lengthened by electrolyte disturbances, some medications, conduction problems, coronary ischemia, or myocardial damage. A congenital heart defect that can cause sudden death without warning may be detectable as a prolonged Q–T interval.

An *arrhythmia* (ā-RITH-mē-uh) is an irregularity in the normal rhythm or force of the heartbeat. Serious arrhythmias may indicate damage to the myocardium, injuries to the pacemaker cells or conducting cell pathways, exposure to drugs, or abnormalities in the electrolyte composition of extracellular fluids. **Spotlight Figure 20-13** describes cardiac arrhythmias.

Cardiac Contractions: Contractile Cells

The Purkinje fibers distribute the stimulus to the **cardiac contractile cells**, which form the bulk of the atrial and ventricular

walls. These cells account for about 99% of the muscle cells in the heart. As noted in Chapter 10, cardiac contractile cells are interconnected by **intercalated** (in-TER-kah-lā-ted) **discs** (**Figure 20-14a**). Intercalated discs transfer the force of contraction from cell to cell and propagate action potentials. At an intercalated disc, the interlocking membranes of adjacent cells are held together by desmosomes and linked by gap junctions (**Figure 20-14b,c**). The desmosomes prevent cells from separating during contraction, while the gap junctions allow ions to pass and electrically couple adjacent cells. This allows the heart muscle to behave as a *functional syncytium* (sin-SI-shē-um), a mechanically, chemically, and electrically coupled, multinucleate tissue.

Tips

The term *intercalated* means “inserted between other elements.” So intercalated discs appear to have been inserted between cardiac muscle cells.

Cardiac Contractile Cells Compared with Skeletal Muscle Fibers

Table 20-1 provides a review of the structural and functional differences between cardiac contractile cells and skeletal muscle fibers. Histological characteristics that distinguish cardiac contractile cells from skeletal muscle fibers include (1) small size; (2) a single, centrally located nucleus; (3) branching interconnections between cells; and (4) the presence of intercalated discs.

Table 20-1 Structural and Functional Differences between Cardiac Contractile Cells and Skeletal Muscle Fibers

Feature	Cardiac Contractile Cells	Skeletal Muscle Fibers
Size	10–20 μm $\times$ 50–100 μm	100 μm $\times$ up to 40 cm
Nuclei	1 (rarely 2–5)	Multiple (hundreds)
Contractile proteins	Sarcomeres along myofibrils	Sarcomeres along myofibrils
Internal membranes	Short T tubules; no triads formed with sarcoplasmic reticulum	Long T tubules form triads with cisternae of the sarcoplasmic reticulum
Mitochondria	Abundant (25% of cell volume)	Much less abundant
Inclusions	Myoglobin, lipids, glycogen	Little myoglobin, few lipids, but extensive glycogen reserves
Blood supply	Very extensive	More extensive than in most connective tissues, but sparse compared with supply to cardiac muscle cells
Metabolism (resting)	Not applicable	Aerobic, primarily lipid based
Metabolism (active)	Aerobic, primarily using lipids and carbohydrates	Anaerobic, through breakdown of glycogen reserves
Contractions	Twitches with brief relaxation periods; long refractory period prevents tetanic contractions	Sustained contractions
Stimulus for contraction	Autorhythmicity of pacemaker cells generates action potentials	Activity of somatic motor neuron generates action potentials in sarcolemma
Trigger for contraction	Calcium ion entry from the extracellular fluid and calcium ion release from the sarcoplasmic reticulum	Calcium ion release from the sarcoplasmic reticulum
Intercellular connections	Branching network with plasma membranes locked together at intercalated discs; connective tissue fibers tie adjacent layers together	Adjacent fibers tied together by connective tissue fibers

Despite the variety of sophisticated equipment available to assess or visualize cardiac function, in the majority of cases the ECG provides the most important diagnostic information. ECG analysis is especially useful in detecting and diagnosing **cardiac arrhythmias** (ā-RITH-mē-uz)—abnormal patterns of cardiac electrical activity. Momentary arrhythmias are not inherently dangerous, but clinical problems appear when arrhythmias reduce the pumping efficiency of the heart.

Premature Atrial Contractions (PACs)

Premature atrial contractions (PACs) often occur in healthy individuals. In a PAC, the normal atrial rhythm is momentarily interrupted by a “surprise” atrial contraction. Stress, caffeine, and various drugs may

increase the incidence of PACs, presumably by increasing the permeabilities of the SA pacemakers. The impulse spreads along the conduction pathway, and a normal ventricular contraction follows the atrial beat.

Paroxysmal Atrial Tachycardia (PAT)

In **paroxysmal** (par-ok-SIZ-mal) **atrial tachycardia**, or **PAT**, a premature atrial contraction triggers a flurry of atrial activity. The ventricles are still able to keep pace, and the heart rate jumps to about 180 beats per minute.

Atrial Fibrillation (AF)

During **atrial fibrillation** (fib-ri-LĀ-shun), the impulses move over the atrial surface at rates of perhaps 500 beats per minute. The atrial wall quivers instead of producing an organized contraction. The ventricular rate cannot follow the atrial rate and may remain within normal

limits. Even though the atria are now nonfunctional, their contribution to ventricular end-diastolic volume (the maximum amount of blood the ventricles can hold at the end of atrial contraction) is so small that the condition may go unnoticed in older individuals.

Premature Ventricular Contractions (PVCs)

Premature ventricular contractions (PVCs) occur when a Purkinje cell or ventricular myocardial cell depolarizes to threshold and triggers a premature contraction. Single PVCs are common and not dangerous. The cell

responsible is called an **ectopic pacemaker**. The frequency of PVCs can be increased by exposure to epinephrine, to other stimulatory drugs, or to ionic changes that depolarize cardiac muscle plasma membranes.

Ventricular Tachycardia (VT)

Ventricular tachycardia is defined as four or more PVCs without intervening normal beats. It is also known as **VT** or **V-tach**. Multiple PVCs and VT may indicate that serious cardiac problems exist.

Ventricular Fibrillation (VF)

Ventricular fibrillation (VF) is responsible for the condition known as **cardiac arrest**. VF is rapidly fatal, because the ventricles quiver and stop pumping blood.

Figure 20–14 Cardiac Contractile Cells.

The functions of cardiac contractile cells and skeletal muscle cells are similar but have some differentiating characteristics. In both types of cells, (1) an action potential leads to the appearance of Ca^{2+} among the myofibrils, and (2) the binding of Ca^{2+} with troponin on the thin filaments initiates the contraction. But cardiac contractile cells and skeletal muscle fibers differ in terms of the nature of the action potential, the source of the Ca^{2+} , and the duration of the resulting contraction.

The Action Potential in Cardiac Contractile Cells

The resting membrane potential of a ventricular contractile cell is approximately -90 mV, comparable to that of a resting skeletal muscle fiber (-85 mV). (The resting membrane potential of an atrial contractile cell is about -80 mV, but the basic principles described here apply to atrial cells as well.)

Process of the Action Potential. An action potential begins when the membrane of the ventricular contractile cell reaches threshold, usually at about -75 mV. Threshold is

normally reached in a portion of the membrane next to an intercalated disc. The typical stimulus is the excitation of an adjacent contractile cell. Once threshold has been reached, the action potential proceeds in three basic steps (**Figure 20–15a**):

1 Rapid Depolarization. The stage of *rapid depolarization* in a cardiac contractile cell resembles that in a skeletal muscle fiber. At threshold, voltage-gated sodium ion channels open, and the membrane suddenly becomes permeable to Na^+ . A massive influx of sodium ions rapidly depolarizes the sarcolemma. The channels involved are called **fast sodium channels**, because they open quickly and remain open for only a few milliseconds.

2 The Plateau. A partial repolarization takes place as some potassium ions (K^+) leave the cell before most K^+ channels close. Voltage-gated calcium channels then open and *extracellular* calcium ions (Ca^{2+}) enter the cytosol. The **slow calcium channels** remain open for a relatively long period—roughly 175 msec. The inflow of positive charges (Ca^{2+}) and reduced outflow of K^+ delay repolarization, causing the membrane

Figure 20–15 Action Potentials in Cardiac Contractile Cells and Skeletal Muscle Fibers.

?

In a ventricular contractile cell, which ion's entry causes rapid depolarization? Which ion's entry causes the plateau? Which ion's exit causes repolarization?

potential to remain near 0 mV for an extended period. This portion of the action potential is called the *plateau*. The extracellular calcium ions initiate contraction and delay repolarization. Their increased concentration within the cell also triggers the release of Ca^{2+} from reserves in the sarcoplasmic reticulum (SR), which continues the contraction.

3 Repolarization. As the plateau continues, slow calcium channels begin closing, and **slow potassium channels** begin opening. As these channels open, potassium ions (K^+) rush out of the cell, and the net result is a period of rapid repolarization that restores the resting membrane potential.

The Refractory Period. As with skeletal muscle fiber contractions, the membrane of a cardiac contractile cell will not respond normally to a second stimulus for some time after an action potential begins. This time is called the **refractory period**. Initially, in the *absolute refractory period*, the membrane cannot respond at all, because the sodium ion channels are either already open or closed and inactivated. In a ventricular contractile cell, the absolute refractory period lasts approximately 200 msec. It includes the plateau and the initial period of rapid repolarization.

The absolute refractory period is followed by a shorter (50-msec) *relative refractory period*. During this period, the

voltage-gated sodium ion channels are closed, but can open. The membrane will respond to a stronger-than-normal stimulus by initiating another action potential. In total, an action potential in a ventricular contractile cell lasts 250–300 msec, about 30 times as long as a typical action potential in a skeletal muscle fiber.

The Role of Calcium Ions in Cardiac or Skeletal Muscle Contractions

The appearance of an action potential in the cardiac contractile cell plasma membrane produces a contraction by causing an increase in the concentration of Ca^{2+} around the myofibrils. This process takes place in two steps:

1. Extracellular calcium ions crossing the plasma membrane during the plateau phase of the action potential provide roughly 20% of the Ca^{2+} required for a contraction.
2. The arrival of extracellular Ca^{2+} triggers the release of additional Ca^{2+} from reserves in the sarcoplasmic reticulum (SR).

Extracellular calcium ions thus have both direct and indirect effects on cardiac contractile cell contraction. For this reason, cardiac muscle tissue is highly sensitive to changes in the Ca^{2+} concentration of the extracellular fluid.

In a skeletal muscle fiber, the action potential is relatively brief and ends as the resulting twitch contraction begins (Figure 20-15b). The twitch contraction is short and ends as the SR reclaims the Ca^{2+} it released. In a cardiac contractile cell, the action potential is prolonged, and calcium ions continue to enter the cell throughout the plateau. As a result, the cell actively contracts until the plateau ends. As the slow calcium channels close, the intracellular calcium ions are pumped back into the SR or out of the cell, and the contractile cell relaxes.

In skeletal muscle fibers, the refractory period ends before peak tension develops. As a result, twitches can add up and tetanus can occur. In cardiac contractile cells, the absolute refractory period continues until relaxation is under way. Because summation is not possible, tetanic contractions cannot occur in a normal cardiac contractile cell, regardless of the frequency or intensity of stimulation. This feature is vital: A heart in tetanus could not pump blood. With a single twitch lasting 250 msec or longer, a normal cardiac contractile cell could reach 300–400 contractions per minute under maximum stimulation. This rate is not reached in a normal heart, due to limitations imposed by the conducting system.

The Energy for Cardiac Contractions

While a normal heart is beating, it gets energy as the mitochondria break down fatty acids (stored as lipid droplets) and glucose (stored as glycogen). These aerobic reactions can occur only when oxygen is readily available.

In addition to obtaining oxygen from the coronary circulation, cardiac contractile cells maintain their own sizable

reserves of oxygen. In these cells, oxygen molecules are bound to the heme units of *myoglobin* molecules. (We discussed this globular protein, which reversibly binds oxygen molecules, and its function in skeletal muscle fibers in Chapter 10.) Normally, the combination of circulatory supplies plus myoglobin reserves is enough to meet the oxygen demands of the heart, even when it is working at maximum capacity.

20-3 The contraction-relaxation events that occur during a complete heartbeat make up a cardiac cycle

Learning Outcome Explain the events of the cardiac cycle, including atrial and ventricular systole and diastole, and relate the heart sounds to specific events in the cycle.

The electrical events of the conducting system initiate the mechanical events of heart contraction. A brief resting phase follows each heartbeat, allowing time for the chambers to relax and prepare for the next heartbeat. The period between the start of one heartbeat and the beginning of the next is a single **cardiac cycle**. It includes alternating periods of contraction and relaxation. For any one chamber in the heart, the cardiac cycle can be divided into two phases: systole and diastole. During **systole** (SIS-tō-lē), or contraction, the chamber contracts and pushes blood into an adjacent chamber or into an arterial trunk. Systole is followed by **diastole** (dī-AS-tō-lē), or relaxation. During diastole, the chamber fills with blood and prepares for the next cardiac cycle.

An Introduction to Pressure and Flow in the Heart

Fluids flow from an area of higher pressure to an area of lower pressure. In the cardiac cycle, the blood pressure within each chamber rises during systole and falls during diastole. Valves between adjacent chambers help ensure that blood flows in the required direction, but blood flows from one chamber to another only if the pressure in the first chamber exceeds that in the second. This basic principle governs the movement of blood between atria and ventricles, between ventricles and arterial trunks, and between major veins and atria.

Figure 20–16 Phases of the Cardiac Cycle. Thin black arrows indicate blood flow, green arrows indicate contractions, and the red-hued areas indicate which heart chambers are in systole.

The correct pressure relationships depend on the careful timing of contractions. For example, blood could not move in the proper direction if an atrium and its attached ventricle contracted at precisely the same time. The heart's elaborate pace-making and conducting systems normally provide the required spacing between atrial systole and ventricular systole.

Phases of the Cardiac Cycle

The phases of the cardiac cycle—*atrial systole*, *atrial diastole*, *ventricular systole*, and *ventricular diastole*—are diagrammed in **Figure 20–16** for a representative heart rate of 75 bpm. At this heart rate, a sequence of systole and diastole in either the atria or the ventricles lasts 800 msec. When the cardiac cycle begins,

all four chambers are relaxed, and the ventricles are partially filled with blood.

Start by focusing on the atria. During **atrial systole**, the atria contract, filling the ventricles completely with blood (**Figure 20–16a,b**). Atrial systole lasts 100 msec. The atria next enter **atrial diastole**, which continues until the start of the next cardiac cycle.

Ventricular systole begins at the same time as atrial diastole. Ventricular systole lasts 270 msec. During this period, the ventricles push blood through the systemic and pulmonary circuits and toward the atria (**Figure 20–16c,d**). The heart then enters **ventricular diastole** (**Figure 20–16e,f**), which lasts 530 msec (the 430 msec remaining in this cardiac cycle, plus the first 100 msec of the next, when the atria are again contracting). For the rest of this cycle, filling occurs passively, and both the atria and the ventricles are relaxed. The next cardiac cycle begins with atrial systole, which completes the filling of the ventricles.

When the heart rate increases, all the phases of the cardiac cycle are shortened. The greatest reduction occurs in the length of time spent in diastole. When the heart rate climbs from 75 bpm to 200 bpm, the time spent in systole drops by less than 40%, but the duration of diastole is reduced by almost 75%.

Pressure and Volume Changes in the Cardiac Cycle

Figure 20–17 plots the pressure and volume changes during the cardiac cycle. It also shows an ECG for the cardiac cycle. The circled numbers in the figure correspond to the numbered paragraphs in the text. The figure shows pressure and volume within the left atrium and left ventricle, but our discussion applies to both sides of the heart. Although pressures are lower in the right atrium and right ventricle, both sides of the heart contract at the same time, and they eject equal volumes of blood.

Atrial Systole

In atrial systole:

- 1 Atrial contraction begins.** At the start of atrial systole, the ventricles are already filled to about 70% of their normal capacity, due to passive blood flow during the end of the previous cardiac cycle.
- 2 Atria eject blood into the ventricles.** As the atria contract, rising atrial pressures provide the remaining 30% by pushing blood into the ventricles through the open right and left AV valves. Atrial systole essentially “tops off” the ventricles. Over this period, blood cannot flow into the atria from the veins because atrial pressure exceeds venous pressure. Yet there is very little backflow into the veins, even though the connections with the venous system lack valves. The reason is that blood takes the path of least resistance. Resistance to blood flow through the wide opening between the atria and

ventricles is less than that through the smaller, angled openings of the large veins.

At the end of atrial systole, each ventricle contains the maximum amount of blood that it will hold in this cardiac cycle. That quantity is called the *end-diastolic volume* (EDV). In an adult who is standing at rest, the end-diastolic volume is typically about 130 mL (about 4.4 oz).

Ventricular Systole and Atrial Diastole

In ventricular systole:

- 3 Atrial systole ends and AV valves close.** As atrial systole ends, ventricular systole begins. As the pressures in the ventricles rise above those in the atria, the AV valves are pushed closed.
- 4 Isovolumetric ventricular contraction occurs.** During the early stage of ventricular systole, the ventricles are contracting, but blood flow has yet to occur. Ventricular pressures are not yet high enough to force open the semilunar valves and push blood into the pulmonary or aortic trunk. Over this period, the ventricles contract isometrically; in other words, they generate tension and pressures rise inside them, but blood does not flow out. The ventricles are in **isovolumetric contraction**: All the heart valves are closed, the volumes of the ventricles do not change, and ventricular pressures are rising.
- 5 Ventricular ejection occurs.** Once pressure in the ventricles exceeds that in the arterial trunks, the semilunar valves are pushed open and blood flows into the pulmonary and aortic trunks. This point marks the beginning of **ventricular ejection**. The ventricles now contract isotonicity: The muscle cells shorten, and tension production remains relatively constant. (To review isotonic versus isometric contractions, look back at **Figure 10–18**.)

During ventricular ejection, each ventricle ejects 70–80 mL of blood, the *stroke volume* (SV) of the heart. The stroke volume at rest is roughly 60% of the end-diastolic volume.

After reaching a peak, ventricular pressures gradually decline near the end of ventricular systole. **Figure 20–17** shows values for the left ventricle and aorta. The right ventricle also undergoes periods of isovolumetric contraction and ventricular ejection.

- 6 Semilunar valves close.** As the end of ventricular systole approaches, ventricular pressures fall rapidly. Blood in the aorta and pulmonary trunk now starts to flow back toward the ventricles, and this movement closes the semilunar valves. As the backflow begins, pressure decreases in the aorta. When the semilunar valves close, pressure rises again as the elastic arterial walls recoil. This small, temporary rise produces a valley in the aortic pressure tracing, called a *dicrotic* (dī-KROT-ik; *dikrotos*, double beating) *notch*.

The amount of blood remaining in the ventricle when the semilunar valve closes is the *end-systolic volume* (ESV). At rest, the end-systolic volume is 50 mL, about 40% of the end-diastolic volume.

Figure 20–17 Pressure and Volume Relationships in the Cardiac Cycle. Major features of the cardiac cycle are shown for a heart rate of 75 bpm. The circled numbers correspond to those in the associated box.

Ventricular Diastole

The period of ventricular diastole lasts for the remainder of the current cardiac cycle and continues through atrial systole in the next cycle.

7 Isovolumetric relaxation occurs. All the heart valves are now closed, and the ventricular myocardium is relaxing. Because

ventricular pressures are still higher than atrial pressures, blood cannot flow into the ventricles. This is **isovolumetric relaxation**. Ventricular pressures drop rapidly over this period because the elasticity of the connective tissues of the heart and cardiac skeleton helps re-expand the ventricles toward their resting dimensions.

8 AV valves open; passive ventricular filling occurs. When ventricular pressures fall below those of the atria, the atrial pressures force the AV valves open. Blood now flows from the atria into the ventricles. Both the atria and the ventricles are in diastole, but the ventricular pressures continue to fall as the ventricular chambers expand. Throughout this period, pressures in the ventricles are so far below those in the major veins that blood pours through the relaxed atria and on through the open AV valves into the ventricles. This passive flow of blood is the primary method of ventricular filling. The ventricles become nearly three-quarters full before the cardiac cycle ends.

The relatively minor contribution that atrial systole makes to ventricular volume explains why individuals can survive quite normally when their atria have been so severely damaged that they can no longer function. In contrast, damage to one or both ventricles can leave the heart unable to pump enough blood through peripheral tissues and organs. A condition of **heart failure** then exists.

Heart Sounds

Listening to the heart, a technique called *auscultation* (aws-kul-TĀ-shun), is a simple and effective method of cardiac assessment. Clinicians use an instrument called a **stethoscope** to listen for normal and abnormal heart sounds. Where the

stethoscope is placed depends on which valve is under examination (**Figure 20–18a**). Valve sounds must pass through the pericardium, surrounding tissues, and the chest wall, and some tissues muffle sounds more than others. For this reason, the placement of the stethoscope differs somewhat from the position of the valve under review.

There are four heart sounds, named S_1 through S_4 (**Figure 20–18b**). Listening to the heart with a stethoscope can detect the *first* and *second heart sounds*. These sounds accompany the closing of heart valves. The first heart sound (S_1), known as “lubb,” lasts a little longer than the second (S_2), called “dupp.” S_1 marks the start of ventricular contraction when the AV valves close and the semilunar valves open. S_2 occurs at the beginning of ventricular filling when the semilunar valves close and the AV valves open. The *third* and *fourth heart sounds* are usually very faint and are seldom audible in healthy adults. These sounds are associated with blood flowing into the ventricles (S_3) and atrial contraction (S_4), rather than with valve action.

If the valve cusps are malformed or there are problems with the papillary muscles or chordae tendineae, the heart valves may not close properly. AV valve regurgitation then occurs during ventricular systole. The surges, swirls, and eddies of turbulent blood flow that accompany regurgitation create a rushing, gurgling sound known as a **heart murmur**. Minor heart murmurs are common and inconsequential.

Figure 20–18 Heart Sounds.

20-4 Cardiac output is determined by heart rate and stroke volume

Learning Outcome Define cardiac output, describe the factors that influence heart rate and stroke volume, and explain how adjustments in stroke volume and cardiac output are coordinated at different levels of physical activity.

When considering cardiac function over time, physicians generally are most interested in the **cardiac output (CO)**, the amount of blood pumped by the left ventricle in 1 minute. In essence, cardiac output is an indication of the blood flow through peripheral tissues—and without adequate blood flow, homeostasis cannot be maintained. The cardiac output provides a useful indication of ventricular efficiency over time.

Figure 20-19 summarizes the factors involved in the normal regulation of cardiac output. Cardiac output can be adjusted by changes in either heart rate or stroke volume. The **heart rate (HR)**, the number of heartbeats per minute, can be adjusted by the activities of the autonomic nervous system or by circulating hormones. **Stroke volume (SV)** is the amount of blood pumped out of a ventricle during each contraction.

We can calculate cardiac output by multiplying the heart rate by the average stroke volume:

$$\begin{array}{ccccc} \text{CO} & = & \text{HR} & \times & \text{SV} \\ \text{cardiac} & & \text{heart} & & \text{stroke} \\ \text{output} & & \text{rate} & & \text{volume} \\ (\text{mL/min}) & & (\text{beats/min}) & & (\text{mL/beat}) \end{array}$$

For example, if the heart rate is 75 bpm and the stroke volume is 80 mL per beat, the cardiac output is

$$75 \text{ bpm} \times 80 \text{ mL/beat} = 6000 \text{ mL/min (6 L/min) CO}$$

Let's look more into stroke volume, as it is the most important factor in an examination of a single cardiac cycle. Stroke volume can be expressed as $SV = EDV - ESV$, where EDV is **end-diastolic volume** and ESV is **end-systolic volume**. EDV is the amount of blood in each ventricle at the end of ventricular diastole, while ESV is the amount of blood remaining in each ventricle at the end of ventricular systole. The *ejection fraction* is the percentage of EDV that is ejected during a ventricular contraction.

If the heart were a simple hand pump, the stroke volume would be the amount of water pumped in one up–down cycle

Figure 20-19 Factors Affecting Cardiac Output.

of the handle (**Figure 20-20**). Where the handle stops when lifted determines how much water the pump contains—the EDV. How far the handle is pushed down determines how much water remains in the pump at the end of the cycle—the ESV. The maximum amount of water is pumped when the handle is pulled all the way to the top and then pushed all the way to the bottom. In other words, the largest stroke volume occurs when the EDV is as large as it can be and the ESV is as small as it can be.

The body precisely adjusts cardiac output to supply peripheral tissues with enough blood as conditions change. When necessary, the heart rate can increase by 250%, and stroke volume in a normal heart can almost double. (In addition, a variety of other factors can influence cardiac output under abnormal circumstances.) For convenience, the discussions in this section consider heart rate and stroke volume independently. However, changes in cardiac output generally reflect changes in both factors.

Factors Affecting the Heart Rate

Under normal circumstances, autonomic activity and circulating hormones make homeostatic adjustments to the heart rate as cardiovascular demands change, thereby adjusting cardiac output. These factors act by modifying the autorhythmicity of the heart. Even a heart removed for a heart transplant continues to beat unless it is kept chilled in a preservation solution.

Autonomic Innervation

The sympathetic and parasympathetic divisions of the autonomic nervous system innervate the heart by means of the nerve network known as the *cardiac plexus* (**Figure 16-6**

Figure 20–20 A Simple Model of Stroke Volume. The stroke volume of the heart can be compared to the amount of water ejected from a simple pump. The amount of water ejected varies with the amount of movement of the pump handle.

and **Figure 20–21**). Postganglionic sympathetic neurons are found in the cervical and upper thoracic ganglia. The vagus nerves (CN X) carry parasympathetic preganglionic fibers to small ganglia in the cardiac plexus. Both ANS divisions innervate the SA and AV nodes and the atrial contractile cells. Both divisions also innervate ventricular contractile cells, but sympathetic fibers far outnumber parasympathetic fibers there.

The *cardiac centers* of the medulla oblongata contain the autonomic headquarters for cardiac control. The **cardioacceleratory center** controls sympathetic neurons that increase the heart rate. The adjacent **cardioinhibitory center** controls the parasympathetic neurons that slow the heart rate. Reflex pathways regulate the cardiac centers. They also receive input from higher centers, especially from the parasympathetic and sympathetic centers in the hypothalamus.

Figure 20–21 Autonomic Innervation of the Heart.

The cardiac centers respond to changes in blood pressure as reported by baroreceptors, and to changes in arterial concentrations of dissolved oxygen and carbon dioxide as reported by chemoreceptors. For example, a decline in the blood pressure or oxygen concentration or an increase in the carbon dioxide level generally means that the heart must work harder to meet the demands of peripheral tissues. The cardiac centers then call for an increase in cardiac activity. (These reflexes and their effects on the heart and peripheral vessels are described in Chapter 21.)

Autonomic Tone. Like other organs with dual innervation, the heart has a resting autonomic tone. Both autonomic divisions are normally active at a steady background level, releasing acetylcholine (ACh) and norepinephrine (NE) at the nodes and into the myocardium. For this reason, cutting the vagus nerves increases the heart rate, and sympathetic blocking agents slow the heart rate.

Parasympathetic effects dominate in a healthy, resting individual. Without autonomic innervation, the pacemaker cells of the SA node establish the heart rate. Such a heart beats at a rate of 80–100 bpm. At rest, a typical adult heart with normal innervation beats more slowly, at 70–80 bpm, due to activity in the parasympathetic nerves innervating the SA node. If parasympathetic activity increases, the heart rate declines further. Conversely, the heart rate increases if parasympathetic activity decreases, or if sympathetic activation occurs. Through dual innervation and adjustments in autonomic tone, the ANS can make very delicate adjustments in cardiovascular function to meet the demands of other systems.

Which division of the autonomic nervous system would increase heart rate?

Tips

To remember the effect of the sympathetic nervous system on cardiac performance, remember that **s**ympathetic input **s**peeds and **s**trengthens the heartbeat.

Cardiac Reflexes. Information about the status of the cardiovascular system arrives over visceral sensory fibers accompanying the vagus nerve and the sympathetic nerves of the cardiac plexus. The cardiac centers monitor baroreceptors and chemoreceptors innervated by the glossopharyngeal (IX) and vagus (X) nerves. Based on the information received, the cardiac centers adjust the heart's activity to maintain adequate circulation to vital organs, such as the brain.

Effects on the Pacemaker Cells of the SA Node. How do the sympathetic and parasympathetic divisions alter the heart rate? They do so by changing the ionic permeabilities of cells in the conducting system. The most dramatic effects take place at the SA node, which affects the heart rate through changes in the rate at which impulses are generated.

Consider the SA node of a resting individual whose heart is beating at 75 bpm (**Figure 20–22a**). Any factor that changes the rate of spontaneous depolarization or the duration of repolarization in pacemaker cells will alter the heart rate by changing the time required for these cells to reach threshold. Acetylcholine released by parasympathetic neurons opens chemically gated K^+ channels in the plasma membrane. Then K^+ leaves the pacemaker cells, dramatically slowing their rate of spontaneous depolarization and slightly extending their duration of repolarization (**Figure 20–22b**). As a result, heart rate decreases.

Figure 20–22 Autonomic Regulation of Pacemaker Cell Function.

Norepinephrine released by sympathetic neurons binds to beta-1 receptors, leading to the opening of sodium ion and calcium ion channels. Then an influx of positively charged ions increases the rate of depolarization and shortens the period of repolarization. The pacemaker cells reach threshold more quickly, and the heart rate increases (**Figure 20–22c**).

Venous Return and the Bainbridge Reflex

Venous return is the amount of blood returning to the heart through veins. Venous return directly affects pacemaker cells. When venous return increases, the atria receive more blood and the walls are stretched. Stretching of the cardiac pacemaker cells of the SA node leads to more rapid depolarization and an increase in the heart rate.

Venous return also has an indirect effect on heart rate. The **Bainbridge reflex**, also called the *atrial reflex*, involves adjustments in heart rate in response to an increase in the venous return. When the walls of the right atrium are stretched, stretch receptors there trigger a reflexive increase in heart rate by stimulating sympathetic activity (**Figure 20–22**). Thus, when the rate of venous return to the heart increases, so does the heart rate, and for this reason the cardiac output increases as well.

Hormones and Factors Affecting Heart Rate

Epinephrine (E), norepinephrine (NE), and thyroid hormone (T_3) increase heart rate by their effects on the SA node. The effects of E on the pacemaker cells of the SA node are like those of NE. Epinephrine also affects the cardiac contractile cells. After massive sympathetic stimulation of the adrenal medullae, the myocardium may become so excitable that abnormal contractions occur. Factors that increase the heart rate are *positively chronotropic* (*chrono-*, time) and factors that decrease the heart rate are *negatively chronotropic*.

Factors Affecting the Stroke Volume

Changes in either EDV or ESV can change the stroke volume, and thus cardiac output. The factors involved in the regulation of stroke volume are indicated in **Figure 20–23**.

The End-Diastolic Volume (EDV)

Two factors affect the EDV, the amount of blood in a ventricle at the end of diastole: the filling time and the venous return. **Filling time** is the duration of ventricular diastole. It depends entirely on the heart rate: The faster the heart rate, the shorter the filling time. Venous return is variable over this period. It varies in response to changes in cardiac output, blood volume, peripheral circulation, skeletal muscle activity, and other factors that affect the rate of blood flow back to the heart. (These factors are discussed in Chapter 21.)

Preload. The degree of stretching in ventricular muscle cells during ventricular diastole is called the **preload**. The preload is directly proportional to the EDV: The greater the EDV, the

Figure 20–23 Factors Affecting Stroke Volume.

larger the preload. Preload matters because it affects the ability of muscle cells to produce tension. As sarcomere length increases past resting length, the amount of force produced during systole increases.

The amount of preload, and therefore the degree of myocardial stretching, varies with the demands on the heart. When a person is standing at rest, their EDV is low. The ventricular muscle is stretched very little, and the sarcomeres are relatively short. During ventricular systole, the cardiac contractile cells develop little power, and the ESV (the amount of blood in the ventricle after contraction) is relatively high because the contractile cells contracted only a short distance. If they begin exercising, venous return increases and more blood flows into their heart. Their EDV increases, and the myocardium stretches further. As the sarcomeres approach optimal lengths, the ventricular contractile cells can contract more efficiently and produce more forceful contractions. They also shorten more, and more blood is pumped out of the heart.

The EDV and Stroke Volume: The Frank–Starling Principle.

In general, the greater the EDV, the larger the stroke volume. Stretching the cardiac contractile cells *past* their optimal length would *reduce* the force of contraction, but this degree of stretching does not normally take place. Myocardial connective tissues, the cardiac skeleton, and the pericardium all limit the expansion of the ventricles.

The relationship between the amount of ventricular stretching and the contractile force means that, within normal physiological limits, increasing the EDV results in a corresponding increase in

the stroke volume. This general rule of “more in = more out” is known as the **Frank–Starling principle**.

Autonomic adjustments to cardiac output normally make the effects of the Frank–Starling principle difficult to see. However, the effects are more clearly seen in heart transplant patients, because the implanted heart is not innervated by the ANS. So the outputs of the left and right ventricles remain balanced under a variety of conditions.

For example, consider a person at rest, with the two ventricles ejecting equal volumes of blood. Although the ventricles contract together, they work in series: When the heart contracts, blood leaving the right ventricle heads to the lungs. During the next ventricular diastole, that volume of blood passes through the left atrium, to be ejected by the left ventricle at the next contraction. If the venous return decreases, the EDV of the right ventricle will decrease. During ventricular systole, the right ventricle will then pump less blood to the lungs. In the next cardiac cycle, the EDV of the left ventricle will be reduced, and that ventricle will eject a smaller volume of blood. The output of the two ventricles will again be in balance, but both will have smaller stroke volumes than they did initially.

The End-Systolic Volume (ESV)

After the ventricle has contracted and ejected the stroke volume, the amount of blood that remains in the ventricle at the end of ventricular systole is the ESV. Three factors that influence the ESV are preload, ventricular contractility, and afterload.

Contractility. **Contractility** is the amount of force produced during a contraction, at a given preload. Under normal circumstances, autonomic innervation or circulating hormones can alter contractility. Under special circumstances, drugs or abnormal ion concentrations in the extracellular fluid can alter contractility.

Factors that strengthen heart contraction are *positively inotropic* (ī-nō-trō-pik) (*ino-*, fiber). Factors that weaken heart contraction are *negatively inotropic*. Positive inotropic agents typically stimulate Ca^{2+} entry into cardiac contractile cells, thus increasing the force and duration of ventricular contractions. Negative inotropic agents may block Ca^{2+} movement or depress cardiac muscle metabolism. Positive and negative inotropic factors include ANS activity, hormones, and changes in extracellular ion concentrations.

Effects of Autonomic Activity on Contractility. Autonomic activity alters the degree of contraction and changes the ESV in the following ways:

- Sympathetic stimulation has a positive inotropic effect. It causes the release of norepinephrine (NE) by postganglionic fibers of the cardiac nerves and the secretion of epinephrine (E) and NE by the adrenal medullae. These hormones affect heart rate. They also stimulate alpha and beta receptors in cardiac contractile cell plasma membranes. This stimulation increases the metabolism of these cells. The net effect is that the ventricles contract more forcefully, increasing the ejection fraction and decreasing the ESV.
- Parasympathetic stimulation from the vagus nerves has a negative inotropic effect. The primary effect of acetylcholine (ACh) is at the cardiac contractile cell membrane surface, where it produces hyperpolarization and inhibition. As a result, the force of cardiac contractions is reduced. The atria show the greatest changes in contractile force because the ventricles are not extensively innervated by the parasympathetic division. However, under strong parasympathetic stimulation or with drugs that mimic ACh, the ventricles contract less forcefully, the ejection fraction decreases, and the ESV becomes larger.

Hormones Affecting Contractility. Many hormones affect heart contractility. For example, epinephrine, norepinephrine, glucagon, and thyroid hormones are positively inotropic. Before synthetic inotropic drugs were available, glucagon was used to stimulate cardiac function. It is still used in cardiac emergencies and to treat some forms of heart disease.

The drugs *isoproterenol*, *dopamine*, and *dobutamine* mimic E and NE by stimulating beta-1 receptors on cardiac contractile cells. Dopamine (at high doses) and dobutamine also stimulate Ca^{2+} entry through alpha-1 receptor stimulation. *Digitalis* elevates the intracellular Ca^{2+} concentration by interfering with Ca^{2+} removal from the cytosol of cardiac contractile cells.

Many of the drugs used to treat *hypertension* (high blood pressure) are negatively inotropic. Beta-blocking drugs such as *propranolol*, *metoprolol*, *atenolol*, and *labetalol* block beta receptors, alpha receptors, or both, and prevent sympathetic stimulation of the heart. Calcium-channel blockers such as *nifedipine* or *verapamil* are negatively inotropic.

Afterload. The **afterload** is the amount of tension that the contracting ventricle must produce to force open the semilunar valve and eject blood. Afterload increases with increased resistance to blood flow out of the ventricle. The greater the afterload, the longer the period of isovolumetric contraction, the shorter the duration of ventricular ejection, and the larger the ESV. In other words, as the afterload increases, the stroke volume decreases.

Any factor that restricts blood flow through the arterial system increases afterload. For example, either the constriction of peripheral blood vessels or a circulatory blockage elevates arterial blood pressure and increases the afterload. If the afterload is too great, the ventricles cannot eject blood. Such a high afterload is rare in a normal heart. However, damage to the heart muscle can weaken the myocardium enough that even a modest rise in arterial blood pressure can decrease the stroke volume to a dangerously low level, producing heart failure. Damage to the semilunar valve that restricts blood flow will also increase afterload.

Summary: The Control of Cardiac Output

Figure 20–24 summarizes the factors that regulate heart rate and stroke volume, which interact to determine cardiac output. The heart rate is influenced by the autonomic nervous system, circulating hormones, and venous return.

- Sympathetic stimulation increases the heart rate, and parasympathetic stimulation decreases it. Under resting conditions, parasympathetic tone dominates, and the heart rate is slightly slower than the intrinsic heart rate. When the activity level rises, venous return increases and triggers the Bainbridge reflex. The result is an increase in sympathetic tone and an increase in heart rate.
- Circulating hormones, specifically E, NE, and T_3 , accelerate heart rate.
- An increase in venous return stretches the pacemaker cells and increases heart rate.
- The stroke volume (SV) is the difference between the end-diastolic volume (EDV) and the end-systolic volume (ESV).
- The EDV is determined by the available filling time and the rate of venous return.
- The ESV is determined by the amount of preload (the degree of myocardial stretching), the degree of contractility (adjusted by hormones and autonomic innervation), and the afterload (the arterial resistance to blood flow out of the heart).

Figure 20–24 A Summary of the Factors Affecting Cardiac Output.

a Cardiac output varies widely to meet metabolic demands

b Factors affecting cardiac output

What is considered an average cardiac output when a person is resting?

During exercise, increasing both the stroke volume and the heart rate can increase the cardiac output by 300–500%, to 18–30 L/min. The difference between resting and maximal cardiac outputs is the **cardiac reserve**. Trained athletes exercising at maximal levels may increase cardiac output by nearly 700%, to 40 L/min.

Cardiac output cannot increase indefinitely, primarily because the available filling time shortens as the heart rate increases. At heart rates up to 160–180 bpm, the combination of increased venous return rate and increased contractility compensates for the reduced filling time. Over this range, cardiac output and heart rate increase together. But if the heart rate continues to climb, the stroke volume begins to drop. Cardiac output first plateaus and then declines.

The Heart and the Vessels of the Cardiovascular System

The purpose of cardiovascular regulation is to maintain adequate blood flow to all body tissues. The heart cannot accomplish this by itself, and it does not work in isolation. For example, when blood pressure changes, the cardiac centers adjust not only the heart rate but also the diameters of peripheral blood vessels. These adjustments work together to keep the blood pressure within normal limits and to maintain circulation to vital tissues and organs. (The cardiovascular responses to changing activities and circulatory emergencies are described in Chapter 21. And we complete our discussion of the cardiovascular system by examining the anatomy of the pulmonary and systemic circuits.)

20 Chapter Review

Study Outline

An Introduction to the Heart as Part of the Cardiovascular System

1. The blood vessels can be subdivided into the **pulmonary circuit** (which carries blood to and from the lungs) and the **systemic circuit** (which transports blood to and from the rest of the body).
2. **Arteries** carry blood away from the heart; **veins** return blood to the heart. **Capillaries**, or *exchange vessels*, are thin-walled, narrow-diameter vessels that connect the smallest arteries and veins. (Figure 20-1)
3. The heart has four chambers: the **right atrium** and **right ventricle**, and the **left atrium** and **left ventricle**.

20-1 The heart is a four-chambered organ that pumps blood through the pulmonary and systemic circuits

4. The heart is surrounded by the **pericardium** and lies within the anterior portion of the **mediastinum**, which separates the two pleural cavities. (Figure 20-2)
5. The pericardial cavity is lined by the **pericardium**. The **visceral layer of serous pericardium (epicardium)** covers the heart's outer surface, and the **parietal layer of serous pericardium** lines the inner surface. (Figure 20-2)
6. The **coronary sulcus**, a deep groove, marks the boundary between the atria and the ventricles. Other surface markings also provide useful reference points in describing the heart and associated structures. (Figure 20-3)
7. The bulk of the heart consists of the muscular **myocardium**. The **endocardium** lines the inner surfaces of the heart, and the **visceral layer of serous pericardium** covers the outer surface. The endothelium of the endocardium is continuous with the endothelium of the attached great vessels. (Figure 20-4)
8. The atria are separated by the **interatrial septum**, and the ventricles are divided by the **interventricular septum**. The right atrium receives blood from the systemic circuit via two large veins, the **superior vena cava** and the **inferior vena cava**. (The atrial walls contain the **pectinate muscles**, prominent muscular ridges.) (Figure 20-5)
9. Blood flows from the right atrium into the right ventricle by the **tricuspid valve (right atrioventricular valve)**. This opening is bounded by three **cusps** of fibrous tissue braced

- PhysioEx

by the **chordae tendineae**, which are connected to **papillary muscles**. (Figure 20-5)

10. Blood leaving the right ventricle enters the **pulmonary trunk** after passing through the **pulmonary valve**. The pulmonary trunk divides to form the **left** and **right pulmonary arteries**. The **left** and **right pulmonary veins** return blood from the lungs to the left atrium. Blood leaving the left atrium flows into the left ventricle through the **mitral valve (left atrioventricular valve or bicuspid valve)**. Blood leaving the left ventricle passes through the **aortic valve** and into the systemic circuit by the **ascending aorta**. (Figure 20-5)
11. Anatomical differences between the ventricles reflect the functional demands placed on them. The wall of the right ventricle is relatively thin, whereas the left ventricle has a massive muscular wall. (Figure 20-6)
12. The connective tissues of the heart (mainly collagen and elastic fibers) and the **cardiac skeleton** support the heart's valves and ventricular muscle cells. (Figure 20-7)
13. Valves normally permit blood flow in only one direction, preventing the **regurgitation** (backflow) of blood. (Figure 20-7)
14. The **coronary circulation** meets the high oxygen and nutrient demands of cardiac muscle cells. The **coronary arteries** originate at the base of the ascending aorta. Interconnections between arteries, called **arterial anastomoses**, ensure a constant blood supply. The **great, posterior, small, anterior, and middle cardiac veins** are epicardial vessels that carry blood from the coronary capillaries to the **coronary sinus**. (Figure 20-8)
15. In **coronary artery disease (CAD)**, portions of the coronary circulation undergo partial or complete blockage. A **myocardial infarction (MI)**, or heart attack, occurs when part of the coronary circulation becomes blocked and muscle tissue dies when it cannot be oxygenated. (Spotlight Figure 20-9)

20-2 The cells of the conducting system distribute electrical impulses through the heart, causing cardiac contractile cells to contract

16. Two general classes of cardiac muscle cells are involved in the normal **heartbeat: autorhythmic cells** and **contractile cells**.
17. The **conducting system** is composed of the *sinoatrial node*, the *atrioventricular node*, and *conducting cells*. The conducting system initiates and distributes electrical impulses within the heart. Nodal cells establish the rate of cardiac contraction, and conducting cells distribute the contractile stimulus from the SA node to the atrial myocardium and the AV node (along *internodal pathways*), and from the AV node to the ventricular myocardium. (Figure 20–10)
18. Unlike skeletal muscle, cardiac muscle contracts without neural or hormonal stimulation. **Pacemaker cells** in the **sinoatrial (SA) node** (*cardiac pacemaker*) normally establish the rate of contraction. From the SA node, the stimulus travels to the **atrioventricular (AV) node**, and then to the **AV bundle**, which divides into **bundle branches**. From there, **Purkinje fibers** convey the impulses to the ventricular myocardium. (Figures 20–10, 20–11)
19. A recording of electrical activities in the heart is an **electrocardiogram (ECG or EKG)**. Important landmarks of an ECG include the **P wave** (atrial depolarization), the **QRS complex** (ventricular depolarization), and the **T wave** (ventricular repolarization). (Figure 20–12)
20. **Cardiac arrhythmias** are abnormal patterns of electrical activity in the heart. (Spotlight Figure 20–13)
21. **Cardiac contractile cells** are interconnected by **intercalated discs**, which convey the force of contraction from cell to cell and conduct action potentials. (Figure 20–14; Table 20–1)
22. **Contractile cells** form the bulk of the atrial and ventricular walls. Cardiac contractile cells have a long refractory period, so rapid stimulation produces twitches rather than tetanic contractions. (Figure 20–15)

20-3 The contraction-relaxation events that occur during a complete heartbeat make up a cardiac cycle

23. The **cardiac cycle** includes periods of **atrial** and **ventricular systole** (contraction) and **atrial** and **ventricular diastole** (relaxation). (Figure 20–16)

24. When the heart beats, the two ventricles eject equal volumes of blood. (Figure 20–17)
25. The closing of valves and rushing of blood through the heart cause characteristic heart sounds, which can be heard during *auscultation*. (Figure 20–18)

20-4 Cardiac output is determined by heart rate and stroke volume

26. Cardiac output can be adjusted by changes in either heart rate or stroke volume. (Figure 20–19)
27. The amount of blood ejected by a ventricle during a single beat is the **stroke volume (SV)**. The amount of blood pumped by a ventricle each minute is the **cardiac output (CO)**. (Figure 20–20)
28. The **cardioacceleratory center** in the medulla oblongata activates sympathetic neurons; the **cardioinhibitory center** controls the parasympathetic neurons that slow the heart rate. These cardiac centers receive inputs from higher centers and from receptors monitoring blood pressure and the concentrations of dissolved gases. (Figure 20–21)
29. The basic heart rate is established by the pacemaker cells of the SA node, but it can be modified by the autonomic nervous system. The **Bainbridge reflex** (*atrial reflex*) accelerates the heart rate when the walls of the right atrium are stretched. (Figure 20–22)
30. Sympathetic activity increases the force of contraction (contractility), which reduces the ESV. Parasympathetic stimulation slows the heart rate, reduces contractility, and raises the ESV.
31. Cardiac output is affected by various factors, including autonomic innervation and hormones. (Figure 20–22)
32. The stroke volume is the difference between the **end-diastolic volume (EDV)** and the **end-systolic volume (ESV)**. The **filling time** and **venous return** interact to determine the EDV. Normally, the greater the EDV, the more powerful the succeeding contraction (the **Frank–Starling principle**). (Figure 20–23)
33. The difference between resting and maximal cardiac outputs is the **cardiac reserve**. (Figure 20–24)
34. The heart does not work in isolation in maintaining adequate blood flow to all tissues.

Review Questions

See the blue Answers tab at the back of the book.

LEVEL 1 Reviewing Facts and Terms

1. Oxygen-rich blood is delivered to the heart muscle by the (a) aorta, (b) aortic sinuses, (c) great cardiac vein, (d) coronary arteries.
2. The conducting system of the heart consists of all of the following structures *except* the (a) sinoatrial node, (b) atrioventricular node, (c) fossa ovalis, (d) atrioventricular bundle.
3. The blood supply to the left ventricle of the heart is mainly provided by the (a) right coronary artery, (b) coronary sinus, (c) left coronary artery, (d) left pulmonary veins.
4. The simple squamous epithelium covering the heart valves is the (a) epicardium, (b) endocardium, (c) myocardium, (d) endothelium.

5. What is *not* related to the right atrium? (a) fossa ovalis, (b) sinus coronarius, (c) papillary muscles, (d) pectinate muscles, (e) venae cavae.
6. The cardiac skeleton of the heart has which *two* of the following functions? (a) It physically isolates the muscle fibers of the atria from those of the ventricles. (b) It maintains the normal shape of the heart. (c) It helps distribute the forces of cardiac contraction. (d) It allows more rapid contraction of the ventricles. (e) It strengthens and helps prevent overexpansion of the heart.
7. Cardiac output is equal to the (a) difference between the end-diastolic volume and the end-systolic volume, (b) product of heart

rate and stroke volume, **(c)** difference between the stroke volume at rest and the stroke volume during exercise, **(d)** stroke volume less the end-systolic volume, **(e)** product of heart rate and blood pressure.

8. Identify the superficial structures in the following diagram of the heart.

- | | |
|-----------|-----------|
| (a) _____ | (b) _____ |
| (c) _____ | (d) _____ |
| (e) _____ | (f) _____ |
| (g) _____ | (h) _____ |

9. Identify the structures in the following diagram of a sectional view of the heart.

- | | | |
|-----------|-----------|-----------|
| (a) _____ | (b) _____ | (c) _____ |
| (d) _____ | (e) _____ | (f) _____ |
| (g) _____ | (h) _____ | (i) _____ |
| (j) _____ | (k) _____ | (l) _____ |
| (m) _____ | | |

10. The first heart sound that you hear when listening to your heart accompanies the closing of **(a)** only the bicuspid valve, **(b)** both the semilunar valves, **(c)** only the tricuspid valve, **(d)** both the atrioventricular valves.
11. Examples of positively inotropic factors are **(a)** beta-blocking drugs, **(b)** drugs mimicking epinephrine, **(c)** calcium-channel blockers, **(d)** low doses of dopamine.
12. What event takes place in the atria of the heart at birth?
13. Describe the three distinct layers that make up the heart wall.
14. What are the valves in the heart, and what is the function of each?
15. Where are the Purkinje fibers located, and what is their function?
16. What is the cardiac cycle? What phases and events are necessary to complete a cardiac cycle?
17. What three factors regulate stroke volume to ensure that the left and right ventricles pump equal volumes of blood?

LEVEL 2 Reviewing Concepts

18. The cells of the conducting system differ from the contractile cells of the heart in that **(a)** conducting cells are larger and contain more myofibrils, **(b)** contractile cells exhibit pacemaker potentials, **(c)** contractile cells do not normally exhibit autorhythmicity, **(d)** both a and b are correct.
19. In an adult who is standing at rest, which of the following is *larger*? **(a)** the end-systolic volume, **(b)** the end-diastolic volume.
20. If the papillary muscles fail to contract, **(a)** the ventricles will not pump blood, **(b)** the atria will not pump blood, **(c)** the semilunar valves will not open, **(d)** the AV valves will not close properly, **(e)** none of these happen.
21. Cardiac output cannot increase indefinitely because **(a)** the available filling time becomes shorter as the heart rate increases, **(b)** the cardiovascular centers adjust the heart rate, **(c)** the rate of spontaneous depolarization decreases, **(d)** the ion concentrations of pacemaker plasma membranes decrease.
22. Can a myocardial infarction be diagnosed through blood tests? Explain.
23. How is a constant blood supply to the heart muscle ensured?
24. What is cardiac reserve? What effect does exercise have on it?
25. From which sources does the heart obtain energy for contractions?
26. What is the meaning of the term pericarditis? Describe the possible consequences of this condition.
27. Why are compounds such as propranolol, metoprolol, atenolol, and labetalol useful in treating hypertension?

LEVEL 3 Critical Thinking and Clinical Applications

28. Elisabeth is seventy-five years old and lately she needs to take repeated moments of rest while shopping. This is often accompanied by chest pain. The doctor suspects angina pectoris. What information can he give Elisabeth?
29. Harvey has a heart murmur in his left ventricle that produces a loud "gurgling" sound at the beginning of systole. Which valve is probably faulty?
30. The following measurements were made on two individuals (the values recorded remained stable for 1 hour):
 Person 1: heart rate, 75 bpm; stroke volume, 60 mL
 Person 2: heart rate, 90 bpm; stroke volume, 95 mL
 Which person has the greater venous return? Which person has the longer ventricular filling time?
31. Karen is taking the medication verapamil, a drug that blocks the calcium channels in cardiac muscle cells. What effect should this medication have on Karen's stroke volume?

CLINICAL CASE Wrap-Up A Needle to the Chest

With the force of the head-on collision, the patient's chest first broke the seat belt and then collided with the steering wheel. This caused fractures of the anterior chest wall, including the sternum and ribs.

The heart, located just deep to the sternum, then hit the steering wheel hard enough to cause bleeding into the pericardial cavity. As the parietal and visceral pericardial linings bled into the pericardial cavity, the tough, fibrous connective tissue of the parietal layer did not expand.

The blood in the pericardial cavity compressed the heart, squeezing the atria and ventricles. During atrial diastole, the atria could not fill. This caused a backup of the venous system that was obvious in the veins of the patient's neck. The compressed ventricles could not fill with blood during ventricular diastole. Because the end-diastolic volume (EDV) was so low, the stroke volume (SV) was also very low. This was evident in

the blood pressure of 80/58, with a narrow difference between the systolic blood pressure and the diastolic blood pressure. The ultrasound confirmed fluid in the pericardial cavity that was compressing the heart.

Dr. Jim knew this victim had cardiac tamponade due to blood in the pericardial space. He also knew the problem was severe enough that with the decreasing stroke volume, the heart could not pump adequate blood to the patient's

brain. So he removed the blood from the pericardial space with a needle, a procedure known as *pericardiocentesis*, and saved this patient's life.

1. Why were the heart sounds muffled and distant?
2. What other cardiac structures were likely to be injured by this collision?

See the blue Answers tab at the back of the book.

Related Clinical Terms

artificial pacemaker: A small, battery-operated device that keeps one's heart beating in a regular rhythm. It may be permanently implanted or temporarily placed externally.

asystole: The absence of cardiac activity with no contraction and no output.

automated external defibrillator (AED): A device that, when applied, automatically checks the function of the heart. Upon detecting a condition that may respond to an electric shock, it delivers a shock to restore normal heartbeat rhythm.

automatic implantable cardioverter defibrillator (AICD): A surgically implanted battery-operated device that monitors the function of the heart. Upon detecting a condition that may respond to an electric shock, such as a disorganized heartbeat, the device delivers a shock to restore normal heartbeat rhythm.

cardiac arrest: Sudden stopping of the pumping action of the heart causing the loss of arterial blood pressure.

cardiology: The branch of medicine dealing with the diagnosis and treatment of heart disorders and related conditions.

cardiomegaly: An enlarged heart, which is a sign of some other condition such as stress, weakening of the heart muscle, coronary artery disease, heart valve problems, or abnormal heart rhythms.

cardiomyoplasty: A surgical procedure that uses stimulated latissimus dorsi muscle to assist with cardiac function. The latissimus dorsi muscle is relocated and wrapped around the left and right ventricles and stimulated to contract during cardiac systole by means of an implanted burst-stimulator.

commotio cordis: Sudden cardiac arrest as the result of a blunt hit or impact to the chest.

congestive heart failure: The heart condition of weakness, edema, and shortness of breath caused by the inability of the heart to

maintain adequate blood circulation in the peripheral tissues and the lungs.

cor pulmonale: Weakness of the right ventricle of the heart due to prolonged high blood pressure in the pulmonary artery and right ventricle; or any disease or malfunction that affects the pulmonary circuit in the lungs.

echocardiography: A noninvasive diagnostic test that uses ultrasound to make images of the heart chambers, valves, and surrounding structures. This diagnostic tool can also measure cardiac output, detect inflammation around the heart, identify abnormal anatomy, and detect infections of the heart valves.

endocarditis: Inflammation or infection of the endocardium, the inner lining of the heart muscle.

fibrillation: Fast twitching of the heart muscle fibers with little or no movement of the whole muscle. Atrial fibrillation occurs in the atria of the heart and is characterized by chaotic quivers and irregular ventricular beating with both atria and ventricles being out of synchrony.

heart block: Delay in the normal electrical pulses that cause the heart to beat.

mitral valve prolapse: A condition in which the mitral (bicuspid) valve cusps do not close properly, causing backward leaking into the left atrium from the left ventricle.

myocarditis: Inflammation of the myocardium, the middle layer of the heart wall tissue.

palpitation: Irregular and rapid beating of the heart.

percutaneous transluminal coronary angioplasty (PTCA): The surgical use of a balloon-tipped catheter to enlarge a narrowed artery.

sick sinus syndrome: A group of heart rhythm disorders or problems in which the sinoatrial node does not work properly to regulate the heart rhythms.

Blood Vessels and Circulation

Learning Outcomes

These Learning Outcomes correspond by number to this chapter's sections and indicate what you should be able to do after completing the chapter.

- 21-1 ■ Distinguish among the types of blood vessels based on their structure and function.
- 21-2 ■ Describe the factors that influence blood pressure and explain how and where fluid and dissolved materials enter and leave the cardiovascular system.
- 21-3 ■ Describe the control mechanisms that regulate blood flow and pressure in tissues, and explain how the activities of the cardiac, vasomotor, and respiratory centers are coordinated to control blood flow through the tissues.
- 21-4 ■ Identify the principal blood vessels and functions of the special circulation to the brain, heart, and lungs, and explain the cardiovascular system's homeostatic response to exercise and hemorrhaging.
- 21-5 ■ Describe the pulmonary and systemic circuits of the cardiovascular system.
- 21-6 ■ Identify the major arteries and veins of the pulmonary circuit.
- 21-7 ■ Identify the major arteries and veins of the systemic circuit.
- 21-8 ■ Identify the differences between fetal and adult circulation patterns and describe the changes in the patterns of blood flow that occur at birth.
- 21-9 ■ Discuss the effects of aging on the cardiovascular system and give examples of interactions between the cardiovascular system and other organ systems.

CLINICAL CASE

Did Ancient Mummies Have Atherosclerosis?

Dr. Iacullo is part of a research team studying ancient mummies from Egypt, Peru, New Mexico, and the Aleutian Islands in Alaska. The study spans 4000 years of human history and cultures from three different continents. Some of the mummies were once members of Egypt's upper class, while others were likely common people from the Americas. Their diets varied greatly and included nuts, berries, farmed corn, domesticated animals, wild game, sea otters, and whales. Their activity patterns varied—the wealthy Egyptians, for instance, were much more sedentary than the hunter-gatherers of the Americas.

Dr. Iacullo is studying the incidence of atherosclerosis (the buildup of arterial plaque) in mummies. Her team uses computerized tomography (CT) scans to look for calcifications in the walls of the mummies' arteries. They discover that one-third of the mummies have CT evidence of plaque buildup. This finding spans all four geographic populations, all diets, and all lifestyle activity levels. **Why do you think these ancient people developed atherosclerosis, which today we usually associate with the unhealthy diet and inactivity of a modern lifestyle? To find out, turn to the Clinical Case Wrap-Up at the end of the chapter.**

An Introduction to Blood Vessels and Circulation

Blood circulates throughout the body, moving from the heart through the tissues and back to the heart, in tubular structures called *blood vessels*. In this chapter we examine the organization of blood vessels and consider the integrated functions of the cardiovascular system. We begin with the histology of *arteries*, *capillaries*, and *veins*. Then we examine the functions of these vessels, the basic principles of cardiovascular regulation, and the distribution of major blood vessels in the body.

21

21-1 Arteries, which are elastic or muscular, and veins, which contain valves, have three-layered walls; capillaries have thin walls with only one layer

Learning Outcome Distinguish among the types of blood vessels based on their structure and function.

The cardiovascular system has five general classes of blood vessels: arteries, arterioles, capillaries, venules, and veins. **Arteries** carry blood away from the heart. As they enter peripheral tissues, they branch repeatedly, and the branches decrease in diameter. The smallest arterial branches are called **arterioles** (ar-TĒR-ē-ōlz). From the arterioles, blood moves into **capillaries**, where diffusion between blood and interstitial fluid takes place. From the capillaries, blood enters small **venules** (VEN-yūlz), which unite to form larger **veins** that return blood to the heart.

Blood leaves the heart through the pulmonary trunk (which originates at the right ventricle) and the aorta (which originates at the left ventricle). The pulmonary arteries that branch from the pulmonary trunk carry blood to the lungs. The systemic arteries that branch from the aorta distribute blood to all other organs. Within these organs, the vessels

branch into several hundred million tiny arterioles that supply blood to more than 10 billion capillaries. Capillaries are barely the diameter of a single red blood cell. If all the capillaries in the body were placed end to end, their combined length would be more than 25,000 miles—enough to circle the planet!

Blood vessels must be resilient enough to withstand changes in pressure and flexible enough to move with underlying tissues and organs. The pressures inside vessels vary with distance from the heart, and the structures of different vessels reflect this fact. The functional differences between arteries, veins, and capillaries are associated with distinctive anatomical features.

Vessel Wall Structure in Arteries and Veins

The walls of arteries and veins have three distinct layers, from deep to superficial—the *tunica intima*, *tunica media*, and *tunica externa* (**Figure 21-1**):

1. The **tunica intima** (IN-ti-muh) is the inner layer of a blood vessel. It includes the endothelial lining and a surrounding layer of connective tissue with a variable number of elastic fibers. In arteries, the outer margin of the tunica intima contains a thick layer of elastic fibers called the **internal elastic membrane**.
2. The **tunica media** is the middle layer of a blood vessel. It contains concentric sheets of smooth muscle tissue in a framework of loose connective tissue. The collagen fibers bind the tunica media to the tunica intima and tunica externa. The tunica media is commonly the thickest layer in a small artery. It is separated from the surrounding tunica externa by a thin band of elastic fibers called the **external elastic membrane**. The smooth muscle cells of the tunica media encircle the endothelium that lines the **lumen** (interior space) of the blood vessel. Large arteries also contain layers of longitudinally arranged smooth muscle cells.

Figure 21–1 Comparison of a Typical Artery and a Typical Vein.

Feature	Typical Artery	Typical Vein
GENERAL APPEARANCE IN SECTIONAL VIEW	Usually round, with relatively thick wall	Usually flattened or collapsed, with relatively thin wall
TUNICA INTIMA		
Endothelium	Usually rippled, due to vessel constriction	Often smooth
Internal elastic membrane	Present	Absent
TUNICA MEDIA		
External elastic membrane	Present	Absent
TUNICA EXTERNA		
	Collagen and elastic fibers	Collagen and elastic fibers and smooth muscle cells

3. The **tunica externa** (eks-TER-nuh), or *tunica adventitia* (ad-ven-TISH-uh), is the outer layer of a blood vessel. It is a protective sheath of connective tissue. In arteries, it contains collagen fibers with scattered bands of elastic fibers. In veins, it is generally thicker than the tunica media and contains networks of elastic fibers and bundles of smooth muscle cells. The connective tissue fibers of the tunica externa typically blend into those of adjacent tissues, stabilizing and anchoring the blood vessel.

Their layered walls give arteries and veins considerable strength. The muscular and elastic components also permit controlled changes in diameter as blood pressure or blood volume changes. When the smooth muscle of the tunica media contracts, the vessel decreases in diameter, and when it relaxes, the diameter increases. However, the walls of arteries and veins are too thick to allow diffusion between the bloodstream and surrounding tissues, or even between the blood and the tissues of the vessel itself. For this reason, the walls of large vessels contain

small arteries and veins that supply the smooth muscle cells and fibroblasts of the tunica media and tunica externa. These blood vessels are called the **vasa vasorum** ("vessels of vessels").

Differences between Arteries and Veins

Arteries and veins supplying the same region lie side by side (**Figure 21–1**). In sectional view, arteries and veins can be distinguished by the following features:

- **Vessel Walls.** In general, the walls of arteries are thicker than the walls of veins. The tunica media of an artery contains more smooth muscle and elastic fibers than a vein does. These components help resist the arterial pressure generated by the heart as it pumps blood into the pulmonary trunk and aorta.
- **Vessel Lumen.** When not opposed by blood pressure, the elastic fibers in the arterial walls recoil, which constricts the lumen. Thus, seen on dissection or in sectional view, the lumen of an artery often looks smaller than that of the

corresponding vein. Because the walls of arteries are relatively thick and strong, they keep their circular shape when sectioned. In contrast, cut veins tend to collapse. In section, veins often look flattened.

- **Vessel Lining.** The endothelial lining of an artery cannot contract, so when an artery constricts, its endothelium folds. Therefore, the sectioned arteries have a pleated appearance. The lining of a vein lacks these folds.
- **Valves.** Veins typically contain *valves*—internal structures that prevent the backflow of blood toward the capillaries. In a vein, the valve appears as a slight swelling of the vessel wall.

Arteries

There are three main types of arteries: elastic, muscular, and arterioles. Their relatively thick, muscular walls make arteries elastic and contractile. Elasticity allows the vessel diameter to change passively in response to changes in blood pressure. For example, it allows arteries to absorb the surging pressure waves that accompany the contractions of the ventricles. Arteries carry blood under great pressure, and their walls are adapted to handle that pressure.

When arterial walls actively change diameter, this change takes place by actions of the sympathetic nervous system. When stimulated, arterial smooth muscles contract, constricting the artery—a process called **vasoconstriction**. When these smooth muscles relax, the diameter of the lumen increases—a process called **vasodilation**. Vasoconstriction and vasodilation affect (1) the afterload on the heart, (2) peripheral blood pressure, and (3) capillary blood flow. We discuss these effects in Section 21-3. Vessel contractility is also important during the vascular phase of hemostasis, when the contraction of a damaged vessel wall helps reduce bleeding.

In traveling from the heart to peripheral capillaries, blood passes through *elastic arteries*, *muscular arteries*, and *arterioles* (**Figure 21-2**). Keep in mind that vessel characteristics change gradually with distance from the heart. Each type of vessel described here actually represents the midpoint in a portion of a continuum. For example, the largest muscular arteries contain a considerable amount of elastic tissue, and the smallest resemble heavily muscled arterioles.

Elastic Arteries

Elastic arteries carry large volumes of blood away from the heart. They are large vessels with an internal, or *luminal*, diameter up to 2.5 cm (1 in.) (**Figure 21-2**). The pulmonary trunk and aorta, as well as their major branches (the *pulmonary*, *common carotid*, *subclavian*, and *common iliac arteries*), are elastic arteries.

The walls of elastic arteries are extremely resilient because the tunica media contains a high density of elastic fibers and

relatively few smooth muscle cells. As a result, elastic arteries can tolerate the pressure changes of the cardiac cycle. Recall that *elastic rebound* in the aorta helps to maintain blood flow in the coronary arteries. Elastic rebound also occurs to some degree in all elastic arteries. During ventricular systole, pressures rise rapidly and the elastic arteries expand as the stroke volume is ejected. During ventricular diastole, blood pressure within the arterial system falls and the elastic fibers recoil to their original dimensions. Their expansion cushions the sudden rise in pressure during ventricular systole, and their recoil slows the drop in pressure during ventricular diastole. In this way, elastic arteries help to make blood flow continuous.

This function is important because blood pressure is the driving force behind blood flow: The greater the fluctuations in pressure, the greater the changes in blood flow. The elasticity of the arterial system dampens the pressure peaks and valleys that accompany the heartbeat. By the time blood reaches the arterioles, the pressure fluctuations have disappeared, and blood flow is continuous.

Muscular Arteries

Muscular arteries, or *medium-sized arteries*, distribute blood to the body's skeletal muscles and internal organs. Most vessels of the arterial system are muscular arteries. They are characterized by a thick tunica media, which contains more smooth muscle cells than the tunica media of elastic arteries (**Figure 21-2**). A typical muscular artery has a luminal diameter of approximately 4 mm (0.16 in.), but some have diameters as small as 0.5 mm. The *external carotid arteries* of the neck, the *brachial arteries* of the arms, the *mesenteric arteries* of the abdomen, and the *femoral arteries* of the thighs are examples of muscular arteries.

Superficial muscular arteries are important as *pressure points*—places in the body where muscular arteries can be pressed against deeper bones to reduce blood flow and control severe bleeding. Major arterial pressure points are the common carotid, radial, brachial, femoral, popliteal, posterior tibial, and dorsal pedal.

Arterioles

Arterioles, with an internal diameter of 30 μm or less, are considerably smaller than muscular arteries. Arterioles have a poorly defined tunica externa. In the larger arterioles, the tunica media consists of one or two layers of smooth muscle cells (**Figure 21-2**). The wall of an arteriole with a luminal diameter of 30 μm can have a 20 μm -thick layer of smooth muscle. In the smallest arterioles, the tunica media contains scattered smooth muscle cells that do not form a complete layer.

The luminal diameters of smaller muscular arteries and arterioles change in response to local conditions or to sympathetic or endocrine stimulation. For example, arterioles in most tissues

Figure 21–2 Histological Structure of Blood Vessels. Representative diagrammatic views of arteries, veins, and capillaries. The relative proportions of wall thickness to luminal diameter are not drawn to scale.

Which type of blood vessel has (a) the largest lumen and (b) the thickest tunica media?

+ Clinical Note Arteriosclerosis

Arteriosclerosis (ar-tēr-ē-ō-skler-ō-sis; *arterio-*, artery + *sklerosis*, hardness) is a thickening and toughening of arterial walls. Complications related to arteriosclerosis account for about half of all deaths in the United States. For example, arteriosclerosis of coronary vessels causes *coronary artery disease* (CAD), and arteriosclerosis of arteries supplying the brain can lead to strokes, or *cerebrovascular accidents* (CVAs).

Arteriosclerosis takes two major forms:

- **Atherosclerosis** (ath-er-ō-skler-ō-sis; *athero-*, fatty) is the formation of lipid deposits (plaque) in the tunica media associated with damage to the endothelial lining. It is the most common form of arteriosclerosis.
- **Focal calcification** is the deposition of calcium salts following the gradual degeneration of smooth muscle in the tunica media. Some focal calcification is a part of the aging process. It may also develop in association with atherosclerosis.

Note the images below. A normal coronary artery is shown in **image a**, and a typical lesion, called a *plaque* (PLAK), is shown in **images b** and **c**. Older people—especially older males—are most likely to develop atherosclerotic plaques. Estrogen may slow plaque formation. After menopause, when estrogen production decreases, the risks of coronary artery

disease, myocardial infarctions (heart attacks), and cerebrovascular accidents in females increase markedly.

In addition to advanced age and male sex, other important risk factors for atherosclerosis include high blood cholesterol level, high blood pressure, and cigarette smoking. Diabetes mellitus, obesity, and stress can promote the development of atherosclerosis in both males and females. Evidence also indicates that at least some forms of atherosclerosis may be linked to chronic infection with *Chlamydia pneumoniae*, a bacterium responsible for several types of respiratory infections, including some forms of pneumonia.

Potential treatments for atherosclerotic plaques include catheterization with balloon angioplasty and stenting, and bypass surgery. In the many cases where changes in diet do not lower circulating cholesterol level sufficiently, medications can bring them under control.

Without question, the best approach to atherosclerosis is avoidance—by eliminating or reducing associated risk factors. Suggestions include (1) reducing the intake of dietary cholesterol, saturated fats, and *trans* fatty acids by restricting consumption of fatty meats, egg yolks, and cream; (2) not smoking; (3) checking one's blood pressure and taking steps to lower it if necessary; (4) having one's blood cholesterol level checked annually; (5) controlling one's weight; and (6) exercising regularly.

c A section of a coronary artery narrowed by plaque formation

vasodilate when the blood oxygen level is low. Also, arterioles vasoconstrict under sympathetic stimulation. Changes in their luminal diameter affect the amount of force required to push blood throughout the cardiovascular system: More pressure is required to push blood through a constricted vessel than through a dilated one. The force opposing blood flow is called *resistance*. For this reason, arterioles are also called **resistance vessels**.

Occasionally, local blood pressure exceeds the capacity of the elastic arterial walls. The result is an **aneurysm** (AN-yū-rizm), or bulge in the weakened arterial wall. The bulge is like a bubble in the wall of a tire—and like a bad tire, the artery can have a catastrophic blowout. The most dangerous aneurysms occur in arteries of the brain (where they cause strokes) or in the aorta (where a rupture will cause fatal bleeding in a matter of minutes).

Capillaries

When considering the cardiovascular system, we think first of the heart or the great blood vessels connected to it. But the microscopic capillaries that permeate most tissues do the real work of the cardiovascular system. These delicate vessels weave throughout active tissues, forming intricate networks that surround muscle fibers. Capillaries radiate through connective tissues and branch beneath the basement membrane of epithelia.

A typical capillary consists of an endothelial tube inside a thin basement membrane. Neither a tunica media nor tunica externa is present (**Figure 21-2**). The average luminal diameter of a capillary is a mere 8 μm , very close to that of a single red blood cell.

Types of Capillaries

The two major types of capillaries are *continuous capillaries* and *fenestrated capillaries*. *Sinusoids* are a third type of capillary, related in structure and function to fenestrated capillaries.

Continuous Capillaries. Continuous capillaries supply most regions of the body. In a **continuous capillary**, the endothelium

is a complete lining. A cross section through a wide continuous capillary cuts across several endothelial cells (**Figure 21-3a**). In a narrow continuous capillary, a single endothelial cell may completely encircle the lumen.

Continuous capillaries are found in all tissues except epithelia and cartilage. Continuous capillaries permit water, small solutes, and lipid-soluble substances to diffuse into the interstitial fluid. At the same time, they prevent the loss of blood cells and plasma proteins. In addition, some exchange may occur between blood and interstitial fluid by *bulk transport*—the movement of materials by endocytosis or exocytosis at the inner endothelial surface.

In specialized continuous capillaries in most of the central nervous system and in the thymus, the endothelial cells are bound together by tight junctions. These capillaries have very restricted permeability. We discussed one example—the capillaries responsible for the *blood-brain barrier*—in Chapters 12 and 14.

Fenestrated Capillaries. **Fenestrated** (FEN-es-trā-ted; *fenestra*, window) **capillaries** contain “windows,” or pores, that penetrate the endothelial lining (**Figure 21-3b**).

Figure 21-3 Capillary Structure.

The pores allow rapid exchange of water and solutes between blood and interstitial fluid. Examples of fenestrated capillaries include the *choroid plexus* of the brain and the blood vessels in a variety of endocrine organs, such as the hypothalamus and the pituitary, pineal, and thyroid glands. Fenestrated capillaries are also found along absorptive areas of the intestinal tract and at filtration sites in the kidneys. Both the number of pores and their permeability vary from one region of the capillary to another.

Sinusoids. Sinusoids (SĪ-nuh-soydz), or **sinusoidal capillaries**, resemble fenestrated capillaries that are flattened and irregularly shaped (**Figure 21-3c**). In contrast to continuous and fenestrated capillaries, they have a discontinuous endothelium. In addition to being fenestrated, sinusoids commonly have gaps between adjacent endothelial cells, and the basement membrane is either thinner or absent. As a result, sinusoids permit the free exchange of water and solutes, such as plasma proteins, between blood and interstitial fluid.

Blood moves through sinusoids relatively slowly, maximizing the time available for exchange across the sinusoidal walls. Sinusoids occur in the liver, bone marrow, spleen, and

many endocrine organs, including the pituitary and adrenal glands. At liver sinusoids, plasma proteins secreted by liver cells enter the bloodstream. Along sinusoids of the liver, spleen, and bone marrow, phagocytic cells monitor the passing blood, engulfing damaged red blood cells, pathogens, and cellular debris.

Capillary Beds

Capillaries function as part of an interconnected network called a **capillary bed** (**Figure 21-4**). A single arteriole generally gives rise to dozens of capillaries, which empty into several venules. A **precapillary sphincter** surrounds the entrance of a capillary and controls arterial blood flow to the tissues. Contraction of the smooth muscle cells of this sphincter narrows the capillary entrance, reducing or stopping the flow of blood. When one precapillary sphincter constricts, blood is diverted into other branches of the network. When a precapillary sphincter relaxes, the entrance dilates, and blood flows into the capillary. The central passageway in the arteriole system is the **thoroughfare channel**. Blood flow through this channel is controlled by the sphincter effect of the arteriole.

Figure 21-4 The Organization of a Capillary Bed.

a A typical capillary bed. Solid arrows indicate consistent blood flow; dashed arrows indicate variable or pulsating blood flow.

b A micrograph of a number of capillary beds.

Anastomoses and Angiogenesis

More than one artery may supply blood to a capillary bed. The multiple arteries are called **collaterals**. They fuse before giving rise to arterioles. The fusion of two collateral arteries that supply a capillary bed is an example of an **arterial anastomosis**. (An *anastomosis* is the joining of blood vessels.) An arterial anastomosis acts like an insurance policy: If one artery is blocked, capillary circulation will continue. The interconnections between the *anterior* and *posterior interventricular arteries* of the heart are arterial anastomoses.

Arteriovenous (ar-tēr-ē-o-VĒ-nus) **anastomoses** are direct connections between arterioles and venules. When an arteriovenous anastomosis is dilated, blood bypasses the capillary bed and flows directly into the venous circulation. The pattern of blood flow through an arteriovenous anastomosis is regulated primarily by sympathetic innervation under the control of the cardiovascular center of the medulla oblongata.

Angiogenesis (an-jē-ō-JEN-e-sis; *angio-*, blood vessel + *genesis*, production) is the formation of new blood vessels from preexisting vessels and occurs under the direction of **vascular endothelial growth factor (VEGF)**. Angiogenesis occurs during embryonic and fetal development as tissues and organs develop. It may also occur at other times in any body tissue in response to factors released by oxygen-starved cells. Clinically, angiogenesis is probably most important in cardiac muscle, where it takes place in response to a chronically constricted or occluded vessel.

Veins

Veins collect blood from all tissues and organs and return it to the heart. The walls of veins can be thinner than those of corresponding arteries because the blood pressure in veins is lower than that of arteries. We classify veins based on their size. Even though their walls are thinner, in general veins have larger luminal diameters than their corresponding arteries (**Figure 21-2**).

Types of Veins

Types of veins include venules, medium-sized veins, and large veins.

Venules. Venules, which are the smallest veins, collect blood from capillary beds. They vary widely in size and structure. An average venule has a luminal diameter about 20 μm . Venules thinner than 50 μm lack a tunica media, and the smallest venules resemble expanded capillaries.

Medium-Sized and Large Veins. **Medium-sized veins** are comparable in size to muscular arteries. They range from 2 to 9 mm in luminal diameter. Their tunica media is thin and contains relatively few smooth muscle cells. The thickest layer of a medium-sized vein is the tunica externa, which contains longitudinal bundles of elastic and collagen fibers.

Large veins include the superior and inferior venae cavae and their branches within the abdominopelvic and thoracic cavities. All large veins have all three layers. The slender tunica media is surrounded by a thick tunica externa composed of a mixture of elastic and collagen fibers.

Venous Valves

The arterial system is a high-pressure system: Almost all the force developed by the heart is required to push blood along the network of arteries and through miles of capillaries. In contrast, blood pressure in a peripheral venule is only about 10% of that in the ascending aorta, and pressures continue to fall along the venous system.

The blood pressure in venules and medium-sized veins is so low that it cannot overcome the force of gravity. In the limbs, veins of this size contain **valves**, folds of the tunica intima that project from the vessel wall into the lumen and point in the direction of blood flow. These valves, like those in the heart, permit blood flow in one direction only. Venous valves prevent blood from moving back toward the capillaries (**Figure 21-5**).

If the valves function normally, any movement that compresses a vein pushes blood toward the heart. This effect improves *venous return*, the amount of blood per unit of time returning to the heart. Valves compartmentalize the blood within the veins, dividing the weight of the blood among the compartments.

Figure 21-5 The Function of Valves in the Venous System.

If the walls of the veins near the valves weaken or become stretched, the valves may not work properly. Blood then pools in the veins, and the vessels become grossly distended. The effects range from mild discomfort and a cosmetic problem, as in superficial *varicose veins* in the thighs and legs, to painful distortion of adjacent tissues, as in **hemorrhoids** (HEM-uh-roydz).

The Distribution of Blood

A person's total blood volume is unevenly distributed among their arteries, veins, and capillaries (**Figure 21–6**). The heart, arteries, and capillaries in the pulmonary and systemic circuits normally contain 30–35% of the blood volume (approximately 1.5 liters of whole blood). The venous system contains the rest (65–70%, or about 3.5 liters). About one-third of the blood in the venous system (about a liter) is circulating within the liver, bone marrow, and skin. These organs have extensive venous networks that at any moment contain large volumes of blood.

Veins are much more *distensible*, or expandable, than arteries because their walls are thinner, with less smooth muscle. For a given rise in blood pressure, a typical vein stretches about eight times as much as a corresponding artery. The *capacitance* of a blood vessel is the relationship between the volume of blood it contains and the blood

pressure. Veins behave like a balloon, expanding easily at low pressures, and they have high capacitance. Arteries behave more like a truck tire, expanding only at high pressures, and they have low capacitance. Veins are called **capacitance vessels**. Because veins have high capacitance, they act as **blood reservoirs**, which can accommodate large changes in blood volume. If the blood volume rises or falls, the elastic walls stretch or recoil, changing the volume of blood in the venous system.

If serious hemorrhaging (profuse blood loss) occurs, sympathetic nerves stimulate smooth muscle cells in the walls of medium-sized veins in the systemic system to constrict. This process, called **venoconstriction** (vē-nō-kon-STRIK-shun), decreases the volume of blood within the venous system, increasing the volume within the arterial system and capillaries. Venoconstriction can keep the blood volume within the arteries and capillaries close to normal levels despite a significant blood loss. As a result, blood flow to active skeletal muscles and delicate organs, such as the brain, can be increased or maintained.

Checkpoint

1. List the five general classes of blood vessels.
2. Which type of vessel is characterized by thin walls with very little smooth muscle tissue in the tunica media?
3. Why are valves in veins but not in arteries?
4. Where in the body are fenestrated capillaries found?

See the blue Answers tab at the back of the book.

Figure 21–6 The Distribution of Blood in the Cardiovascular System.

Clinical Note Varicose Veins

Distended veins run like thick, blue ropes up the lower leg and popliteal region in some people. These **varicose veins** have a familial link and are more commonly found in people who stand for long time periods. The veins may be considered unsightly, but superficial varicose veins are only a cosmetic issue. Minimally invasive techniques such as *sclerotherapy* (the injection of an irritant chemical) can shut down the dilated veins and improve the appearance of the legs.

However, varicosity of deep leg veins poses a threat. Here venous blood flow slows to a crawl and triggers coagulation. The result is **deep vein thrombosis (DVT)**. The *thrombus*, or clot, can impair venous return to the right atrium. Worse still, multiple DVTs can dislodge and become *emboli*, or traveling clots. The clots may end up in the lungs, producing a potentially fatal condition called **pulmonary embolism**.

21-2 Pressure and resistance determine blood flow and affect rates of capillary exchange

Learning Outcome Describe the factors that influence blood pressure and explain how and where fluid and dissolved materials enter and leave the cardiovascular system.

Adequate amounts of blood must flow to the capillary beds in organs and peripheral tissues. Under normal circumstances, blood flow is equal to cardiac output. When cardiac output increases, blood flow through capillary beds increases, and when cardiac output decreases, capillary blood flow decreases.

Introduction to Pressure and Flow in Blood Vessels

Capillary blood flow is determined by the interplay between **pressure (P)** and **resistance (R)** in the cardiovascular network. To keep blood moving, the heart must generate enough pressure to overcome the resistance to blood flow in the pulmonary and systemic circuits. In general terms, **flow (F)** is directly proportional to the pressure (increased pressure → increased flow), and inversely proportional to resistance (increased resistance → decreased flow). However, the absolute pressure is less important than the pressure *gradient*—the difference in pressure from one end of the vessel to the other. This relationship can be summarized as

$$F \propto \frac{\Delta P}{R}$$

where the symbol $\propto$ means “is proportional to” and Δ (the Greek symbol *delta*) means “difference” or “change.” The largest pressure gradient is found between the base of the aorta and the proximal ends of peripheral capillary beds. The cardiovascular center can alter this pressure gradient, and change the rate of capillary blood flow, by adjusting cardiac output and peripheral resistance.

Blood leaving the peripheral capillaries enters the venous system. The pressure gradient across the venous system is relatively small, but venous resistance is very low. The low venous blood pressure—aided by valves, skeletal muscle contraction, gravity, and other factors—is enough to return the blood to the heart. When necessary, however, cardiovascular control centers can raise venous pressure (by venoconstriction) to improve venous return and maintain adequate cardiac output.

We begin this section by examining blood pressure and resistance more closely. We then consider the mechanisms of *capillary exchange*, the transfer of liquid and solutes between the blood and interstitial fluid. Capillary exchange provides tissues with oxygen and nutrients and removes the carbon dioxide and wastes generated by active cells.

Active tissues need more blood flow than inactive ones. Even something as simple as a change in position—going from sitting to standing, for instance—triggers several cardiovascular

changes. This section ends with a discussion of what those cardiovascular changes are and how they are coordinated.

Pressures Affecting Blood Flow

When talking about cardiovascular pressures, three values are important:

- **Blood Pressure.** The term **blood pressure (BP)** refers to arterial pressure, usually reported in millimeters of mercury (mm Hg). Systemic arterial pressures in adults average 120 mm Hg at the entrance to the aorta to about 35 mm Hg at the start of a capillary network.
- **Capillary Hydrostatic Pressure.** *Hydrostatic pressure* is the force exerted by a fluid pressing against a wall. **Capillary hydrostatic pressure (CHP)**, or *capillary pressure*, is the pressure of blood within capillary walls. Along the length of a typical capillary, pressures decrease from approximately 35 mm Hg to about 18 mm Hg.
- **Venous Pressure.** **Venous pressure** is the pressure of the blood within the venous system. Venous pressure is quite low: The pressure gradient from the venules to the right atrium is only about 18 mm Hg.

The difference in pressure (ΔP) across the entire systemic circuit, sometimes called the *circulatory pressure*, averages about 100 mm Hg.

Total Peripheral Resistance

For circulation to occur, the circulatory pressure must overcome the **total peripheral resistance**—the resistance of the entire cardiovascular system. The arterial network has by far the largest pressure gradient (85 mm Hg), and this primarily reflects the relatively high resistance of the arterioles. The total peripheral resistance of the cardiovascular system reflects a combination of factors: *vascular resistance*, *blood viscosity*, and *turbulence*.

Vascular Resistance

Vascular resistance, the forces that oppose blood flow in the blood vessels, is the largest component. The most important factor in vascular resistance is **friction** between blood and the vessel walls. The degree of friction depends on two features: vessel length and internal vessel diameter (**Figure 21-7**).

Vessel Length. Increasing the length of a blood vessel increases friction: The longer the vessel, the greater the surface area in contact with blood. For example, a person can easily blow the water out of a snorkel that is 2.5 cm (1 in.) in diameter and 25 cm (10 in.) long, but not out of a 15-m (16-yard)-long garden hose, because the total friction is too great. The most dramatic changes in blood vessel length occur between birth and maturity, as individuals grow to adult size. In adults, vessel length can increase or decrease gradually when individuals

Figure 21-7 Factors Affecting Friction and Vascular Resistance.

Which of the following would *increase* vascular resistance? increased vessel length, increased vessel luminal diameter, turbulence.

gain or lose weight, but on a day-to-day basis this component of vascular resistance can be considered constant.

Vessel Luminal Diameter. The effects of friction on blood act in a narrow zone closest to the internal vessel wall. In a small-diameter vessel, friction with the luminal wall slows nearly all the blood flow. Resistance is therefore relatively high.

Blood near the center of a large-diameter vessel does not encounter friction with the luminal wall, so the resistance in large vessels is low.

Differences in diameter have much more significant effects on resistance than do differences in length. If two vessels are equal in radius (one-half the diameter) but one is twice the length of the other, the longer vessel offers twice as much resistance to blood flow. But for two vessels of equal length, one twice the radius of the other, the narrower one offers 16 times as much resistance to blood flow. This relationship, expressed in terms of the vessel radius r and resistance R , can be summarized as $R \propto 1/r^4$.

More significantly, there is no way to control vessel length, but vessel luminal diameter can change quickly through vasoconstriction or vasodilation. Most of the peripheral resistance occurs in arterioles. When their smooth muscles contract or relax, peripheral resistance increases or decreases, respectively. Because a small change in luminal diameter produces a large change in resistance, mechanisms that alter the diameters of arterioles provide control over peripheral resistance and blood flow.

Blood Viscosity

Viscosity is the resistance to flow caused by interactions among molecules and suspended materials in a liquid. Liquids of low viscosity, such as water flow at low pressures. Syrupy fluids, such as molasses flow only under higher pressures. Whole blood has a viscosity about ten times that of water, due to its plasma proteins and blood cells. Under normal conditions, the viscosity of blood remains stable. Anemia, polycythemia, and other disorders that affect the hematocrit also change blood viscosity, and thus peripheral resistance.

Turbulence

High flow rates, irregular surfaces, and sudden changes in vessel luminal diameter upset the smooth flow of blood, creating eddies and swirls. This phenomenon, called **turbulence**, increases resistance and slows blood flow.

Turbulence normally occurs when blood flows between the atria and the ventricles, and between the ventricles and the aortic and pulmonary trunks. It also develops in large arteries, such as the aorta, when cardiac output and arterial flow rates are very high. However, turbulence seldom occurs in smaller vessels unless their walls are damaged. For example, an atherosclerotic plaque creates abnormal turbulence and restricts blood flow (**Figure 21-7**). Because turbulence makes a distinctive sound, or *bruit* (brū-Ē), plaques in large blood vessels can often be detected with a stethoscope.

Table 21-1 provides a review of the terms and relationships discussed in this section.

Table 21–1 Key Terms and Relationships Pertaining to Blood Circulation

Blood flow (F)	The volume of blood flowing per unit of time through a vessel or a group of vessels; may refer to circulation through a capillary, a tissue, an organ, or the entire vascular network. Total blood flow is equal to cardiac output.
Blood pressure (BP)	The hydrostatic pressure in the arterial system that pushes blood through capillary beds.
Circulatory pressure	The pressure difference between the base of the ascending aorta and the entrance to the right atrium.
Hydrostatic pressure	A pressure exerted by a liquid in response to an applied force.
Peripheral resistance (PR)	The resistance of the arterial system; affected by such factors as vascular resistance, viscosity, and turbulence.
Resistance (R)	A force that opposes movement (in this case, blood flow).
Total peripheral resistance	The resistance of the entire cardiovascular system.
Turbulence	A resistance due to the irregular, swirling movement of blood at high flow rates or exposure to irregular surfaces.
Vascular resistance	A resistance due to friction within a blood vessel, primarily between the blood and the vessel walls. Increases with increasing length or decreasing diameter; vessel length is constant, but vessel diameter can change.
Venous pressure	The hydrostatic pressure in the venous system.
Viscosity	A resistance to flow due to interactions among molecules within a liquid.
RELATIONSHIPS AMONG THE PRECEDING TERMS	
$F \propto \Delta P$	Flow is proportional to the pressure gradient.
$F \propto 1/R$	Flow is inversely proportional to resistance.
$F \propto \Delta P/R$	Flow is directly proportional to the pressure gradient, and inversely proportional to resistance.
$F \propto BP/PR$	Flow is directly proportional to blood pressure, and inversely proportional to peripheral resistance.
$R \propto 1/r^4$	Resistance is inversely proportional to the fourth power of the vessel radius.

An Overview of Cardiovascular Pressures

The graphs in **Figure 21–8** provide an overview of the vessel luminal diameters, cross-sectional area of vessel lumen, pressures, and velocity of blood flow in the systemic circuit.

- **Vessel Luminal Diameters.** As blood flows from the aorta toward the capillaries, vessels diverge. The arteries branch repeatedly, and each branch is smaller in luminal diameter than the preceding one (**Figure 21–8a**). As blood flows from the capillaries toward the venae cavae, vessels converge. Vessel luminal diameters increase as venules combine to form small and medium-sized veins.
- **Total Cross-Sectional Areas.** Although arterioles, capillaries, and venules are small in luminal diameter, the body has large numbers of them. All the blood flowing through the aorta also flows through peripheral capillaries. Blood pressure and the speed of blood flow are proportional to the cross-sectional area of the vessels involved. What is important is not the cross-sectional area of each individual vessel, but the *combined* cross-sectional area of *all* the vessel lumens (**Figure 21–8b**). In effect, blood moves from one big pipe (the aorta, with a cross-sectional area of 4.5 cm²) into countless tiny ones (the peripheral capillaries, with a total cross-sectional area of 5000 cm²), and then blood travels back to the heart through two large pipes (the venae cavae).
- **Pressures.** As arteries branch, their total cross-sectional area increases, and blood pressure falls rapidly (**Figure 21–8c**). Most of the decline takes place in the small arteries and arterioles. Venous pressures are relatively low.

- **Velocity of Blood Flow.** As the total cross-sectional area of the vessel lumens increases from the aorta toward the capillaries, the velocity of blood flow decreases (**Figure 21–8d**). Blood flow velocity then increases as the total cross-sectional area decreases from the capillaries toward the venae cavae.

Figure 21–9 illustrates the blood pressure throughout the cardiovascular system. Systemic pressures are highest in the aorta, peaking at about 120 mm Hg. Pressures reach a minimum of 2 mm Hg at the entrance to the right atrium. Pressures in the pulmonary circuit are much lower than those in the systemic circuit. The right ventricle does not ordinarily develop high pressures because the pulmonary vessels are much shorter and more distensible than the systemic vessels, thus providing less resistance to blood flow. Let's examine pressures throughout the systemic circuit.

Arterial Blood Pressure

Arterial pressure is important because it maintains blood flow through capillary beds. To do this, it must always be high enough to overcome the peripheral resistance. Arterial pressure is not constant. Rather, it rises during ventricular systole and falls during ventricular diastole. The peak blood pressure measured during ventricular systole is called **systolic pressure**, and the minimum blood pressure at the end of ventricular diastole is called **diastolic pressure**. In recording blood pressure, we separate systolic and diastolic pressures by a slash, as in "120/80" ("one-twenty over eighty") or "110/75."

Figure 21–8 Relationships among Vessel Luminal Diameter, Cross-Sectional Area, Blood Pressure, and Blood Velocity within the Systemic Circuit.

Figure 21–9 Pressures within the Systemic Circuit. Note the general reduction in circulatory pressure within the systemic circuit and the elimination of the pulse pressure within the arterioles.

A *pulse* is a rhythmic fluctuation in pressure that accompanies each heartbeat. The difference between the systolic and diastolic pressures is the **pulse pressure** (Figure 21–9). To report a single blood pressure value, we use the **mean arterial pressure (MAP)**. It is calculated for someone at rest by adding one-third of the pulse pressure to the diastolic pressure:

$$\text{MAP} = \text{diastolic pressure} + \frac{\text{pulse pressure}}{3}$$

For a systolic pressure of 120 mm Hg and a diastolic pressure of 90 mm Hg, we calculate MAP as follows:

$$\text{MAP} = 90 + \frac{(120 - 90)}{3} = 90 + 10 = 100 \text{ mm Hg}$$

A normal range of systolic and diastolic pressures occurs in healthy individuals. When pressures shift outside the normal range, clinical problems develop. Abnormally high blood pressure is termed **hypertension**. Abnormally low blood pressure is **hypotension**. Hypertension is much more common. In fact, many cases of hypotension result from overly aggressive drug treatment for hypertension.

The usual criterion established by the American Heart Association for stage 1 hypertension in adults is a systolic blood pressure range of 140–159 and a diastolic range of 90–99.

Values from 120–139 for systolic pressure and 80–89 for diastolic pressure indicate *pre-hypertension*. Blood pressure less than 120/80 is normal. Cardiologists often recommend some combination of diet modification and drug therapy for people whose blood pressures are consistently pre-hypertensive.

Cardiac workload is how hard the heart must work to pump blood throughout the body. Hypertension significantly increases the workload on the heart, and the left ventricle gradually enlarges. More muscle mass means a greater demand for oxygen. When the coronary circulation cannot keep pace, signs and symptoms of *coronary ischemia* appear. Increased arterial pressures also place a physical stress on the walls of blood vessels throughout the body. This stress promotes or accelerates the development of arteriosclerosis. It also increases the risk of aneurysms, heart attacks, and strokes.

Elastic Rebound in Arteries

As systolic pressure climbs, the arterial walls stretch, just as an extra puff of air expands a partially inflated balloon. This expansion allows the arterial system to accommodate some of the blood ejected during ventricular systole. When diastole begins and blood pressures fall, the arteries recoil to their original dimensions. This phenomenon is called **elastic rebound**. Some blood is forced back toward the left ventricle, closing the aortic valve and helping to drive additional blood into the coronary arteries. However, most of the push from elastic rebound forces blood toward the capillaries. This maintains blood flow along the arterial network while the left ventricle is in diastole.

Pressures in Muscular Arteries and Arterioles

The mean arterial pressure and the pulse pressure become smaller as the distance from the heart increases (**Figure 21–9**):

- The mean arterial pressure declines as the arterial branches become smaller and more numerous. In essence, blood pressure decreases as it overcomes friction and produces blood flow.
- The pulse pressure lessens due to the cumulative effects of elastic rebound along the arterial system. The effect can be likened to a series of ever-softer echoes following a loud shout. Each time an echo is produced, the reflecting surface absorbs some of the sound energy. Eventually, the echo disappears. The pressure surge accompanying ventricular ejection is like the shout, and it is reflected by the wall of the aorta, echoing down the arterial system until it finally disappears at the level of the small arterioles. By the time blood reaches a precapillary sphincter, no pressure fluctuations remain, and the blood pressure is steady at approximately 35 mm Hg.

Venous Pressure and Venous Return

Venous pressure, although low, determines **venous return**—the amount of blood arriving at the right atrium each minute.

Venous return has a direct impact on cardiac output. Blood pressure at the start of the venous system is only about one-tenth that at the start of the arterial system, but the blood must still travel through a vascular network as complex as the arterial system before returning to the heart.

Pressures at the entrance to the right atrium fluctuate, but they average about 2 mm Hg. Thus, the effective pressure in the venous system is about 16 mm Hg (from 18 mm Hg in the venules to 2 mm Hg in the venae cavae). This venous pressure gradient contrasts with 65 mm Hg in the arterial system (from 100 mm Hg at the aorta to 35 mm Hg at the capillaries). Yet, although venous pressures are low, veins offer comparatively little resistance, so pressure declines very slowly as blood moves through the venous system. As blood moves toward the heart, the veins become larger, resistance drops, and the velocity of blood flow increases (**Figure 21–8**).

When standing, venous blood returning from inferior to the heart must overcome gravity as it travels up the inferior vena cava. Two factors assist the low venous pressures in propelling blood toward the heart: *muscular compression* of peripheral veins and the *respiratory pump* during inhalation.

Muscular Compression. Skeletal muscle contractions near a vein compress it, helping to push blood toward the heart. The valves in small and medium-sized veins ensure that blood flows in one direction only (**Figure 21–5**). When a person is standing and walking, the cycles of contraction and relaxation that accompany such movements assist venous return. Muscular compression is particularly important when a person is standing because blood returning from the feet must overcome gravity to ascend to the heart. While standing, one's leg muscles undergo cycles of rapid contraction and relaxation, helping to push blood toward the trunk. Venous valves play a smaller part in venous return when one is lying down because the heart and major vessels are at the same level.

If a person stands at attention, with knees locked and leg muscles immobilized, that assistance is lost. The reduction in venous return then leads to a decrease in cardiac output, which reduces the blood supply to the brain. This decrease is sometimes enough to cause **fainting**, a temporary loss of consciousness. The person would then collapse; but if the person were in a horizontal position, both venous return and cardiac output would return to normal.

The Respiratory Pump. As one inhales, the thoracic cavity expands, reducing the pressure within the thoracic cavity. When the pressure in the thoracic cavity decreases below atmospheric pressure, air will enter the lungs. At the same time, the decrease in venous pressure in the chest makes it easier for blood to be forced into the inferior vena cava and right atrium from the smaller veins of the abdominal cavity and lower body. The effect on venous return through the superior vena cava is

less noticeable because blood in that vessel is normally assisted by gravity. As one exhales, the thoracic cavity decreases in size. Internal pressure then rises, forcing air out of the lungs and pushing venous blood into the right atrium. This mechanism is called the **respiratory pump**. Such pumping becomes more important during heavy exercise when respirations are deep and frequent.

Capillary Exchange and Capillary Pressures

The vital functions of the cardiovascular system depend entirely on events at the capillary level: All chemical and gaseous exchange between blood and interstitial fluid takes place across capillary walls. This process, called **capillary exchange**, plays a key role in homeostasis. Cells rely on capillary exchange to obtain nutrients and oxygen and to remove metabolic wastes, such as carbon dioxide and urea.

Exchange takes place very rapidly because the distances involved are very short. Few cells lie more than 125 μm (0.005 in.) from a capillary. In addition, blood flows through capillaries slowly, allowing time for the diffusion or active transport of materials across the capillary walls. In this way, the histological structure of capillaries permits a two-way exchange of substances between blood and interstitial fluid. Capillaries are the *only* blood vessels whose walls permit such exchange. The most important processes that move materials across typical capillary walls are *diffusion*, *filtration*, and *reabsorption*.

Diffusion

Diffusion is the net movement of ions or molecules from an area where their concentration is higher to an area where their concentration is lower. The difference between the high and low concentrations represents a *concentration gradient*. Diffusion tends to eliminate that gradient. Diffusion occurs most rapidly when (1) the distances involved are short, (2) the concentration gradient is steep, and (3) the ions or molecules involved are small.

Different substances diffuse across capillary walls by different routes:

- *Water, ions, and small organic molecules, such as glucose, amino acids, and urea, can usually enter or leave the bloodstream by diffusion between adjacent endothelial cells or through the pores of fenestrated capillaries.*
- *Many ions, including sodium, potassium, calcium, and chloride, can diffuse across endothelial cells by passing through channels in plasma membranes.*
- *Large water-soluble compounds are unable to enter or leave the bloodstream except at fenestrated capillaries, such as those of the hypothalamus, the kidneys, many endocrine organs, and the intestinal tract.*
- *Lipids, such as fatty acids and steroids, and lipid-soluble materials, including soluble gases such as oxygen and*

carbon dioxide, can cross capillary walls by diffusion through the endothelial plasma membranes.

- *Plasma proteins are normally unable to cross the endothelial lining anywhere except in sinusoids, such as those of the liver, where plasma proteins enter the bloodstream.*

Filtration

Filtration is the removal of solutes as a solution passes through a porous membrane. Solutes too large to pass through the pores are filtered out of the solution. The driving force for filtration is hydrostatic pressure. As we saw earlier, it pushes water from an area of higher pressure to an area of lower pressure.

In *capillary filtration*, water and small solutes are forced across a capillary wall, leaving larger solutes and suspended proteins in the bloodstream (**Figure 21-10**). The solute molecules that leave the bloodstream are small enough to pass between adjacent endothelial cells or through the pores in a fenestrated capillary. Filtration takes place primarily at the arterial end of a capillary, where capillary hydrostatic pressure (CHP) is highest.

Reabsorption

Reabsorption occurs as the result of osmosis. *Osmosis* is the diffusion of water across a selectively permeable membrane that

Figure 21-10 Capillary Filtration. Capillary hydrostatic pressure (CHP) forces water and solutes through the gaps between adjacent endothelial cells in continuous capillaries. The sizes of solutes that move across the capillary wall are determined by the dimensions of the gaps.

separates two solutions of differing solute concentrations. Water molecules tend to diffuse across a membrane *toward* the solution containing the higher solute concentration.

The **osmotic pressure (OP)** of a solution represents the pressure that must be applied to prevent osmotic movement across a membrane. The higher the solute concentration of a solution, the greater the solution's osmotic pressure. Suspended proteins that cannot cross capillary walls creates an osmotic pressure called *blood colloid osmotic pressure (BCOP)*. Clinicians often use the term *oncotic pressure (onkos, a swelling)* when referring to the colloid osmotic pressure of body fluids. The two terms are equivalent. Osmotic water movement continues until either the solute concentrations are equalized or an opposing hydrostatic pressure prevents the movement.

Bulk Flow: The Interplay between Filtration and Reabsorption

Now let's look at how filtration and reabsorption function together along the length of a typical capillary. The continuous net movement of water out of the capillaries, through peripheral tissues, and then back to the bloodstream by way of the lymphatic system is known as *bulk flow*. This process has four important functions:

- It ensures that plasma and interstitial fluid, two major components of extracellular fluid, communicate and exchange materials constantly.
- It accelerates the distribution of nutrients, hormones, and dissolved gases throughout tissues.
- It assists in the transport of insoluble lipids and tissue proteins that cannot cross the capillary walls and enter the bloodstream.
- It flushes out bacterial toxins and other chemicals, carrying them to lymphatic tissues and organs responsible for immunity to disease.

Capillary hydrostatic pressure is highest in the arterial end and decreases as blood flows to the venous end of a capillary. As a result, the rates of filtration and reabsorption gradually change as blood passes along the length of a capillary. The factors involved are diagrammed in **Figure 21–11**.

The *net capillary hydrostatic pressure* is the difference between the hydrostatic pressure inside the capillary and the hydrostatic pressure outside the capillary. This pressure tends

Figure 21–11 Forces Acting across Capillary Walls. At the arterial end of a capillary, capillary hydrostatic pressure (CHP) is greater than blood colloid osmotic pressure (BCOP), so fluid moves out of the capillary (filtration). Near the venule, CHP is lower than BCOP, so fluid moves into the capillary (reabsorption). In this model, interstitial fluid colloid osmotic pressure (ICOP) and interstitial fluid hydrostatic pressure (IHP) are assumed to be 0 mm Hg and so are not shown.

to push water and solutes out of capillaries and into the interstitial fluid. Factors that contribute to the net hydrostatic pressure include

- the capillary hydrostatic pressure (CHP), which ranges from 35 mm Hg at the arterial end of a capillary to 18 mm Hg at the venous end, and
- the *interstitial fluid hydrostatic pressure (IHP)*. Measurements of IHP have yielded very small values that differ from tissue to tissue—from +6 mm Hg in the brain to -6 mm Hg in subcutaneous tissues. A positive IHP opposes CHP, so in this situation the tissue hydrostatic pressure must be overcome before fluid can move out of a capillary. A negative IHP assists CHP, and additional fluid will leave the capillary. However, under normal circumstances the average IHP is 0 mm Hg, and we can assume that the net hydrostatic pressure is equal to CHP. (For this reason, IHP is not included in **Figure 21–11**.)

Plasma proteins in capillary blood create capillary colloid osmotic pressure. The *net capillary colloid osmotic pressure* tends to cause water and solutes, by bulk flow, to enter the capillary from the interstitial fluid. The net colloid osmotic pressure is the difference between

- the *blood colloid osmotic pressure* (BCOP), which is about 25 mm Hg, and
- the *interstitial fluid colloid osmotic pressure* (ICOP). The ICOP is as variable and low as the IHP because the interstitial fluid in most tissues contains negligible quantities of suspended proteins. Reported values of ICOP vary from 0 to 5 mm Hg, within the range of pressures recorded for the IHP. It is thus safe to assume that under normal circumstances the net colloid osmotic pressure is equal to the BCOP. (For this reason, ICOP is not included in **Figure 21-11**.)

The **net filtration pressure (NFP)** is the difference between the net hydrostatic pressure and the net osmotic pressure. In terms of the factors just listed, this means that

$$\begin{array}{rclcl} \text{net filtration} & = & \text{net hydrostatic} & - & \text{net colloid} \\ \text{pressure} & & \text{pressure} & & \text{osmotic pressure} \\ \text{NFP} & = & (\text{CHP} - \text{IHP}) & - & (\text{BCOP} - \text{ICOP}) \end{array}$$

At the arterial end of a capillary, the net filtration pressure can be calculated as follows:

$$21 \quad \text{NFP} = (35 - 0) - (25 - 0) = 35 - 25 = 10 \text{ mm Hg}$$

Because this value is positive, it indicates that fluid will tend to move *out* of the capillary and into the interstitial fluid.

At the venous end of the capillary, the net filtration pressure will be

$$\text{NFP} = (18 - 0) - (25 - 0) = 18 - 25 = -7 \text{ mm Hg}$$

The minus sign indicates that fluid tends to move *into* the capillary; that is, reabsorption is occurring.

The transition between filtration and reabsorption occurs where the CHP is 25 mm Hg, because at that point the hydrostatic and osmotic forces are equal—that is, the NFP is 0 mm Hg. If the maximum filtration pressure at the arterial end of the capillary were equal to the maximum reabsorption pressure at the venous end, this transition point would lie midway along the length of the capillary. Under these circumstances, filtration would occur along the first half of the capillary, and an identical amount of reabsorption would occur along the second half. However, the maximum filtration pressure is higher than the maximum reabsorption pressure, so the transition point between filtration and reabsorption normally lies closer to the venous end of the capillary than to the arterial end. As a result, more filtration than reabsorption occurs along the capillary. Of the nearly 24 liters of fluid that move out of the plasma and into the interstitial fluid each day, 20.4 liters (85%) are reabsorbed. The remainder (3.6 liters) flows through the tissues and

into lymphatic vessels, for eventual return to the venous system (**Figure 21-11**).

Any condition that affects hydrostatic or osmotic pressures in the blood or tissues will shift the balance between hydrostatic and osmotic forces. We can predict the effects of these changes based on an understanding of capillary dynamics. For example:

- If hemorrhaging occurs, both blood volume and blood pressure decrease. This reduction in CHP lowers the NFP and increases the amount of reabsorption. The result is a decrease in the volume of interstitial fluid and an increase in the circulating plasma volume. This process is known as a *recall of fluids*.
- If dehydration occurs, the plasma volume decreases due to water loss, and the concentration of plasma proteins increases. The increase in BCOP accelerates reabsorption and a recall of fluids that delays the onset and severity of clinical signs and symptoms.
- If the CHP rises or the BCOP declines, fluid moves out of the blood and builds up in peripheral tissues, a condition called *edema*.

Clinical Note Edema

Edema (eh-DĒ-muh) is an abnormal accumulation of interstitial fluid. The underlying problem is a disturbance in the normal balance between hydrostatic and osmotic forces at capillaries. For instance:

- A person usually has swelling with a bruise. When a capillary is damaged, plasma proteins cross the capillary wall and enter the interstitial fluid. The resulting rise in the interstitial fluid colloid osmotic pressure (ICOP) reduces the rate of capillary reabsorption and produces a localized edema.
- In starvation, the liver cannot synthesize enough plasma proteins to maintain normal concentrations in the blood, so the blood colloid osmotic pressure (BCOP) decreases. Fluids then begin moving from the blood into peripheral tissues. In children, fluid builds up in the abdominopelvic cavity, producing swollen bellies. Blood colloid osmotic pressure (BCOP) is also reduced after severe burns and in several types of liver and kidney diseases.
- In the U.S. population, most serious cases of edema result from increases in arterial blood pressure, venous pressure, or total circulatory pressure. The increase may be due to heart problems such as heart failure or venous blood clots that elevate venous pressures. The net result is an increase in capillary hydrostatic pressure (CHP) that accelerates fluid movement into the tissues.

21-3 Blood flow and pressure in tissues are controlled by both autoregulation and central regulation

Learning Outcome Describe the control mechanisms that regulate blood flow and pressure in tissues, and explain how the activities of the cardiac, vasomotor, and respiratory centers are coordinated to control blood flow through the tissues.

Homeostatic mechanisms regulate cardiovascular activity to ensure that the amount of blood flow through tissues, called **tissue perfusion**, is adequate to meet the demand for oxygen and nutrients. The factors that affect tissue perfusion are (1) cardiac output, (2) peripheral resistance, and (3) blood pressure. (Cardiac output was discussed in Chapter 20. Peripheral resistance and blood pressure were considered earlier in this chapter.)

Most cells are relatively close to capillaries. When a group of cells becomes active, the circulation to that region must increase to bring the necessary oxygen and nutrients, and to carry away the wastes and carbon dioxide they generate. The purpose of cardiovascular regulation is to ensure that these blood flow changes occur (1) at an appropriate time, (2) in the right area, and (3) without drastically changing blood pressure and blood flow to vital organs. In this section, we examine how blood is distributed to capillaries, and then, the regulatory mechanisms that control how that distribution occurs.

Vasomotion

Although blood normally flows from arterioles to venules at a constant rate, the flow within each capillary is quite variable. Each precapillary sphincter alternately contracts and relaxes, perhaps a dozen times per minute. These rhythmic changes in vessel diameter are called **vasomotion**. As a result, the blood flow within any capillary occurs in pulses rather than as a steady and constant stream. The net effect is that blood may reach the venules by one route now and by a different route later.

When a person is resting, blood flows through about 25% of their capillary bed vessels. The cardiovascular system does not contain enough blood to maintain adequate blood flow to all the capillaries in all the capillary beds at the same time.

As a result, when many tissues become active, blood flow through capillary beds must be coordinated.

Overview of Autoregulation and Central Regulation

Homeostatic mechanisms operating at the local, regional, and systemic levels adjust blood flow through the capillaries to meet the demands of peripheral tissues. They can be grouped into three regulatory mechanisms:

- **Autoregulation.** Local factors change the pattern of blood flow within capillary beds as precapillary sphincters open and close in response to chemical changes in interstitial fluids. This is an example of autoregulation at the tissue level. Autoregulation causes immediate, localized homeostatic adjustments.
- If autoregulation fails to normalize conditions at the tissue level, *central regulation*, involving both neural and endocrine homeostatic mechanisms, is activated. These central regulation mechanisms focus on controlling cardiac output and blood pressure to restore adequate blood flow after blood pressure decreases.
- **Neural Mechanisms.** Neural mechanisms respond to changes in arterial pressure or blood gas levels sensed at specific sites. When those changes occur, the cardiovascular center of the autonomic nervous system makes short-term adjustments to cardiac output and peripheral resistance to maintain blood pressure and ensure adequate blood flow.
- **Endocrine Mechanisms.** The endocrine system releases hormones that enhance short-term adjustments and that direct long-term changes in cardiovascular performance.

Next, we consider how each regulatory mechanism responds to inadequate blood flow (perfusion) in skeletal muscles. The regulatory relationships are diagrammed in **Figure 21–12**.

Autoregulation of Blood Flow within Tissues

Under normal resting conditions, cardiac output remains stable, and peripheral resistance within individual tissues is adjusted to control local blood flow. Vasomotion is controlled locally by changes in the concentrations of chemicals and dissolved gases in the interstitial fluids. This process is an example of capillary **autoregulation**.

Factors that promote the dilation of precapillary sphincters are called **vasodilators**. For example, when the dissolved oxygen concentration decreases within a tissue, **local vasodilators** cause the capillary sphincters to relax, so blood flow to the area increases. Local vasodilators include the following:

- Decreased oxygen level or increased CO₂ level in tissue.
- Lactate generated by tissue cells.
- Nitric oxide (NO) released from endothelial cells.

Figure 21–12 Short-Term and Long-Term Cardiovascular Responses. This diagram indicates general regulatory mechanisms that compensate for a decrease in blood flow, blood volume, and blood pressure.

For blood flow to be autoregulated, what types of stimuli signal inadequate local blood flow and blood pressure?

- Increasing concentration of potassium ions or hydrogen ions in the interstitial fluid.
- Chemicals released during local inflammation, including histamine.
- Elevated body temperature.

The presence of any vasodilator indicates that tissue conditions are to some degree abnormal. An increase in blood flow, which brings oxygen, nutrients, and buffers, may be sufficient to restore homeostasis.

Aggregating platelets and damaged tissues produce compounds that constrict precapillary sphincters. These compounds are **local vasoconstrictors**. Examples include prostaglandins and thromboxanes released by activated platelets and white blood cells, and the endothelins released by damaged endothelial cells.

Local vasodilators and vasoconstrictors control blood flow within a single capillary bed (**Figure 21–4**). In high concentrations, these factors also affect arterioles, increasing or decreasing blood flow to capillary beds in each region.

Central Regulation: Neural Mechanisms

The nervous system adjusts cardiac output and peripheral resistance to maintain adequate blood flow to vital tissues and organs. The center primarily responsible for these regulatory activities is the **cardiovascular center** of the medulla oblongata. The cardiovascular center is made up of the *cardiac centers* and the *vasomotor center*. Although these centers are difficult to distinguish anatomically, in functional terms, they often act independently.

The cardiac centers are composed of the cardioinhibitory center and the cardioacceleratory center. The *cardioacceleratory center* increases cardiac output through sympathetic innervation. The *cardioinhibitory center* decreases cardiac output through parasympathetic innervation. The vasomotor center directs vasomotor responses in blood vessels. Let's examine the functions of these centers.

The Vasomotor Center and Vasomotor Tone

The vasomotor center contains two populations of neurons: (1) a very large group responsible for widespread vasoconstriction and (2) a smaller group responsible for the vasodilation of arterioles in skeletal muscles and the brain. The vasomotor center controls the activity of sympathetic motor neurons:

- **Control of Vasoconstriction.** The neurons innervating peripheral blood vessels in most tissues are *adrenergic*; that is, they release the neurotransmitter norepinephrine (NE). Norepinephrine stimulates smooth muscles in the walls of arterioles, producing vasoconstriction.
- **Control of Vasodilation.** Vasodilator neurons innervate blood vessels in skeletal muscles and in the brain. The stimulation of these neurons relaxes smooth muscle cells in the walls of

arterioles, producing vasodilation. This relaxation is triggered by the appearance of nitric oxide (NO) in the surroundings. The vasomotor center may control NO release indirectly or directly. The most common vasodilator synapses are *cholinergic*—their axon terminals release acetylcholine (ACh). Acetylcholine stimulates endothelial cells in the area to release nitric oxide, causing local vasodilation. Other vasodilator synapses are *nitroxidergic*—their axon terminals release nitric oxide as a neurotransmitter. Nitric oxide has an immediate and direct relaxing effect on the vascular smooth muscle cells in the area.

In Chapter 16, we saw how autonomic tone sets a background level of neural activity that can increase or decrease on demand. The sympathetic vasoconstrictor nerves are always active, producing a significant **vasomotor tone**. This vasoconstrictor activity normally keeps the arterioles partially constricted. Under maximal stimulation, arterioles constrict to about half their resting diameter. (To dilate fully, an arteriole increases its resting diameter by about 1.5 times.)

Constriction has a large effect on resistance, because resistance increases sharply as the luminal diameter of a vessel decreases. The resistance of a maximally constricted arteriole is about 80 *times* that of a fully dilated arteriole. Because blood pressure varies directly with peripheral resistance, the vasomotor center can control arterial blood pressure very effectively by making modest adjustments in vessel diameters. Extreme stimulation of the vasomotor center also produces venoconstriction and mobilizes the venous blood reservoir (blood in veins).

Reflex Control of Cardiovascular Function by the Cardiovascular Center

The cardiovascular center detects changes in tissue demand by monitoring arterial blood, especially its blood pressure, pH, and concentrations of dissolved gases. The *baroreceptor reflexes* (*baro-*, pressure) respond to changes in blood pressure, and the *chemoreceptor reflexes* (*chemo-*, chemical) monitor changes in the chemical composition of arterial blood. These reflexes are regulated through a negative feedback loop: The stimulation of a receptor by an abnormal condition leads to a short-term response that counteracts the stimulus and restores normal conditions.

Baroreceptor Reflexes. Baroreceptors are specialized receptors that monitor the degree of stretch in the walls of expandable organs. The baroreceptors involved in cardiovascular regulation are found in the walls of (1) the **carotid sinuses**, expanded chambers near the bases of the *internal carotid arteries* of the neck (**Figure 21–21**); (2) the **aortic arch**, which curves over the superior surface of the heart; and (3) the wall of the right atrium. These receptors are part of the **baroreceptor reflexes**, which adjust cardiac output and peripheral resistance to maintain normal arterial pressures.

Aortic baroreceptors monitor blood pressure within the ascending aorta. Any changes trigger the **aortic reflex**, which adjusts blood pressure to maintain adequate blood pressure and blood flow through the systemic circuit. Carotid sinus baroreceptors trigger reflexes that maintain adequate blood flow to the brain. The carotid sinus receptors are extremely sensitive because blood flow to the brain must remain constant. **Figure 21-13** presents the basic organization of the baroreceptor reflexes triggered by changes in blood pressure at the carotid sinuses and aortic arch.

When blood pressure rises, the increased output from the baroreceptors alters activity in the cardiovascular center and produces two major effects (upper half of **Figure 21-13**):

- *A decrease in cardiac output*, due to parasympathetic stimulation and the inhibition of sympathetic activity. This results from the stimulation of the cardioinhibitory center and the inhibition of the cardioacceleratory center.
- *Widespread peripheral vasodilation*, due to the inhibition of excitatory neurons in the vasomotor center.

Figure 21-13 Baroreceptor Reflexes of the Carotid Sinuses and Aortic Arch.

The decrease in cardiac output reflects primarily a reduction in heart rate due to the release of acetylcholine at the sinoatrial (SA) node. The widespread vasodilation lowers peripheral resistance, and this effect, combined with a reduction in cardiac output, leads to a fall in blood pressure to a normal level.

When blood pressure falls below normal, baroreceptor output is reduced accordingly (lower half of **Figure 21-13**). This change has two major effects working together to raise blood pressure:

- *An increase in cardiac output*, through the stimulation of sympathetic innervation to the heart. This results from stimulation of the cardioacceleratory center that is accompanied by inhibition of the cardioinhibitory center.
- *Widespread peripheral vasoconstriction*, caused by the stimulation of sympathetic vasoconstrictor neurons by the vasomotor center.

The effects on the heart result from the release of norepinephrine (NE) by sympathetic neurons innervating the SA node, the atrioventricular (AV) node, and the general myocardium. In a crisis, such as significant blood loss, sympathetic activation occurs, and its effects are enhanced by the release of both NE and epinephrine (E) from the adrenal medullae. The net effect is an immediate increase in heart rate and stroke volume, and a corresponding increase in cardiac output.

The vasoconstriction, which also results from the release of NE by sympathetic neurons, increases peripheral resistance. These adjustments—increased cardiac output and increased peripheral resistance—work together to raise blood pressure.

Atrial baroreceptors monitor blood pressure at the end of the systemic circuit—at the venae cavae and the right atrium. Recall from the previous chapter that the **Bainbridge reflex** responds to a stretching of the wall of the right atrium.

Under normal circumstances, the heart pumps blood into the aorta at the same rate at which blood arrives at the right atrium. When blood pressure rises at the right atrium, blood is arriving at the heart faster than it is being pumped out. The atrial baroreceptors correct the situation by stimulating the cardiovascular center to increase cardiac output until the backlog of venous blood is removed. Atrial pressure then returns to normal.

A procedure known as the Valsalva maneuver is a simple way to check for normal cardiovascular responses to changes in arterial pressure and venous return. The *Valsalva maneuver* involves trying to exhale forcefully with closed lips and nostrils so that no air can leave the lungs and pressure in the thoracic cavity rises sharply. This action causes reflexive changes in blood pressure and cardiac output due to increased intrathoracic pressure, which impedes venous return to the right atrium. When internal pressures rise, the venae cavae collapse, and venous return decreases. The resulting drop in cardiac output and blood pressure stimulates the aortic and carotid

baroreceptors, causing a reflexive increase in heart rate and peripheral vasoconstriction. When the glottis opens and pressures return to normal, venous return increases suddenly and so does cardiac output. Because vasoconstriction has occurred, blood pressure rises sharply, and this inhibits the baroreceptors. As a result, cardiac output, heart rate, and blood pressure quickly return to normal levels.

Chemoreceptor Reflexes. The **chemoreceptor reflexes** respond to changes in carbon dioxide, oxygen, or pH levels in blood and cerebrospinal fluid (CSF) (**Figure 21-14**). The chemoreceptors involved are sensory neurons. They are found in the **carotid bodies**, situated in the neck near the carotid sinuses, and the **aortic bodies**, near the aortic arch. These receptors monitor the composition of arterial blood. Additional chemoreceptors located on the ventrolateral surfaces of the medulla oblongata monitor the composition of CSF.

When chemoreceptors in the carotid bodies or aortic bodies detect either an increase in the carbon dioxide concentration or a decrease in the pH of arterial blood, the cardioacceleratory and vasomotor centers are stimulated. At the same time, the cardioinhibitory center is inhibited. This dual effect causes an increase in cardiac output, peripheral vasoconstriction, and an increase in blood pressure. A decrease in the oxygen level at the aortic bodies has the same effects. Strong stimulation of the carotid or aortic chemoreceptors causes widespread sympathetic activation, with more dramatic increases in heart rate and cardiac output.

The chemoreceptors of the medulla oblongata are primarily involved with the control of respiratory function, and secondarily with regulating blood flow to the brain. For example, a steep rise in the CSF carbon dioxide level triggers the vasodilation of cerebral vessels but produces vasoconstriction in most other organs. The result is increased blood flow—and increased oxygen delivery—to the brain.

Coordination of cardiovascular and respiratory activities is vital because accelerating blood flow in the tissues is useful only if the circulating blood contains an adequate amount of oxygen. The arterial CO₂ level can be decreased and the O₂ level increased most effectively by coordinating cardiovascular and respiratory activities. Chemoreceptor stimulation also stimulates the respiratory centers, and the increase in cardiac output and blood pressure is associated with an increased respiratory rate. In addition, an increase in the respiratory rate accelerates venous return through the action of the respiratory pump. (Other aspects of chemoreceptor activity and respiratory control are considered in Chapter 23.)

The Cardiovascular Center and CNS Activities

The output of the cardiovascular center can also be influenced by activities in other areas of the brain. For example, the

Figure 21–14 The Chemoreceptor Reflexes.

activation of either division of the autonomic nervous system affects output from the cardiovascular center. A general sympathetic activation stimulates the cardioacceleratory and vasomotor centers. As a result, cardiac output and blood pressure increase. In contrast, when the parasympathetic division is activated, the cardioinhibitory center is stimulated. The result is a decrease in cardiac output. Parasympathetic activity does not directly affect the vasomotor center, but vasodilation takes place as sympathetic activity declines.

The higher brain centers can also affect blood pressure. Our thought processes and emotional states can produce significant changes in blood pressure by influencing cardiac output and vasomotor tone. For example, strong emotions of anxiety, fear, and rage are accompanied by an increase in blood pressure, due to cardiac stimulation and vasoconstriction.

Central Regulation: Endocrine Mechanisms

The endocrine system regulates cardiovascular performance in both the short term and the long term. As noted, epinephrine (E) and norepinephrine (NE) from the adrenal medullae stimulate cardiac output and peripheral vasoconstriction. Here we will look at other hormones important in regulating cardiovascular function: (1) antidiuretic hormone (ADH), (2) angiotensin II,

(3) erythropoietin (EPO), and (4) the natriuretic peptides (ANP and BNP). All four are concerned primarily with the long-term regulation of blood volume (**Figure 21–15**). ADH and angiotensin II also affect blood pressure.

Antidiuretic Hormone

Antidiuretic hormone (ADH) is released at the posterior lobe of the pituitary gland in response to a decrease in blood volume, to an increase in the osmotic concentration of the plasma, or (secondarily) to circulating angiotensin II. It causes peripheral vasoconstriction that increases blood pressure. This hormone also stimulates water conservation by the kidneys, thus preventing a reduction in blood volume that would further reduce blood pressure (**Figure 21–15**).

Angiotensin II

Angiotensin II appears in the blood when specialized cells in kidney arterioles, called *juxtaglomerular cells*, release the enzyme *renin* (RE-nin) in response to a decrease in renal blood pressure (**Figure 21–15**). Once in the bloodstream, renin starts an enzymatic chain reaction. In the first step, renin converts *angiotensinogen*, a plasma protein produced by the liver, to *angiotensin I*.

Figure 21–15 The Hormonal Regulation of Blood Pressure and Blood Volume.

What hormones are released as a short-term response to a decrease in blood pressure and blood volume?

In the capillaries of the lungs, *angiotensin-converting enzyme* (ACE) then modifies angiotensin I to angiotensin II, an active hormone with diverse effects.

Angiotensin II has four important functions:

- It stimulates the adrenal production of aldosterone, causing Na^+ reabsorption and K^+ loss by the kidneys.
- It stimulates the secretion of ADH, in turn stimulating water reabsorption by the kidneys and complementing the effects of aldosterone.
- It stimulates thirst, resulting in increased fluid consumption. (The presence of ADH and aldosterone ensures that the additional water consumed will be retained, increasing blood volume.)
- It stimulates cardiac output and triggers the constriction of arterioles, in turn increasing the systemic blood pressure. The effect of angiotensin II on blood pressure is four to eight times greater than the effect of norepinephrine.

Erythropoietin

The kidneys release *erythropoietin* (EPO) if blood pressure falls or if the oxygen content of the blood becomes abnormally low (**Figure 21-15**). Erythropoietin acts directly on blood vessels, causing vasoconstriction, thereby increasing blood pressure. Erythropoietin also stimulates the production and maturation of red blood cells. These cells increase the volume and viscosity of the blood and improve its oxygen-carrying capacity.

Natriuretic Peptides

Cardiac muscle cells in the wall of the right atrium of the heart produce *atrial natriuretic peptide* ($\text{n}\bar{\text{a}}\text{-tr}\bar{\text{e}}\text{-y}\bar{\text{u}}\text{-RET-ik}$; *natrium*, sodium + *ouresis*, urination), or ANP, in response to excessive stretching during diastole. Ventricular muscle cells exposed to comparable stimuli produce a related hormone called *brain natriuretic peptide*, or BNP. These peptide hormones reduce blood volume and blood pressure. They do so by (1) increasing sodium ion excretion by the kidneys; (2) promoting water loss by increasing the volume of urine produced; (3) reducing thirst; (4) blocking the release of ADH, aldosterone, epinephrine, and norepinephrine; and (5) stimulating peripheral vasodilation (**Figure 21-15**). As blood volume and blood pressure decrease, the stresses on the walls of the heart are reduced, and natriuretic peptide production ceases.

21-4 The cardiovascular system adapts to physiological stress while maintaining a special vascular supply to the brain, heart, and lungs

Learning Outcome Identify the principal blood vessels and functions of the special circulation to the brain, heart, and lungs, and explain the cardiovascular system's homeostatic response to exercise and hemorrhaging.

In this chapter and the previous two, we have considered the blood, the heart, and the blood vessels of the cardiovascular system as individual entities. Yet in our day-to-day lives, the cardiovascular system operates as an integrated complex. These interactions are very important when physical or physiological conditions are changing rapidly. In this section we begin by looking at the patterns of blood supply to the brain, heart, and lungs, in which blood flow is controlled by separate mechanisms. We then look at the patterns of cardiovascular responses to exercise and hemorrhaging.

Vascular Supply to Special Regions

The vasoconstriction that takes place in response to a decrease in blood pressure or an increase in CO_2 level affects many tissues and organs at the same time. The term *special circulation* refers to the vascular supply through organs in which blood flow is controlled by separate mechanisms. We consider three important examples: the blood flow to the brain, the heart, and the lungs.

Blood Flow to the Brain

The blood-brain barrier isolates most CNS tissue from the general circulation. The brain has a very high demand for oxygen and receives a substantial supply of blood. Under a variety of conditions, blood flow to the brain remains steady at about 750 mL/min. That means that about 12% of the cardiac output is delivered to an organ that makes up less than 2% of body weight.

Neurons do not have significant energy reserves, and the cardiovascular system treats blood flow to the brain as the top priority. Even during a cardiovascular crisis, blood flow through the brain remains as near normal as possible: While the cardiovascular center is calling for widespread peripheral vasoconstriction, the cerebral vessels are instructed to dilate.

Total blood flow to the brain remains relatively constant, but blood flow to specific regions of the brain changes from moment to moment. These changes occur in response to local changes in the composition of interstitial fluid that accompany neural activity. When a person reads, writes, speaks, or walks, specific regions of their brain become active. Blood flow to those regions increases almost instantaneously. These changes ensure that the active neurons will receive the oxygen and nutrients they require.

The brain receives arterial blood through four arteries. A slowly developing interruption of flow in any one of these large vessels may not significantly reduce blood flow to the brain because these arteries form anastomoses inside the cranium and other vessels may enlarge or establish alternative routes. However, a plaque or a blood clot may still block a small artery, and weakened arteries may rupture. Such incidents temporarily or permanently shut off blood flow to a localized area of the brain, damaging or killing the dependent neurons. Signs and symptoms of a *stroke*, or *cerebrovascular accident* (CVA), then appear.

Blood Flow to the Heart

The coronary arteries arise at the base of the ascending aorta, where systemic pressures are highest. Each time the heart contracts, it squeezes the coronary vessels, so blood flow is reduced. In the left ventricle, systolic pressures are high enough that blood can flow into the myocardium only during diastole. Over this period, elastic rebound helps drive blood along the coronary vessels. Cardiac contractile cells can tolerate these brief circulatory interruptions because they have substantial oxygen reserves.

At rest, coronary blood flow is about 250 mL/min. When the heart's workload increases, local factors, such as reduced O₂ and increased lactate levels, dilate the coronary vessels and increase blood flow. Epinephrine released during sympathetic stimulation causes vasodilation of coronary vessels. It also increases heart rate and the strength of cardiac contractions. As a result, coronary blood flow increases while vasoconstriction occurs in other tissues.

For reasons that are not clear, some people have *coronary spasms*. These spasms can temporarily restrict coronary circulation and produce angina (pain or pressure in the chest.) The heart's ability to increase its output, even under maximal stimulation, can be limited by certain conditions. These conditions include a permanent restriction or blockage of coronary vessels (as in coronary artery disease) and tissue damage (as caused by a myocardial infarction). When the cardiac workload increases much above the resting level, individuals with these conditions experience signs and symptoms of *heart failure*.

Blood Flow to the Lungs

The lungs have about 300 million *alveoli* (al-VEŏ-lĭ; *alveolus*, sac), thin epithelial pockets where gas exchange takes place. An extensive capillary network surrounds each alveolus. Local responses to the oxygen level within each alveolus regulate blood flow through the lungs. How does this local regulation work? When an alveolus contains plenty of oxygen, its blood vessels dilate. Blood flow then increases, promoting the absorption of oxygen from air inside the alveolus. When the oxygen content of the air is very low, the vessels constrict. They shunt blood to other alveoli that contain more oxygen. This local mechanism makes the respiratory system very efficient.

There is no benefit in circulating blood through the capillaries of an alveolus that contains little oxygen.

This mechanism is precisely the opposite of that in other tissues, where a decline in the oxygen level causes local vasodilation rather than vasoconstriction. The difference makes functional sense, but its physiological basis remains unclear.

Blood pressure in pulmonary capillaries (average: 10 mm Hg) is lower than that in systemic capillaries. The BCOP (25 mm Hg) is the same as elsewhere in the bloodstream. As a result, reabsorption exceeds filtration in pulmonary capillaries. Fluid moves continuously into the pulmonary capillaries across the alveolar surfaces. This flow prevents fluid from building up in the alveoli and interfering with the diffusion of respiratory gases. If the blood pressure in pulmonary capillaries rises above 25 mm Hg, fluid enters the alveoli, causing *pulmonary edema*.

Cardiovascular Response to Exercise

At rest, cardiac output averages about 5800 mL/min (5.8 L/min). That amount changes dramatically during exercise. In addition, the pattern of blood distribution changes markedly, as detailed in **Table 21–2**.

Light Exercise

Before beginning exercise, heart rate increases slightly due to a general rise in sympathetic activity as a person thinks about the workout ahead. As light exercise begins, three interrelated changes take place:

- *Extensive vasodilation occurs* as skeletal muscles consume oxygen more quickly. Peripheral resistance decreases, blood flow through the capillaries increases, and blood enters the venous system at a faster rate.
- *The venous return increases* as skeletal muscle contractions squeeze blood along the peripheral veins and faster breathing pulls blood into the venae cavae by the respiratory pump.
- *Cardiac output rises*, primarily in response to (1) increased venous return (the Frank–Starling principle) and

Table 21–2 Changes in Blood Distribution at Rest and during Exercise

Organ	Tissue Blood Flow (mL/min)		
	Rest	Light Exercise	Strenuous Exercise
Skeletal muscles	1200	4500	12,500
Heart	250	350	750
Brain	750	750	750
Skin	500	1500	1900
Kidney	1100	900	600
Abdominal viscera	1400	1100	600
Miscellaneous	600	400	400
Total cardiac output	5800	9500	17,500

(2) atrial stretching (the Bainbridge reflex). Some sympathetic stimulation occurs, leading to increases in heart rate and contractility, but the sympathetic nervous system is not greatly activated. The increased cardiac output keeps pace with the elevated demand, and arterial pressures are maintained despite the drop in peripheral resistance.

This regulation by venous feedback produces a gradual increase in cardiac output to about double resting levels. The increase supports accelerated blood flow to skeletal muscles, cardiac muscle, and the skin. The flow to skeletal and cardiac muscles increases as arterioles and precapillary sphincters dilate in response to local factors. The flow to the skin increases in response to the rise in body temperature.

Heavy Exercise

At higher levels of exertion, other physiological adjustments take place as the cardiac and vasomotor centers activate the sympathetic nervous system. Cardiac output increases toward maximal levels. Major changes in the peripheral distribution of blood improve blood flow to active skeletal muscles.

Under intense sympathetic stimulation, the cardioacceleratory center can increase cardiac output to levels as high as 20–25 L/min. But that is still not enough to meet the demands of active skeletal muscles unless the vasomotor center severely restricts the blood flow to “nonessential” organs, such as those of the digestive system. During exercise at maximal levels, blood essentially races between the skeletal muscles and the lungs and heart. Although blood flow to most tissues is diminished, skin perfusion increases further, to cool the body as body temperature continues to climb. Only the blood supply to the brain remains unaffected.

Exercise, Cardiovascular Fitness, and Health

Cardiovascular performance improves significantly with training. **Table 21–3** compares the cardiac performance of athletes with that of nonathletes. Trained athletes have larger hearts and greater stroke volumes than do nonathletes. These functional differences are important—recall that cardiac output is equal to the stroke volume times the heart rate. For the same cardiac output, the person with a greater stroke volume has a slower heart rate. An athlete at rest can maintain normal blood flow to peripheral tissues at a heart rate as low as 32 bpm (beats

per minute). When necessary, the athlete’s cardiac output can increase to levels 50% higher than those of nonathletes. Thus, a trained athlete can tolerate sustained levels of activity that are well beyond the capabilities of nonathletes.

Exercise and Cardiovascular Disease

Regular exercise can lower the risk of cardiovascular disease. Even a moderate exercise routine (jogging 5 miles a week, for example) can lower total blood cholesterol levels. Exercise lowers cholesterol by stimulating enzymes that help move *low-density lipoproteins* (LDLs, or so-called “bad cholesterol”) from the blood to the liver. In the liver, the cholesterol is converted to bile and excreted from the body. Exercise also increases the size of the lipoprotein particles that carry cholesterol, making it harder for small proteins to lodge in the vessel walls. A high cholesterol level is one of the major risk factors for atherosclerosis, which leads to cardiovascular disease and strokes. In addition, a healthy lifestyle that includes regular exercise, a balanced diet, weight control, and not smoking reduces stress, lowers blood pressure, and slows the formation of plaques.

Regular moderate exercise (30 minutes most days of the week) may cut the incidence of heart attack, or *myocardial infarction*, almost in half. However, only an estimated 8% of adults in the United States currently exercise at the recommended level. Exercise also speeds recovery after a heart attack. Regular light-to-moderate exercise (such as walking, jogging, or bicycling), coupled with a low-fat diet and a low-stress lifestyle, reduces symptoms of *coronary artery disease* (such as *angina*, an-JĪ-nuh; chest pain). Such exercise also improves a person’s mood and overall quality of life. However, exercise does not remove underlying medical problems. For example, atherosclerotic plaques do not disappear and seldom grow smaller with exercise.

There is no evidence that *intense* athletic training lowers the incidence of cardiovascular disease. On the contrary, the strains placed on all body systems—including the cardiovascular system—during an ultramarathon, Ironman Triathlon, or other extreme athletic event can be severe. People with congenital aneurysms, cardiomyopathy (chronic disease of heart muscle), or cardiovascular disease risk fatal cardiovascular problems, such as an arrhythmia or heart attack, during severe exercise. Even healthy individuals can develop acute physiological disorders, such as kidney failure, after extreme exercise.

Table 21–3 Effects of Training on Cardiovascular Performance

Subject	Heart Weight (g)	Stroke Volume (mL)	Heart Rate (bpm)	Cardiac Output (L/min)	Blood Pressure (systolic/diastolic)
Nonathlete (rest)	300	60	83	5.0	120/80
Nonathlete (maximum)		104	192	19.9	187/75
Trained athlete (rest)	500	100	53	5.3	120/80
Trained athlete (maximum)		167	182	30.4	200/90*

*Diastolic pressures in athletes during maximal activity have not been accurately measured.

The Cardiovascular Response to Hemorrhaging and Shock

We have previously considered the local cardiovascular reaction to a break in the wall of a blood vessel. When hemostasis fails to prevent significant blood loss, the entire cardiovascular system adjusts (**Figure 21-16**). The immediate problem is to maintain adequate blood pressure and peripheral blood flow. The long-term problem is to restore normal blood volume.

Short-Term Elevation of Blood Pressure

Almost as soon as blood pressure starts to decrease, several short-term responses appear:

- In the initial neural response, carotid and aortic reflexes increase cardiac output and cause peripheral vasoconstriction. With blood volume reduced, an increase in heart rate, typically up to 180–200 bpm, maintains cardiac output.

- The combination of stress and anxiety stimulates the sympathetic nervous system headquarters in the hypothalamus, which in turn triggers a further increase in vasomotor tone, constricting the arterioles and raising blood pressure. At the same time, venoconstriction mobilizes the venous blood reservoirs and quickly improves venous return.
- Short-term hormonal effects also occur. For instance, sympathetic activation causes the adrenal medullae to secrete E and NE. These hormones increase cardiac output and extend peripheral vasoconstriction.

This combination of short-term responses elevates blood pressure and improves peripheral blood flow. It often restores normal arterial pressures and peripheral circulation after blood losses of up to 20% of total blood volume. Such adjustments are more than enough to compensate for the blood loss when a person donates blood. Most blood banks collect 500 mL (nearly 17 oz)

Figure 21-16 Cardiovascular Responses to Blood Loss. These mechanisms cope with blood losses equivalent to approximately 30% of total blood volume.

of whole blood, about 10% of total blood volume. If compensatory mechanisms fail, the individual develops signs of *shock*.

Long-Term Restoration of Blood Volume

Short-term responses temporarily compensate for a reduction in blood volume. Long-term responses are geared to restoring normal blood volume. This process can take several days after a serious hemorrhage. The responses include the following:

- The decrease in capillary blood pressure triggers a recall of fluids from the interstitial spaces.
- Aldosterone and ADH promote fluid retention and reabsorption at the kidneys, preventing a further reduction in blood volume.
- Thirst increases, and the digestive tract absorbs additional water. This intake of fluid increases the blood volume and ultimately replaces the interstitial fluids “borrowed” at the capillaries.
- Erythropoietin targets the red bone marrow. It stimulates the maturation of red blood cells, which increases blood volume and improves oxygen delivery to peripheral tissues.
- ADH release by the posterior lobe of the pituitary gland and the production of angiotensin II enhance vasoconstriction.

12. Why does blood pressure increase during exercise?
13. Name the immediate and long-term problems related to the cardiovascular response to hemorrhaging.
14. Explain the role of aldosterone and ADH in long-term restoration of blood volume.

See the blue Answers tab at the back of the book.

21-5 The vessels of the cardiovascular system make up both pulmonary and systemic circuits

Learning Outcome Describe the pulmonary and systemic circuits of the cardiovascular system.

As noted previously, the cardiovascular system consists of the *pulmonary circuit* and the *systemic circuit*. The pulmonary circuit consists of arteries and veins that transport blood between the heart and the lungs. This circuit begins at the right ventricle and ends at the left atrium. From the left ventricle, the arteries of the systemic circuit transport oxygenated blood and nutrients to all organs and tissues. Veins of the systemic circuit ultimately return deoxygenated blood to the right atrium. **Figure 21-17** shows the main distribution routes within the pulmonary and systemic circuits.

In the next two sections, we examine the vessels of the pulmonary and systemic circuits further. As you study these vessels, keep in mind some general observations about their organization. First, the peripheral distributions of arteries and

veins on the body’s left and right sides are generally identical, except near the heart, where the largest vessels connect to the atria or ventricles. Corresponding arteries and veins usually follow the same path. For example, the left and right subclavian *arteries* parallel the left and right subclavian *veins*.

Figure 21-17 A Schematic Overview of the Pattern of Circulation. RA stands for right atrium, LA for left atrium.

In addition, a single vessel may have several names as it crosses specific anatomical boundaries. These names make accurate anatomical descriptions possible when the vessel extends far into the periphery. For example, the *external iliac artery* becomes the *femoral artery* as it leaves the trunk and enters the lower limb. Finally, several arteries and veins usually service tissues and organs. Often, anastomoses between adjacent arteries or veins reduce the impact of a temporary or even permanent blockage, or *occlusion*, in a single blood vessel.

✓ Checkpoint

15. Identify the two circuits of the cardiovascular system.
16. Identify the major blood vessel patterns in the pulmonary and systemic circuits of the cardiovascular system.

See the blue Answers tab at the back of the book.

21-6 In the pulmonary circuit, deoxygenated blood enters the lungs in arteries, and oxygenated blood leaves the lungs by veins

Learning Outcome Identify the major arteries and veins of the pulmonary circuit.

Blood entering the right atrium has just returned from the peripheral capillary beds, where it released oxygen and absorbed carbon dioxide. After traveling through the right atrium and ventricle, this deoxygenated blood enters the pulmonary trunk, the start of the pulmonary circuit (**Figure 21-18**). At the lungs, oxygen is replenished, and carbon dioxide is released. The oxygenated blood returns to the heart for distribution by the systemic circuit.

Compared with the systemic circuit, the pulmonary circuit is short: The base of the pulmonary trunk and the lungs are only about 15 cm (6 in.) apart.

Figure 21-18 The Pulmonary Circuit. The pulmonary circuit consists of pulmonary arteries, which deliver deoxygenated blood from the right ventricle to the lungs; pulmonary capillaries, where gas exchange occurs; and pulmonary veins, which deliver oxygenated blood to the left atrium. As the enlarged view shows, diffusion across the capillary walls at alveoli removes carbon dioxide and provides oxygen to the blood.

The arteries of the pulmonary circuit differ from those of the systemic circuit in that they carry deoxygenated blood. (For this reason, these color-coded diagrams show the pulmonary arteries in blue, the same color as systemic veins.) As the pulmonary trunk curves over the superior border of the heart, it gives rise to the **left** and **right pulmonary arteries**. These large arteries enter the lungs before branching repeatedly, giving rise to smaller and smaller arteries. The smallest branches, the *pulmonary arterioles*, provide blood to capillary networks that surround *alveoli*. The walls of these small air pockets are thin enough for gas to be exchanged between the capillary blood and inspired air. As oxygenated blood leaves the alveolar capillary network, it enters venules that in turn unite to form larger vessels carrying blood toward the **pulmonary veins**. These four veins, two from each lung, empty into the left atrium, to complete the pulmonary circuit.

Tips

Arteries and veins are defined by the direction of blood flow relative to the heart, not by the oxygen content of the blood they carry. So if you remember that **arteries** carry blood **away** from the heart, and **veins** carry blood toward the heart, you can remember that the pulmonary **arteries** carry oxygen-poor blood **away** from the heart to the lungs, and the pulmonary **veins** deliver oxygen-rich blood to the heart.

21

✓ Checkpoint

17. Name the blood vessels that enter and exit the lungs, and whether they contain primarily oxygenated or deoxygenated blood.
18. Trace the path of a drop of blood through the lungs, beginning at the right ventricle and ending at the left atrium.

See the blue Answers tab at the back of the book.

21-7 The systemic circuit carries oxygenated blood from the left ventricle to tissues and organs other than the lungs, and returns deoxygenated blood to the right atrium

Learning Outcome Identify the major arteries and veins of the systemic circuit.

The systemic circuit supplies the capillary beds in all parts of the body not serviced by the pulmonary circuit. This circuit begins at the left ventricle and ends at the right atrium. At any moment the systemic circuit contains about 84% of total blood volume.

Systemic Arteries

Figure 21-19 provides an overview of the systemic arterial system and shows the relative locations of major systemic arteries. **Figures 21-20 to 21-25** show the detailed distribution of these

vessels and their branches. By convention, several large arteries are called *trunks*. Examples are the *pulmonary*, *brachiocephalic*, *thyrocervical*, and *celiac trunks*. Most of the major arteries are paired, with one artery of each pair on each side of the body. For this reason, the terms *right* and *left* appear in figures only when the arteries on both sides are labeled.

The Ascending Aorta

The **ascending aorta** (**Figure 21-20**) begins at the aortic valve of the left ventricle. The left and right coronary arteries originate in the aortic sinuses at the base of the ascending aorta, just superior to the aortic valve. (The distribution of coronary vessels was described in Chapter 20 and illustrated in **Figure 20-8**.)

The Aortic Arch

The **aortic arch** curves like the handle of a cane across the superior surface of the heart, connecting the ascending aorta with the *descending aorta* (**Figure 21-19**). Three elastic arteries originate along the aortic arch and deliver blood to the head, neck, shoulders, and upper limbs: (1) the **brachiocephalic** (brā-kē-ō-se-FAL-ik) **trunk**, (2) the **left common carotid artery**, and (3) the **left subclavian artery** (**Figure 21-21**). The brachiocephalic trunk, also called the *innominate artery* (i-NOM-i-nat; unnamed), ascends for a short distance before branching to form the **right subclavian artery** and the **right common carotid artery**.

Humans have only one brachiocephalic trunk, with the left common carotid and left subclavian arteries arising separately from the aortic arch. However, in terms of their peripheral distribution, the vessels on the left side are mirror images of those on the right side. **Figures 21-20** and **21-22** illustrate the major branches of these arteries.

The Subclavian Arteries. The subclavian arteries supply blood to the arms, chest wall, shoulders, back, and CNS (**Figures 21-19** and **21-20**). Three major branches arise before a subclavian artery leaves the thoracic cavity: (1) the **internal thoracic artery**, supplying the pericardium and anterior wall of the chest; (2) the **vertebral artery**, which provides blood to the brain and spinal cord; and (3) the **thyrocervical trunk**, which provides blood to muscles and other tissues of the neck, shoulder, and upper back.

After leaving the thoracic cavity and passing across the superior border of the first rib, the subclavian is called the **axillary artery**. This artery crosses the axilla to enter the arm, where it gives rise to *humeral circumflex arteries*, which supply structures near the head of the humerus. Distally, it becomes the **brachial artery**, which supplies blood to the rest of the upper limb. The brachial artery gives rise to the *deep brachial artery*, which supplies deep structures on the posterior aspect of the arm, and the *ulnar collateral arteries*, which supply the area around the elbow.

Figure 21–19 An Overview of the Major Systemic Arteries.

Figure 21–20 Arteries of the Chest and Upper Limb.

Figure 21–21 Arteries of the Neck and Head. Shown as seen from the right side.

The superficial temporal, maxillary, occipital, facial, and lingual arteries are all branches of what carotid artery?

As it approaches the coronoid fossa of the humerus, the brachial artery divides into the **radial artery**, which follows the radius, and the **ulnar artery**, which follows the ulna to the wrist. These arteries supply blood to the forearm and, through the *ulnar recurrent arteries*, the region around the elbow. At the wrist, the radial and ulnar arteries fuse to form the **superficial and deep palmar arches**, which supply blood to the hand and to the **digital arteries** of the thumb and fingers.

The Carotid Artery and the Blood Supply to the Brain. The common carotid arteries ascend deep in the tissues of the neck.

The carotid artery is located by pressing gently along either side of the windpipe (trachea) until a strong pulse is felt.

Each common carotid artery divides into an **external carotid artery** and an **internal carotid artery** (Figure 21–21). The *carotid sinus*, located at the base of the internal carotid artery, may extend along a portion of the common carotid. The external carotid arteries supply blood to the structures of the neck, esophagus, pharynx, larynx, lower jaw, and face. The internal carotid arteries enter the skull through the carotid canals of the temporal bones, delivering blood to the brain.

Figure 21–22 Arteries of the Brain.**Tips**

Remember that the *external* carotid artery supplies the face (which is external), and that the *internal* carotid supplies the brain (which is internal).

The internal carotid arteries ascend to the level of the optic nerves, where each artery divides into three branches: (1) an **ophthalmic artery**, which supplies the eyes; (2) an **anterior cerebral artery**, which supplies the frontal and parietal lobes of the brain; and (3) a **middle cerebral artery**, which supplies the midbrain and lateral surfaces of the cerebral hemispheres (Figures 21–21 and 21–22).

The brain is extremely sensitive to changes in blood supply. An interruption of blood flow for several seconds produces unconsciousness. After 4 minutes some permanent neural damage can occur. Such crises are rare, because blood reaches the brain through the vertebral arteries as well as by way of the internal carotid arteries. The left and right vertebral arteries arise from the subclavian arteries and ascend within the transverse foramina of the cervical vertebrae. The vertebral arteries enter the cranium at the foramen magnum, where they fuse along the ventral surface of the medulla oblongata to form the **basilar artery**. The vertebral arteries and the basilar artery supply blood to the spinal cord, medulla oblongata, pons, and cerebellum. They then divide into the **posterior cerebral arteries**, which in turn branch off into the **posterior communicating arteries** (Figure 21–22).

The internal carotid arteries normally supply the arteries of the anterior half of the cerebrum, and the rest of the brain receives blood from the vertebral arteries. But this pattern of blood flow can easily change because the internal carotid arteries and the basilar artery are interconnected. They form a ring-shaped anastomosis called the **cerebral arterial circle**, or *circle of Willis*, which encircles the optic chiasm and the infundibulum of the pituitary gland (**Figure 21–22**). With this arrangement, the brain can receive blood from either the carotid or the vertebral arteries, reducing the likelihood of a serious interruption of circulation.

Strokes, or *cerebrovascular accidents* (CVAs), are interruptions of the vascular supply to a portion of the brain. The *middle cerebral artery*, a major branch of the cerebral arterial circle, is the most common site of a stroke. Superficial branches deliver blood to the temporal lobe and large portions of the frontal and parietal lobes. Deep branches supply the basal nuclei and portions of the thalamus. If a stroke blocks the middle cerebral artery on the left side of the brain, this results in aphasia and sensory and motor paralysis of the right side of the body. In a stroke affecting the middle cerebral artery on the right side, the individual experiences a loss of sensation and motor control over the left side of the body, and the person has difficulty drawing or interpreting spatial relationships. Strokes affecting vessels that supply the brainstem also produce distinctive symptoms. Strokes affecting the lower brainstem are commonly fatal.

The Descending Aorta

The **descending aorta** is continuous with the aortic arch. The diaphragm divides the descending aorta into a superior **thoracic aorta** and an inferior **abdominal aorta** (**Figures 21–23** and **21–24**).

The Thoracic Aorta. The thoracic aorta begins at the level of vertebra T₅ and penetrates the diaphragm at the level of vertebra T₁₂. It travels within the mediastinum, on the posterior thoracic wall, slightly to the left of the vertebral column. This vessel supplies blood to branches that service the tissues and organs of the mediastinum, the muscles of the chest and the diaphragm, and the thoracic spinal cord.

The branches of the thoracic aorta are grouped anatomically as either visceral or somatic (**Figure 21–23**):

- *Visceral branches* supply the organs of the chest. The **bronchial arteries** supply the tissues of the lungs not involved in gas exchange. The **pericardial arteries** supply the pericardium. The **esophageal arteries** supply the esophagus, and the **mediastinal arteries** supply the tissues of the mediastinum.
- *Somatic branches* supply the chest wall. The **intercostal arteries** supply the chest muscles and the vertebral column area. The **superior phrenic** (FREN-ik) **arteries** deliver blood to the superior surface of the diaphragm, which separates the thoracic and abdominopelvic cavities.

Clinical Note Aortic Aneurysm

Over many years, atherosclerosis and hypertension may take their toll on the aorta. The wall of the aorta becomes damaged and stretches out to form a pouch, or aneurysm. This structural change can weaken the aorta so much that it tears. The ensuing pain can come on without warning. Visualize the path of the aorta as it plunges deep through the thorax and abdomen, and think about how daunting it is for a surgeon to reach a ruptured aortic aneurysm, stop blood loss, and save the patient's life.

The Abdominal Aorta. The abdominal aorta is a continuation of the thoracic aorta (**Figure 21–23**). It begins immediately inferior to the diaphragm and descends slightly to the left of the vertebral column but posterior to the peritoneal cavity. A cushion of adipose tissue commonly surrounds the abdominal aorta. At the level of vertebra L₄, the abdominal aorta splits into two major arteries—the *left and right common iliac arteries*—that supply deep pelvic structures and the lower limbs. The region where the abdominal aorta splits is called the *terminal segment of the aorta*.

The abdominal aorta delivers blood to all the abdominopelvic organs and structures. The major branches to visceral organs are unpaired. They arise on the anterior surface of the abdominal aorta and extend into the mesenteries. By contrast, branches to the body wall, the kidneys, the urinary bladder, and other structures outside the peritoneal cavity are paired. They originate along the lateral surfaces of the abdominal aorta. **Figure 21–23** shows the major arteries of the trunk after most thoracic and abdominal organs have been removed. **Figure 21–24** shows the distribution of those arteries to abdominopelvic organs.

Tips

The aorta resembles a walking cane: the ascending aorta, aortic arch, and the start of the descending aorta form the cane's handle, while the thoracic and abdominal segments of the descending aorta form the cane's shaft.

The abdominal aorta gives rise to three unpaired arteries (**Figures 21–23** and **21–24**).

1. The **celiac** (SĒ-lē-ak) **trunk** delivers blood to the liver, stomach, and spleen. The celiac trunk divides into three branches: (a) The **left gastric artery** supplies the stomach and the inferior portion of the esophagus. (b) The **splenic artery** supplies the spleen and arteries to the stomach (*left gastro-epiploic artery*) and pancreas (*pancreatic arteries*). (c) The **common hepatic artery** supplies arteries to the liver (*hepatic artery proper*), stomach (*right gastric artery*),

Figure 21–23 Major Arteries of the Trunk.**a** A diagrammatic view, with most of the thoracic and abdominal organs removed

gallbladder (*cystic artery*), and duodenal area (*gastroduodenal*, *right gastro-epiploic*, and *superior pancreaticoduodenal arteries*).

2. The **superior mesenteric** (mez-en-TER-ik) **artery** arises about 2.5 cm (1 in.) inferior to the celiac trunk. It supplies arteries to the pancreas and duodenum (*inferior pancreaticoduodenal artery*), small intestine (*intestinal arteries*), and most of the large intestine (*right and middle colic* and the *ileocolic arteries*).
3. The **inferior mesenteric artery** arises about 5 cm (2 in.) superior to the terminal aorta. It delivers blood to the terminal portions of the colon (*left colic* and *sigmoid arteries*) and the rectum (*rectal arteries*).

The abdominal aorta also gives rise to five paired arteries (**Figure 21–23**):

1. The **inferior phrenic arteries** supply the inferior surface of the diaphragm and the inferior portion of the esophagus.
2. The **adrenal arteries** originate on either side of the aorta near the base of the superior mesenteric artery. Each

adrenal artery supplies one adrenal gland, which caps the superior part of a kidney.

3. The short (about 7.5 cm) **renal arteries** arise along the posterolateral surface of the abdominal aorta, about 2.5 cm (1 in.) inferior to the superior mesenteric artery. They travel posterior to the peritoneal lining to reach the adrenal glands and kidneys.
4. The **gonadal** (gō-NAD-al) **arteries** originate between the superior and inferior mesenteric arteries. In males, they are called *testicular arteries* and are long, thin arteries that supply blood to the testes and scrotum. In females, they are termed *ovarian arteries* and supply blood to the ovaries, uterine tubes, and uterus. The distribution of gonadal vessels (both arteries and veins) differs by sex.
5. Small **lumbar arteries** arise on the posterior surface of the aorta. They supply the vertebrae, spinal cord, and abdominal wall.

Figure 21–23 Major Arteries of the Trunk. (Continued)**b** A flowchart showing major arteries of the trunk**Arteries of the Pelvis and Lower Limbs**

Near the level of vertebra L_4 , the terminal segment of the abdominal aorta divides to form a pair of elastic arteries—the **right** and **left common iliac** (IL-ē-ak) **arteries**—plus the small **median sacral artery** (Figure 21–23a). The common iliac arteries carry blood to the pelvis and lower limbs. They descend posterior to the cecum and sigmoid colon along the inner surface of the ilium. At the level of the lumbosacral joint, each common iliac divides to form an **internal iliac artery** and an **external iliac artery** (Figure 21–23b). The internal iliac arteries enter the pelvic cavity to supply the urinary bladder, the internal and external walls of the pelvis, the external genitalia, the medial side of the thigh, and, in females, the uterus and vagina. The major branches of the internal iliac artery are the *gluteal*, *internal pudendal*, *obturator*, and *lateral sacral* arteries. The external iliac arteries supply blood to the lower limbs. They are much larger in diameter than the internal iliac arteries.

Arteries of the Thigh and Leg. Each external iliac artery crosses the surface of an iliopsoas muscle and penetrates the abdominal wall midway between the anterior superior iliac spine and the pubic symphysis on that side. It emerges on the anterior, medial surface of the thigh as the **femoral artery** (Figure 21–25). Approximately 5 cm (2 in.) distal to the emergence of the femoral artery, the **deep femoral artery** branches off its lateral surface. The deep femoral artery supplies blood to the ventral and lateral regions of the skin and deep muscles of the thigh. It gives rise to the *femoral circumflex arteries*.

The femoral artery continues inferiorly and posterior to the femur. As it approaches the knee, it gives rise to the *descending genicular artery*, which supplies the area around the knee. At the popliteal fossa, posterior to the knee joint, the femoral artery becomes the **popliteal** (pop-LIT-ē-al) **artery**, which then branches to form the **posterior** and **anterior tibial arteries**. The posterior tibial artery gives rise to the **fibular artery**, or *peroneal* (*perone*, fibula) *artery*, and then continues inferiorly along the posterior surface of the tibia. The anterior tibial artery passes between the tibia and fibula. It emerges on the anterior surface of the tibia. As it descends toward the foot, the anterior tibial artery provides blood to the skin and muscles of the anterior portion of the leg.

Arteries of the Foot. At the ankle, the anterior tibial artery becomes the **dorsalis pedis artery**. It then branches repeatedly, supplying the ankle and dorsal portion of the foot (Figure 21–25). Figure 21–25c charts the flow of blood from the external iliac artery to the lower limbs.

At the ankle, the posterior tibial artery divides to form the **medial** and **lateral plantar arteries**. They supply blood to the plantar surface of the foot. These

Figure 21–24 Arteries Supplying the Abdominopelvic Organs.

arteries are connected to the dorsalis pedis artery through a pair of anastomoses. The arrangement produces a **dorsal arch** (*arcuate arch*) and a **plantar arch**. Small arteries branching off these arches supply the distal portions of the foot and the toes.

Systemic Veins

Veins collect blood from the tissues and organs of the body by means of an elaborate venous network that drains into the right atrium of the heart by the superior and inferior venae cavae (**Figure 21–26**). The branching pattern of peripheral veins is much more variable than is the branching pattern of arteries. The most common arrangement of veins is discussed next. Complementary arteries and veins commonly run side by side. In many cases they have comparable names.

One significant difference between the arterial and venous systems involves the distribution of major veins in the neck and limbs. Arteries in these areas are deep beneath the skin, protected by bones and surrounding soft tissues. In contrast,

the neck and limbs generally have two sets of peripheral veins, one superficial and the other deep. This dual venous drainage is important for controlling body temperature. In hot weather, venous blood flows through superficial veins, where heat can easily be lost. In cold weather, blood is routed to the deep veins to minimize heat loss.

The Superior Vena Cava

All the body's systemic veins (except the cardiac veins) ultimately drain into either the superior vena cava or the inferior vena cava. The **superior vena cava (SVC)** receives blood from the tissues and organs of the head, neck, chest, shoulders, and upper limbs.

Venous Return from the Cranium. Numerous veins drain the cerebral hemispheres. The *superficial cerebral veins* and small veins of the brainstem empty into a network of dural sinuses (**Figure 21–27a,b**). These sinuses include the *superior* and *inferior sagittal sinuses*, the *petrosal sinuses*, the *occipital sinus*, the *left* and *right transverse sinuses*, and the *straight sinus* (**Figure 21–27c**).

Figure 21–25 Arteries of the Lower Limb.

Figure 21–26 An Overview of the Major Systemic Veins.

Figure 21–27 Major Veins of the Head, Neck, and Brain.

The superior sagittal sinus, occipital sinus, straight sinus, and two transverse sinuses connect at the *confluence of sinuses*. The largest, the **superior sagittal sinus**, is in the falx cerebri (Figure 14–3). Most of the *inferior cerebral veins* converge within the brain to form the **great cerebral vein**. It delivers blood from the interior of the cerebral hemispheres and the choroid plexus to the **straight sinus**. Other cerebral veins drain into the **cavernous sinus** with numerous small veins from the orbit. Blood from the cavernous sinus reaches the internal jugular vein through the petrosal sinuses.

The venous sinuses converge within the dura mater in the region of the lambdoid suture. The left and right transverse sinuses begin at the confluence of the occipital, sagittal, and straight sinuses. Each transverse sinus drains into a **sigmoid sinus**, which penetrates the jugular foramen and leaves the skull as the **internal jugular vein**. It descends parallel to the common carotid artery in the neck.

Vertebral veins drain the cervical spinal cord and the posterior surface of the skull. These vessels descend within the transverse foramina of the cervical vertebrae, along with the vertebral arteries. The vertebral veins empty into the *brachiocephalic veins* of the chest (discussed later in the chapter).

Superficial Veins of the Head and Neck. The superficial veins of the head converge to form the **temporal, facial, and maxillary veins** (Figure 21–27c). The temporal vein and the maxillary vein drain into the **external jugular vein**. The facial vein drains into the internal jugular vein. A broad anastomosis between the external and internal jugular veins at the angle of the mandible provides dual venous drainage of the face, scalp, and cranium. The external jugular vein descends toward the chest just deep to the skin on the anterior surface of the sternocleidomastoid muscle. Posterior to the clavicle, the external jugular vein empties into the *subclavian vein*. In healthy individuals, the external jugular vein is easily palpable. A *jugular venous pulse* (JVP) is sometimes detectable at the base of the neck.

Venous Return from the Upper Limbs. The **digital veins** empty into the **superficial and deep palmar veins** of the hand, which interconnect to form the **palmar venous arches** (Figure 21–28). The superficial arch empties into the **cephalic vein**, which ascends along the radial side of the forearm; the **median antebrachial vein**; and the **basilic vein**, which ascends on the ulnar side. Anterior to the elbow is the superficial **median cubital vein**, which passes from the cephalic vein, medially and at an oblique angle, to connect to the basilic vein. (Venous blood samples are typically collected from the median cubital.) From the elbow, the basilic vein passes superiorly along the medial surface of the biceps brachii muscle.

The deep palmar veins drain into the **radial vein** and the **ulnar vein**. These veins fuse to form the **brachial vein**, running parallel to the brachial artery. As the brachial vein

continues toward the trunk, it merges with the basilic vein and becomes the **axillary vein**, which enters the axilla.

Formation of the Superior Vena Cava. The cephalic vein joins the axillary vein on the lateral surface of the first rib, forming the **subclavian vein**, which continues into the chest. The subclavian vein passes superior to the first rib and along the superior margin of the clavicle. It merges with the external and internal jugular veins of that side. This fusion creates the **brachiocephalic vein**, or *innominate vein*, which penetrates the body wall and enters the thoracic cavity.

Each brachiocephalic vein receives blood from the vertebral vein of the same side, which drains the back of the skull and spinal cord. Near the heart, at the level of the first and second ribs, the left and right brachiocephalic veins join, creating the superior vena cava. Close to the point of fusion, the **internal thoracic vein** empties into the brachiocephalic vein.

The unpaired **azygos (AZ-T-gos) vein** is the major branch of the superior vena cava. This vein ascends from the lumbar region over the right side of the vertebral column to enter the thoracic cavity through the diaphragm. The azygos vein joins the superior vena cava at the level of vertebra T₂. On the left side, the azygos receives blood from the smaller **hemi-azygos vein**, which in many people also drains into the left brachiocephalic vein through the *highest intercostal vein*.

The azygos and hemi-azygos veins are the chief collecting vessels of the thorax. They receive blood from (1) **intercostal veins**, which in turn receive blood from the chest muscles; (2) **esophageal veins**, which drain blood from the inferior portion of the esophagus; and (3) smaller veins draining other mediastinal structures.

Figure 21–29 diagrams the venous branches of the superior vena cava.

Clinical Note Preparing the Circulation for Dialysis

When a patient's kidneys fail from chronic disease (diabetes mellitus, for example), the patient requires **dialysis** to cleanse the blood as the kidneys would normally do. A minor outpatient surgical procedure called an **arteriovenous fistula** prepares the circulation for successful dialysis. The surgeon connects a large vein, usually in the arm, to the nearby artery. Soon the higher pressure in the artery acts on the vein to enlarge its diameter. In a few weeks, the fistula heals and can accept a dialysis needle. The patient's "dirty" blood (blood containing nitrogenous waste, such as urea) is withdrawn from the artery, "cleaned" in the dialysis machine, and returned easily to their enlarged vein. The fistula can last for several years before a new one needs to be created at another site.

Figure 21–28 The Venous Drainage of the Abdomen and Chest.

The Inferior Vena Cava

The **inferior vena cava (IVC)** collects most of the venous blood from organs inferior to the diaphragm. (A small amount reaches the superior vena cava by the azygos and hemi-azygos veins.)

Veins Draining the Lower Limbs. Blood leaving capillaries in the sole of each foot collects into a network of **plantar veins**, which supply the **plantar venous arch** (Figure 21–30a). The plantar network sends blood to the deep veins of the leg: the **anterior tibial vein**, the **posterior tibial vein**, and the **fibular vein**. The **dorsal venous arch** collects blood from capillaries on the superior surface of the foot and the **digital veins** of the toes. The plantar arch and the dorsal arch are extensively interconnected, and the path of blood flow can easily shift from superficial to deep veins.

Two superficial veins drain the dorsal venous arch: the **great saphenous** (sa-FE-nus; *saphenes*, prominent) **vein** and the

small saphenous vein. The great saphenous vein ascends along the medial aspect of the leg and thigh, draining into the *femoral vein* near the hip joint. The small saphenous vein arises from the dorsal venous arch and ascends along the posterior and lateral aspect of the calf. This vein then enters the popliteal fossa, where it meets the **popliteal vein**, formed by the union of the fibular and

Figure 21–29 Flowchart of Circulation to the Superior and Inferior Venae Cavae.

Figure 21–30 Venous Drainage from the Lower Limb.

both tibial veins (**Figure 21–30a,b**). The popliteal vein is easily palpated in the popliteal fossa adjacent to the adductor magnus muscle. At the femur, the popliteal vein becomes the **femoral vein**, which ascends along the thigh, next to the femoral artery. Immediately before penetrating the abdominal wall, the femoral vein receives blood from (1) the great saphenous vein; (2) the **deep femoral vein**, which collects blood from deeper structures in the thigh; and (3) the **femoral circumflex vein**, which drains the region around the neck and head of the femur. The femoral vein penetrates the body wall and emerges in the pelvic cavity as the **external iliac vein**.

Veins Draining the Pelvis. The external iliac veins receive blood from the lower limbs, the pelvis, and the lower

abdomen. As the left and right external iliac veins cross the inner surface of the ilium, they are joined by the **internal iliac veins**, which drain the pelvic organs (**Figure 21–29**). The internal iliac veins are formed by the fusion of the *gluteal*, *internal pudendal*, *obturator*, and *lateral sacral veins* (**Figure 21–30a**).

The union of external and internal iliac veins forms the **common iliac vein**. Its right and left branches ascend at an oblique angle. The left common iliac vein receives blood from the *median sacral vein*, which drains the area supplied by the median sacral artery (**Figure 21–28**). Anterior to vertebra L₅, the common iliac veins unite to form the inferior vena cava.

Veins Draining the Abdomen. The inferior vena cava ascends posterior to the peritoneal cavity, parallel to the aorta. The abdominal portion of the inferior vena cava collects blood from six major veins (**Figures 21–28** and **21–29**):

- **Lumbar veins** drain the lumbar portion of the abdomen, including the spinal cord and body wall muscles. Superior branches of these veins are connected to the azygos vein (right side) and hemi-azygos vein (left side), which empty into the superior vena cava.
- **Gonadal (ovarian or testicular) veins** drain the ovaries or testes. The right gonadal vein empties into the inferior vena cava. The left gonadal vein generally drains into the left renal vein.
- **Hepatic veins** from the liver empty into the inferior vena cava at the level of vertebra T₁₀.

- **Renal veins**, the largest branches of the inferior vena cava, collect blood from the kidneys.
- **Adrenal veins** drain the adrenal glands. In most people, only the right adrenal vein drains into the inferior vena cava. The left adrenal vein drains into the left renal vein.
- **Phrenic veins** drain the diaphragm. Only the right phrenic vein drains into the inferior vena cava. The left drains into the left renal vein.

Figure 21–29 diagrams the branches of the inferior vena cava.

The Hepatic Portal System

The **hepatic portal system** begins in the capillaries of the digestive organs and ends in the liver sinusoids (**Figure 21–31**).

Figure 21–31 The Hepatic Portal System.

(Recall from Chapter 18, a blood vessel connecting two capillary beds is called a *portal vessel*. The network is a *portal system*.) Blood flowing in the hepatic portal system is quite different from blood in other systemic veins because it contains substances absorbed from the stomach and intestines. For example, levels of blood glucose and amino acids in the hepatic portal vein often exceed those found anywhere else in the cardiovascular system. The hepatic portal system delivers these and other absorbed compounds directly to the liver for storage, metabolic conversion, or excretion.

The largest vessel of the hepatic portal system is the **hepatic portal vein** (Figure 21–31). It delivers venous blood to the liver. It receives blood from three large veins draining organs within the peritoneal cavity:

- The **inferior mesenteric vein** collects blood from capillaries along the inferior portion of the large intestine. Its branches include the *left colic vein*, *sigmoid vein*, and the *superior rectal veins*. They drain the descending colon, sigmoid colon, and rectum.
- The **splenic vein** is formed by the union of the inferior mesenteric vein and veins from the spleen, the lateral border of the stomach (*left gastro-epiploic vein*), and the pancreas (*pancreatic veins*).
- The **superior mesenteric vein** collects blood from veins draining the stomach (*right gastro-epiploic vein*), the small intestine (*intestinal* and *pancreaticoduodenal veins*), and two-thirds of the large intestine (*ileocolic*, *right colic*, and *middle colic veins*).

The hepatic portal vein forms through the fusion of the superior mesenteric, inferior mesenteric, and splenic veins. The superior mesenteric vein normally contributes the greater volume of blood and most of the nutrients. As it proceeds, the hepatic portal vein receives blood from the left and right **gastric veins**, which drain the medial border of the stomach, and from the **cystic vein** of the gallbladder.

After passing through liver sinusoids, blood collects in the hepatic veins, which empty into the inferior vena cava.

The composition of the blood in the systemic circuit is relatively stable despite changes in diet and digestive activity. The reason for this stability is that blood from the intestines goes to the liver first, and the liver regulates the nutrient content of the blood before it enters the inferior vena cava.

19. A blockage of which branch from the aortic arch would interfere with blood flow to the left arm?
20. Why would compression of the common carotid arteries cause a person to lose consciousness?

21. Isabella is in an automobile accident, and her celiac trunk is ruptured. Which organs will be affected most directly by this injury?
22. Whenever Noah gets angry, a large vein bulges in the lateral region of his neck. Which vein is this?
23. A thrombus that blocks the popliteal vein would interfere with blood flow in which other veins?

See the blue Answers tab at the back of the book.

21-8 Modifications of fetal and maternal cardiovascular systems promote the exchange of materials; the fetal cardiovascular system changes to function independently after birth

Learning Outcome Identify the differences between fetal and adult circulation patterns and describe the changes in the patterns of blood flow that occur at birth.

The fetal cardiovascular system differs from the adult cardiovascular system because the fetus and the adult have different sources of respiratory and nutritional support. Most strikingly, the fetal lungs are collapsed and nonfunctional, and the digestive tract has nothing to digest. Instead, diffusion across the placenta provides for the respiratory and nutritional needs of the fetus. This situation changes dramatically at birth when the newborn's system is separated from the female's.

Fetal Circulatory Route and Placental Blood Supply

Fetal patterns of blood flow are diagrammed in Figure 21–32a. Blood flows to the placenta through a pair of **umbilical arteries**. They arise from the internal iliac arteries and enter the umbilical cord. Blood returns from the placenta in the single **umbilical vein**, bringing oxygen and nutrients to the developing fetus. The umbilical vein drains into the **ductus venosus**, a vascular connection to an intricate network of veins within the developing liver. The ductus venosus collects blood from the veins of the liver and from the umbilical vein, and empties into the inferior vena cava.

Fetal Heart and Great Vessels

An interesting aspect of cardiovascular development is that of the heart, which reflects the differences between the life of an embryo or fetus and that of an infant. The interatrial and interventricular septa develop early in fetal life, but the interatrial partition remains functionally incomplete until birth. The **foramen ovale**, or *interatrial opening*, is associated with a long flap that acts as a valve. Blood can flow freely from the right atrium to the left atrium, but any backflow closes the valve and isolates the two chambers from one another. Thus, blood entering the heart at the right atrium can bypass the pulmonary

Figure 21–32 Fetal Circulation.**a** Blood flow to and from the placenta in full-term fetus (before birth)**b** Blood flow through the neonatal (newborn) heart after delivery

circuit. A second short circuit exists between the pulmonary and aortic trunks. This connection, the **ductus arteriosus**, consists of a short, muscular vessel.

With the lungs collapsed, the capillaries are compressed and little blood flows through the lungs. During diastole, blood enters the right atrium and flows into the right ventricle, but it also passes into the left atrium through the foramen ovale. About 25% of the blood arriving at the right atrium bypasses the pulmonary circuit in this way. In addition, more than 90% of the blood leaving the right ventricle passes through the ductus arteriosus and enters the systemic circuit rather than continuing to the lungs.

Cardiovascular Changes at Birth

At birth, notable changes take place. When the placental connection is broken at birth, blood stops flowing in the umbilical vessels, and they soon degenerate. Remnants of these vessels persist throughout life as fibrous cords. When an infant takes

the first breath, the lungs expand, and so do the pulmonary vessels. The resistance in the pulmonary circuit decreases suddenly, and blood rushes into the pulmonary vessels. Within a few seconds, rising O_2 levels stimulate the constriction of the ductus arteriosus, isolating the pulmonary and aortic trunks from one another. As pressures rise in the left atrium, the valvular flap closes the foramen ovale. In adults, the interatrial septum bears the *fossa ovalis*, a shallow depression that marks the site of the foramen ovale (review **Figure 20–5a**). The remnants of the ductus arteriosus persist throughout life as the *ligamentum arteriosum*, a fibrous cord.

If the proper cardiovascular changes do not take place at birth or shortly after, problems eventually develop. Their severity depends on which connection remains open and on the size of the opening. Treatment may involve surgery to close the foramen ovale, the ductus arteriosus, or both. Other congenital heart defects result from abnormal cardiac development or inappropriate connections between the heart and major arteries and veins.

Spotlight Figure 21–33 focuses on congenital heart problems.

Although minor individual variations in the vascular network are quite common, congenital heart problems serious enough to threaten homeostasis are relatively rare.

Patent Foramen Ovale and Patent Ductus Arteriosus

If the foramen ovale remains open, or *patent*, blood recirculates through the pulmonary circuit instead of entering the left ventricle. The movement, driven by the relatively high systemic pressure, is called a “left-to-right shunt.” Arterial oxygen content is normal, but the left ventricle must work much harder than usual to provide adequate blood flow through the systemic circuit. Hence, pressures rise in the pulmonary circuit. If

the pulmonary pressures rise enough, they may force blood into the systemic circuit through the ductus arteriosus. This condition—a patent ductus arteriosus—creates a “right-to-left shunt.” Because the circulating blood is not adequately oxygenated, it develops a deep red color. The skin then develops the blue tones typical of cyanosis and the infant is known as a “blue baby.”

Tetralogy of Fallot

The tetralogy of Fallot (fa-LŌ) is a complex group of heart and circulatory defects that affect 0.10% of newborn infants. In this condition, (1) the pulmonary trunk is abnormally narrow (pulmonary stenosis), (2) the interventricular septum is incomplete, (3) the aorta originates where the interventricular septum normally ends,

and (4) the right ventricle is enlarged and both ventricles thicken in response to the increased workload.

Ventricular Septal Defect

A ventricular septal defect is an abnormal opening in the wall (septum) between the left and right ventricles. It affects 0.12% of newborns. The opening between the two ventricles has an effect similar to a connection between the atria: When the more powerful left ventricle beats, it ejects blood into the right ventricle and pulmonary circuit.

Atrioventricular Septal Defect

In an atrioventricular septal defect, both the atria and ventricles are incompletely separated. The results are quite variable, depending on the extent of the defect and the effects on the atrioventricular valves. This type of defect most commonly affects infants with Down syndrome, a disorder caused by the presence of an extra copy of chromosome 21.

Transposition of the Great Vessels

In the transposition of the great vessels, the aorta is connected to the right ventricle instead of to the left ventricle, and the pulmonary artery is connected to the left ventricle instead of the right ventricle. This malformation affects 0.05% of newborn infants.

Normal Heart Structure

Most congenital heart problems result from abnormal formation of the heart or problems with the connections between the heart and the great vessels.

✓ Checkpoint

24. Name the three vessels that carry blood to and from the placenta.
25. A blood sample taken from an umbilical cord contains high levels of oxygen and nutrients, and low levels of carbon dioxide and waste products. Is this sample from an umbilical artery or the umbilical vein? Explain.
26. Name the structures in the fetal circulation that stop functioning at birth. What becomes of these structures?

See the blue Answers tab at the back of the book.

21-9 Aging affects the blood, heart, and blood vessels

Learning Outcome Discuss the effects of aging on the cardiovascular system and give examples of interactions between the cardiovascular system and other organ systems.

The capabilities of the cardiovascular system gradually decline. Aging causes the following major cardiovascular system changes:

- **Age-related changes in blood** may include (1) a decreased hematocrit; (2) constriction or blockage of peripheral veins by a stationary blood clot called a *thrombus*, which can become detached, pass through the heart, and become wedged in a small artery (commonly in the lungs), causing *pulmonary embolism*; and (3) pooling of blood in the veins of the legs because valves are not working effectively.
- **Age-related changes in the heart** include (1) a reduction in maximum cardiac output, (2) changes in the activities of pacemaker and conducting cells, (3) a reduction in the

elasticity of the cardiac (fibrous) skeleton, (4) progressive atherosclerosis that can restrict coronary circulation, and (5) replacement of damaged cardiac contractile cells by scar tissue.

- **Age-related changes in blood vessels** may be linked to arteriosclerosis: (1) The inelastic walls of arteries become less tolerant of sudden pressure increases, which can lead to an aneurysm, whose rupture may (depending on the vessel) cause a cerebrovascular accident (CVA), myocardial infarction, or massive blood loss; (2) calcium salts can be deposited on weakened vascular walls, increasing the risk of a CVA or myocardial infarction; (3) lipid deposits in the tunica media associated with a damaged endothelial lining and calcium salts can form atherosclerotic plaques; and (4) thrombi can form at atherosclerotic plaques.

The cardiovascular system is both anatomically and functionally linked to all other systems. Build Your Knowledge **Figure 21-34** shows the functional relationships between the cardiovascular system and the other body systems we have studied so far. The organization and function of the lymphatic system are considered in the next chapter.

✓ Checkpoint

27. Identify components of the cardiovascular system that are affected by age.
28. Define thrombus.
29. Define aneurysm.
30. Describe what the cardiovascular system provides for all other body systems.
31. What is the relationship between the skeletal system and the cardiovascular system?

See the blue Answers tab at the back of the book.

Build Your Knowledge

Figure 21–34 Integration of the CARDIOVASCULAR system with the other body systems presented so far.

21 Chapter Review

Study Outline

An Introduction to Blood Vessels and Circulation

1. Blood circulates throughout the body, moving from the heart, then through the body tissues, and then back to the heart, in tubular structures called *blood vessels*.

21-1 Arteries, which are elastic or muscular, and veins, which contain valves, have three-layered walls; capillaries have thin walls with only one layer

2. Blood flows through a network of arteries, veins, and capillaries. All chemical and gaseous exchange between blood and interstitial fluid takes place across capillary walls.
3. **Arteries** and **veins** form an internal distribution system through which the heart propels blood. Arteries branch repeatedly, decreasing in size until they become **arterioles**. From the arterioles, blood enters **capillary** networks. Blood flowing from the capillaries enters small **venules** before entering larger veins.
4. The walls of arteries and veins contain three layers: the innermost **tunica intima**, the **tunica media**, and the outermost **tunica externa**. (Figure 21-1)
5. In general, the walls of arteries are thicker than those of veins. Arteries constrict when blood pressure does not distend them, but veins constrict very little. The endothelial lining cannot contract, so when constriction occurs, the lining of an artery becomes folded. (Figure 21-1)
6. The arterial system includes the large **elastic arteries**, medium-sized **muscular arteries**, and smaller **arterioles**. As blood proceeds toward the capillaries, the number of vessels increases, but the luminal diameters of the individual vessels decrease and the walls become thinner. (Figure 21-2)
7. **Atherosclerosis**, a type of **arteriosclerosis**, is associated with changes in the endothelial lining of arteries. Fatty masses of tissue called **plaques** typically develop during atherosclerosis.
8. Capillaries are the only blood vessels whose walls are thin enough to permit an exchange between blood and interstitial fluid. Capillaries are **continuous** or **fenestrated**. **Sinusoids** have fenestrated walls and a discontinuous endothelium, and form networks that allow very slow blood flow. Sinusoids occur in the liver and in various endocrine organs. (Figure 21-3)
9. Capillaries form interconnected networks called **capillary beds**. A band of smooth muscle, the **precapillary sphincter**, adjusts the blood flow into each capillary. The entire capillary bed may be bypassed by blood flow through **arteriovenous anastomoses**. (Figure 21-4)
10. Venules collect blood from the capillaries and merge into **medium-sized veins** and then **large veins**. The arterial system is a high-pressure system; blood pressure in veins is much lower. **Valves** in veins prevent the backflow of blood. (Figures 21-1, 21-2, 21-5)
11. Veins expand easily at low pressures and have high **capacitance**. Veins act as **blood reservoirs** and can accommodate large changes in blood volume. Peripheral **venoconstriction**

helps maintain adequate blood volume in the arterial system after a hemorrhage. (Figure 21-6)

21-2 Pressure and resistance determine blood flow and affect rates of capillary exchange

12. Cardiovascular regulation involves the manipulation of blood pressure and resistance to control the rates of blood flow and capillary exchange.
13. Blood flows from an area of higher pressure to one of lower pressure, and blood flow is proportional to the pressure gradient. The **circulatory pressure** is the pressure gradient across the systemic circuit. It is reported as three values: **arterial blood pressure (BP)**, **capillary hydrostatic pressure (CHP)**, and **venous pressure**.
14. The **resistance (R)** determines the rate of blood flow through the systemic circuit. The major determinant of blood flow rate is the **peripheral resistance**—the resistance of the arterial system. Neural and hormonal control mechanisms regulate blood pressure and peripheral resistance.
15. **Vascular resistance** is the resistance of blood vessels. It is the largest component of peripheral resistance and depends on vessel length and vessel luminal diameter. (Figure 21-7)
16. **Viscosity** and **turbulence** also contribute to peripheral resistance. (Table 21-1)
17. The high arterial pressures overcome peripheral resistance and maintain blood flow through peripheral tissues. Capillary pressures are normally low, and small changes in capillary pressure determine the rate of movement of fluid into or out of the bloodstream. Venous pressure, normally low, determines **venous return** and affects cardiac output and peripheral blood flow. (Figures 21-8, 21-9; Table 21-1)
18. Arterial blood pressure rises during ventricular systole and falls during ventricular diastole. The difference between these two blood pressures is the **pulse pressure**. (Figures 21-8, 21-9)
19. Valves, muscular compression, and the **respiratory pump** help the relatively low venous pressures propel blood toward the heart. (Figures 21-5, 21-8)
20. At the capillaries, hydrostatic pressure forces water and solutes out of the plasma, across capillary walls. Water moves out of the capillaries, through the peripheral tissues, and back to the bloodstream by way of the lymphatic system. Water movement across capillary walls is determined by the interplay between hydrostatic pressures and osmotic pressures. (Figure 21-10)

21. **Osmotic pressure (OP)** is a measure of the pressure that must be applied to prevent osmotic movement across a membrane. Osmotic water movement continues until either solute concentrations are equalized or the movement is prevented by an opposing hydrostatic pressure.
22. The rates of filtration and reabsorption gradually change as blood passes along the length of a capillary, as determined by the **net filtration pressure** (the difference between the net hydrostatic pressure and the net osmotic pressure). (Figure 21–11)

21-3 Blood flow and pressure in tissues are controlled by both autoregulation and central regulation

23. Homeostatic mechanisms ensure that **tissue perfusion** (blood flow) delivers adequate oxygen and nutrients.
24. Autoregulation, neural mechanisms, and endocrine mechanisms influence the coordinated regulation of cardiovascular function. Autoregulation involves local factors changing the pattern of blood flow within capillary beds in response to chemical changes in interstitial fluids. Neural mechanisms respond to changes in arterial pressure or blood gas levels. Hormones can assist in short-term adjustments (changes in cardiac output and peripheral resistance) and long-term adjustments (changes in blood volume that affect cardiac output and gas transport). (Figure 21–12)
25. Peripheral resistance is adjusted at the tissues by local factors that result in the dilation or constriction of precapillary sphincters. (Figure 21–4)
26. **The cardiovascular center** of the medulla oblongata is responsible for adjusting cardiac output and peripheral resistance to maintain adequate blood flow. Its vasomotor center contains one group of neurons responsible for controlling vasoconstriction, and another group responsible for controlling vasodilation. Its cardiac centers include a *cardioacceleratory center* (which increases cardiac output through sympathetic innervation) and *cardioinhibitory center* (which decreases cardiac output through parasympathetic innervation).
27. **Baroreceptor reflexes** monitor the degree of stretch within expandable organs. Baroreceptors are located in the **carotid sinuses**, the **aortic arch**, and the right atrium. (Figure 21–13)
28. **Chemoreceptor reflexes** respond to changes in the oxygen or CO₂ levels in the blood. They are triggered by sensory neurons located in the **carotid bodies** and the **aortic bodies**. (Figure 21–14)
29. The endocrine system provides short-term regulation of cardiac output and peripheral resistance with epinephrine and norepinephrine from the adrenal medullae. Hormones involved in the long-term regulation of blood pressure and volume are *antidiuretic hormone* (ADH), *angiotensin II*, *erythropoietin* (EPO), and *natriuretic peptides* (ANP and BNP). (Figure 21–15)

21-4 The cardiovascular system adapts to physiological stress while maintaining a special vascular supply to the brain, heart, and lungs

30. The blood-brain barrier, the coronary circulation, and the capillary network in the lungs are examples of special circulations, in which cardiovascular dynamics and regulatory mechanisms differ from those in other tissues.
31. During exercise, blood flow to skeletal muscles increases at the expense of blood flow to nonessential organs, and cardiac output rises. Cardiovascular performance improves with training. Athletes have larger stroke volumes, slower resting heart rates, and larger cardiac reserves than do nonathletes. (Tables 21–2, 21–3)

32. Blood loss lowers blood volume and venous return and decreases cardiac output. Compensatory mechanisms include an increase in cardiac output, mobilization of venous blood reservoirs, peripheral vasoconstriction, and the release of hormones that promote the retention of fluids and the manufacture of erythrocytes. (Figure 21–16)

21-5 The vessels of the cardiovascular system make up both pulmonary and systemic circuits

33. The peripheral distributions of arteries and veins are generally identical on both sides of the body, except near the heart. (Figure 21–17)

21-6 In the pulmonary circuit, deoxygenated blood enters the lungs in arteries, and oxygenated blood leaves the lungs by veins

34. The pulmonary circuit includes the pulmonary trunk, the **left** and **right pulmonary arteries**, and the **pulmonary veins**, which empty into the left atrium. (Figure 21–18)

21-7 The systemic circuit carries oxygenated blood from the left ventricle to tissues and organs other than the lungs, and returns deoxygenated blood to the right atrium

35. The **ascending aorta** gives rise to the coronary circulation. The **aortic arch** communicates with the **descending aorta**. (Figures 21–19 to 21–25)
36. Three elastic arteries originate along the aortic arch: the **left common carotid artery**, the **left subclavian artery**, and the **brachiocephalic trunk**. (Figures 21–20 to 21–22)
37. The remaining major arteries of the body originate from the **descending aorta**. (Figures 21–23 to 21–25)
38. Arteries in the neck and limbs are deep beneath the skin; in contrast, there are generally two sets of peripheral veins, one superficial and one deep. This dual venous drainage is important for controlling body temperature. (Figure 21–26)
39. The **superior vena cava** receives blood from the head, neck, chest, shoulders, and arms. (Figures 21–26 to 21–29)
40. The **inferior vena cava** collects most of the venous blood from organs inferior to the diaphragm. (Figures 21–28 to 21–30)
41. The **hepatic portal system** directs blood from the other digestive organs to the liver before the blood returns to the heart. (Figure 21–31)

21-8 Modifications of fetal and maternal cardiovascular systems promote the exchange of materials; the fetal cardiovascular system changes to function independently after birth

42. Blood flows to the placenta in a pair of **umbilical arteries** and from the placenta in a single **umbilical vein**. (Figure 21–32)
43. The interatrial partition remains functionally incomplete until birth. The **foramen ovale** allows blood to flow freely from the right to the left atrium, and the **ductus arteriosus** short-circuits the pulmonary trunk.
44. At birth, the foramen ovale closes, leaving the fossa ovalis. The ductus arteriosus constricts, leaving the ligamentum arteriosum. (Figure 21–32)
45. Congenital cardiovascular problems generally reflect abnormalities of the heart or of interconnections between the heart and great vessels. (Spotlight Figure 21–33)

21-9 Aging affects the blood, heart, and blood vessels

46. Age-related changes in the blood include (1) a decreased hematocrit, (2) constriction or blockage of peripheral veins by a *thrombus* (stationary blood clot), and (3) pooling of blood in the veins of the legs because valves are not working effectively.
47. Age-related changes in the heart include (1) a reduction in the maximum cardiac output, (2) changes in the activities of nodal and conducting cells, (3) a reduction in the elasticity of the cardiac skeleton, (4) progressive atherosclerosis that can restrict coronary circulation, and (5) the replacement of damaged cardiac muscle cells by scar tissue.
48. Age-related changes in blood vessels, commonly related to arteriosclerosis, include (1) a weakening in the walls of arteries, potentially leading to the formation of an *aneurysm*; (2) deposition of calcium salts on weakened vascular walls, increasing the risk of a stroke or myocardial infarction; (3) lipid deposits in the tunica media associated with damaged endothelial lining and calcium salts forming atherosclerotic plaques; and (4) the formation of a thrombus at atherosclerotic plaques.
49. The cardiovascular system is anatomically and functionally connected to all other body systems. (Figure 21–34)

Review Questions

See the blue Answers tab at the back of the book.

LEVEL 1 Reviewing Facts and Terms

1. Identify the major arteries in the following diagram.

- | | |
|-----------|-----------|
| (a) _____ | (b) _____ |
| (c) _____ | (d) _____ |
| (e) _____ | (f) _____ |
| (g) _____ | (h) _____ |
| (i) _____ | |

2. The blood vessels that play the most important role in regulating blood pressure and blood flow to a tissue are the (a) arteries, (b) arterioles, (c) veins, (d) venules, (e) capillaries.
3. Cardiovascular function is regulated by all the following *except* (a) local factors, (b) neural factors, (c) endocrine factors, (d) venous return, (e) conscious control.
4. Chemoreceptors that respond to changes in carbon dioxide and oxygen levels in blood are located in the (a) aortic sinuses, (b) aortic bodies, (c) right atrium, (d) brainstem, (e) atrioventricular node.

5. The layer(s) of the vessel walls whose presence distinguishes between arteries and veins is/are the (a) tunica media, (b) tunica intima, (c) tunica externa, (d) elastic membranes.
6. Large molecules such as peptides and proteins move into and out of the bloodstream by way of (a) continuous capillaries, (b) fenestrated capillaries, (c) thoroughfare channels, (d) venules.
7. Blood flow is (a) proportional to the pressure gradient, (b) proportional to the fourth power of the vessel radius, (c) inversely proportional to blood pressure, (d) proportional to peripheral resistance.
8. Blood is transported through the venous system by means of (a) skeletal muscle contractions, (b) decreasing blood pressure, (c) the respiratory pump, (d) a and c.
9. Identify the major veins in the following diagram.

- | | |
|-----------|-----------|
| (a) _____ | (b) _____ |
| (c) _____ | (d) _____ |
| (e) _____ | (f) _____ |
| (g) _____ | (h) _____ |
| (i) _____ | |

10. The most important factor in vascular resistance is **(a)** the viscosity of the blood, **(b)** the diameter of the lumen of blood vessels, **(c)** turbulence due to irregular surfaces of blood vessels, **(d)** the length of the blood vessels.
11. Net hydrostatic pressure forces water _____ a capillary; net osmotic pressure reabsorbs water _____ a capillary. **(a)** into; out of, **(b)** out of; into, **(c)** out of; out of, **(d)** into; into.
12. The three arteries formed by the branching of the celiac trunk are the **(a)** common hepatic, left gastric, and splenic, **(b)** left colic, sigmoid, and rectal, **(c)** middle colic, right colic, and ileocolic, **(d)** gastroduodenal, cystic, and right gastric.
13. The unpaired arteries supplying blood to the visceral organs include **(a)** the adrenal, renal, and lumbar arteries, **(b)** the iliac, gonadal, and femoral arteries, **(c)** the celiac and superior and inferior mesenteric arteries, **(d)** all of these.
14. The paired arteries supplying blood to the body wall and other structures outside the abdominopelvic cavity include the **(a)** left gastric, hepatic, splenic, and phrenic arteries, **(b)** adrenal, colic, lumbar, and gonadal arteries, **(c)** iliac, femoral, and lumbar arteries, **(d)** celiac, left gastric, and superior and inferior mesenteric arteries.
15. Peripheral distributions of arteries and veins are identical on the left and right sides of the body, *except* near the **(a)** gonads, **(b)** heart, **(c)** kidneys, **(d)** lower limbs.
16. The vessel that transports venous blood from organs in the peritoneal cavity to the liver is the **(a)** inferior vena cava, **(b)** hepatic vein, **(c)** cystic vein, **(d)** hepatic portal vein.
17. What are the primary forces that move fluid out of a capillary at its arterial end and into the interstitial fluid? What are the primary forces that move interstitial fluid into a capillary at its venous end?
18. What age-related changes occur in blood vessels?
20. Which of the following conditions would have the *greatest* effect on peripheral resistance? **(a)** doubling the length of a vessel, **(b)** doubling the diameter of a vessel, **(c)** doubling the viscosity of the blood, **(d)** doubling the turbulence of the blood, **(e)** doubling the number of white cells in the blood.
21. Baroreceptors stimulated by increased blood pressure **(a)** induce vasoconstriction and cause an increase in cardiac output, **(b)** induce vasodilation and cause a decrease in cardiac output, **(c)** do none of these.
22. Relate the anatomical differences between arteries and veins to their functions.
23. How is arterial blood flow to the tissues controlled by the capillaries?
24. How is blood pressure maintained in veins to counter the force of gravity?
25. Compare hypertension and hypotension.
26. Why is blood flow to the brain relatively continuous and constant?
27. Compare the effects of the cardioacceleratory and cardioinhibitory centers on cardiac output and blood pressure.

LEVEL 3 Critical Thinking and Clinical Applications

28. Josh is sitting outside on a warm day and is sweating profusely. Mary wants to practice taking blood pressures, and he agrees to play the patient. Mary finds that Josh's blood pressure is elevated, even though he is resting and has lost fluid from sweating. (She reasons that fluid loss should lower blood volume and, thus, blood pressure.) Why is Josh's blood pressure high instead of low?
29. People with allergies commonly take antihistamines with decongestants to relieve their symptoms. The container warns that individuals who are being treated for high blood pressure should not take the medication. Why not?
30. Jolene awakens suddenly to the sound of her alarm clock. Realizing that she is late for class, she jumps to her feet, feels light-headed, and falls back on her bed. What probably caused this reaction? Why doesn't this happen all the time?

LEVEL 2 Reviewing Concepts

19. A major difference between the arterial and venous systems is that **(a)** arteries are usually more superficial than veins, **(b)** in the limbs there is dual venous drainage, **(c)** veins are usually less branched compared to arteries, **(d)** veins exhibit a much more orderly pattern of branching in the limbs, **(e)** veins are not found in the abdominal cavity.

CLINICAL CASE Wrap-Up Did Ancient Mummies Have Atherosclerosis?

Many Americans have atherosclerotic plaques in their arteries by age 50. The disease is usually thought of as a modern one resulting from inactivity and diets rich in fat and excessive calories. But what could account for its incidence in the ancient mummies?

The degree of atherosclerosis discovered in the mummies turns out to be correlated with their age at death. The average age at death for mummies without visible atherosclerosis is only 32. Among the mummies of people over age 40 that were examined, 50% had atherosclerosis.

Atherosclerosis is a vascular disease that progresses over many years. It is influenced by both genetics and environment. The most important risk factor, however, seems to be increasing

age. Diet, high levels of cholesterol in the blood, smoking, hypertension, and obesity are additional risk factors.

The prevalence of atherosclerosis in varied, preindustrial populations raises the possibility of a basic, human predisposition to the disease. Atherosclerosis appears to have been stalking humans for millennia.

1. Why does the finding of calcium, which is easily seen on a CT scan, within systemic arteries indicate the presence of atherosclerosis?
2. Why is atherosclerosis not seen in veins?

See the blue Answers tab at the back of the book.

Related Clinical Terms

angiogram: An x-ray of a blood vessel that becomes visible due to a prior injection of dye into the subject's bloodstream.

carotid sinus massage: A procedure that involves rubbing the large part of the arterial wall at the point where the common carotid artery divides into its two main branches.

intermittent claudication: A limp that results from cramping leg pain that is typically caused by obstruction of the arteries.

Korotkoff sounds: Distinctive sounds, caused by turbulent arterial blood flow, heard through the stethoscope while measuring blood pressure.

normotensive: Having normal blood pressure.

orthostatic hypotension: A form of low blood pressure that occurs when a person stands up from sitting or lying down. It can cause dizziness or a light-headed feeling.

phlebitis: Inflammation of a vein.

Raynaud's phenomenon: A condition caused by decreased blood flow to the extremities (fingers, toes, ears, and nose) characterized by pain, numbness, and discoloration when a person is subjected to cold temperatures or emotional stress.

sclerotherapy: The treatment of varicose veins in which an irritant is injected to cause inflammation, coagulation of blood, and a narrowing of the blood vessel wall.

sphygmomanometer: A device that measures blood pressure using an inflatable cuff placed around a limb.

syncope: A temporary loss of consciousness due to a sudden drop in blood pressure.

thrill: A vibration felt in a blood vessel that usually occurs due to abnormal blood flow. It is also often noticed at the fistula of a hemodialysis patient.

thrombophlebitis: An inflammation in a vein associated with the formation of a thrombus (clot).

vascular murmur: Periodic abnormal sounds heard with auscultation that result from turbulent blood flow.

white coat hypertension: A short-term increase in blood pressure triggered by the sight of medical personnel in white coats or other medical attire.

The Lymphatic System and Immunity

Learning Outcomes

These Learning Outcomes correspond by number to this chapter's sections and indicate what you should be able to do after completing the chapter.

- 22-1 ■ Identify the major components of the lymphatic system, describe the structure and functions of each component, and discuss the importance of lymphocytes.
- 22-2 ■ Distinguish between innate (nonspecific) and adaptive (specific) immunity and explain the role of lymphocytes in the immune response.
- 22-3 ■ List the body's innate defenses, and describe the components, mechanisms, and functions of each.
- 22-4 ■ Define adaptive (specific) defenses, identify the forms and properties of immunity, and distinguish between cell-mediated (cellular) immunity and antibody-mediated (humoral) immunity.
- 22-5 ■ Discuss the types of T cells and their roles in the adaptive immune response and describe the mechanisms of T cell activation and differentiation.
- 22-6 ■ Discuss the mechanisms of B cell activation and differentiation, describe the structure and function of antibodies, and explain the primary and secondary responses to antigen exposure.
- 22-7 ■ Describe the development of immunocompetence, discuss the effects of stress on immune function, and list and explain examples of immune disorders and allergies.
- 22-8 ■ Describe the effects of aging on the lymphatic system and the immune response.
- 22-9 ■ Give examples of interactions between the lymphatic system and other organ systems we have studied so far and explain how the nervous and endocrine systems influence the immune response.

CLINICAL CASE

Isn't There a Vaccine for That?

Baby Ruthie is standing and holding on to a play table when her mother arrives to pick her up from daycare. Ruthie is 11 months old and not yet walking. She hasn't had an appetite since yesterday, and last night she had a fever. When her mother gives Ruthie a hug, she notices a small blister near the corner of Ruthie's mouth. She also notices that Ruthie seems feverish again.

"Ruthie didn't do much today," reports the daycare attendant. "Did you notice this little blister on her face?" asks Ruthie's mother. "No. It must have just appeared," the attendant replies. "Bukanya, one of our older kids, had a little blister like that on his cheek just last week. He hasn't been back since."

That night, Ruthie's fever worsens. She won't eat and seems to have a sore throat when trying to swallow. She is listless (lacking energy). When her mother undresses her for bed, she notices more small blisters on Ruthie's face, abdomen, and back. She takes her straight to the Urgent Care Center.

"This looks like chickenpox," says the doctor. "Thanks to vaccines, we don't see this disease very often." **Ruthie's mother is certain that Ruthie is current on all her vaccinations. How could Ruthie**

have come down with chickenpox? To find out, turn to the Clinical Case Wrap-Up at the end of the chapter.

An Introduction to the Lymphatic System and Immunity

The world is not always kind to the human body. Accidental bumps, cuts, and scrapes; chemical and thermal burns; extreme cold; and ultraviolet radiation are just a few of the hazards in our physical environment. Making matters worse, the world around us contains an assortment of viruses, bacteria, fungi, and parasites capable of not only surviving but thriving inside our bodies—and potentially causing us great harm. These disease-causing organisms, called **pathogens**, are responsible for many diseases. Each pathogen has a different lifestyle and attacks the body in a specific way. For example, viruses spend most of their time hidden within cells, which they often eventually destroy. Many bacteria multiply in interstitial fluids, where they release foreign proteins—enzymes or toxins—that can damage cells, tissues, even entire organ systems. Some large parasites, such as roundworms, can burrow through internal organs. And as if that were not enough, we are constantly at risk from renegade body cells that have the potential to produce lethal cancers.

Many organs and systems work together to keep us alive and healthy. One system that plays a central role in the ongoing struggle to maintain health is the lymphatic system. The lymphatic system (also called the *lymphoid system*) includes the cells, tissues, and organs responsible for defending the body. This system acts both against environmental hazards, such as various pathogens, and against internal threats, such as cancer cells. *Lymphocytes*, the primary cells of the lymphatic system, were introduced earlier (Chapters 4 and 19). These cells are vital to the body's ability to resist or overcome infection and disease.

The ability to resist infection and disease is called **immunity**. All the cells and tissues involved in producing immunity are part of the immune system. The immune system is a *functional*

system, and it includes parts of the integumentary, skeletal, lymphatic, cardiovascular, respiratory, and digestive systems.

We begin by examining the organization of the lymphatic system, lymphoid tissues, and lymphoid organs, and then we look at how this system interacts with other systems to defend the body against infection and disease.

22-1 The vessels, tissues, and organs of the lymphatic system maintain fluid volume and function in body defenses

Learning Outcome Identify the major components of the lymphatic system, describe the structure and functions of each component, and discuss the importance of lymphocytes.

The lymphatic system consists of (1) *lymph*, a fluid that resembles plasma but contains a much lower concentration of suspended proteins; (2) a network of *lymphatic vessels*, which begin in peripheral tissues and connect to veins; (3) an array of **lymphoid tissues** and **lymphoid organs** scattered throughout the body; and (4) *lymphoid cells*, including lymphocytes and smaller numbers of phagocytes and other cells.

Primary lymphoid tissues and organs are sites where lymphocytes are formed and mature. They include *red bone marrow* and the *thymus*. (Recall that red bone marrow is where other defense cells, monocytes and macrophages, are also formed.) *Secondary lymphoid tissues and organs* are where lymphocytes are activated. These structures include *tonsils*, mucosa-associated lymphatic tissue (MALT), *lymph nodes*, and the *spleen*.

A network of **meningeal lymphatics** is found in the dura mater, alongside the dural venous sinuses and middle meningeal arteries. Recall from Chapter 14 that the dural venous sinuses are large collecting veins within the dural folds of the brain.

Figure 22–1 The Components of the Lymphatic System.

Meningeal lymphatics drain cerebrospinal fluid (CSF) to cervical lymph nodes, remove wastes, and transport immune cells. Because the meningeal lymphatics also remove amyloid- β , a protein associated with Alzheimer's disease, multiple sclerosis, and Parkinson's disease, their physiological roles are topics of intense research. **Figure 22–1** provides a general overview of the components of the lymphatic system.

Functions of the Lymphatic System

The primary function of the lymphatic system is to produce, maintain, and distribute lymphocytes and other lymphoid cells that provide defense against infections and foreign substances. To provide an effective defense, lymphocytes must detect problems, and they must be able to reach the site of injury or infection. Lymphocytes and other cells circulate within the blood. They can enter or leave the capillaries that supply most of the body's tissues.

Recall that capillaries normally deliver more fluid to peripheral tissues than they carry away (Chapter 21). The excess fluid returns to the bloodstream through lymphatic vessels. This continuous circulation of extracellular fluid helps transport lymphocytes and white blood cells from one organ to another. In the process, it maintains normal blood volume. It also eliminates local variations in the composition of the interstitial fluid by distributing hormones, nutrients, and wastes from their tissues of origin to the general circulation.

Lymphatic Vessels and Circulation of Lymph

Lymphatic vessels, often called *lymphatics*, carry lymph from peripheral tissues to the venous system. **Lymph** is interstitial fluid that has entered lymphatic vessels, which vary in size. Lymph first enters *lymphatic capillaries* and then drains into larger major lymph-collecting vessels, known as *trunks* and *ducts*.

Lymphatic Capillaries

The lymphatic network begins with **lymphatic capillaries**, which branch through peripheral tissues. Lymphatic capillaries differ from blood capillaries in several ways. They (1) are closed at one end rather than forming continuous

Figure 22-2 Lymphatic Capillaries.

a The interwoven network formed by blood capillaries and lymphatic capillaries. Arrows indicate the movement of fluid out of blood capillaries and the net flow of interstitial fluid and lymph.

b A sectional view indicating the movement of fluid from the plasma, through the tissues as interstitial fluid, and into the lymphatic system as lymph.

tubes, (2) have larger luminal diameters, (3) have thinner walls, and (4) typically have a flattened or irregular outline in sectional view (**Figure 22-2**).

Lymphatic capillaries are lined by endothelial cells, but the basement membrane is incomplete or absent. The endothelial cells of a lymphatic capillary are not bound tightly together, but they do overlap. The region of overlap acts as a one-way valve. It permits fluids and solutes (including proteins) to enter, along with viruses, bacteria, and cell debris, but it prevents them from returning to the intercellular spaces.

Lymphatic capillaries are present in almost every tissue and organ in the body. Important lymphatic capillaries in the small intestine, called *lacteals*, transport lipids absorbed by the digestive tract. Lymphatic capillaries are absent in areas without a blood supply, such as the cornea of the eye.

Small Lymphatic Vessels

From the lymphatic capillaries, lymph flows into larger lymphatic vessels that lead toward the body's trunk. The walls of these vessels contain three layers comparable to those of veins. Small to medium-sized lymphatic vessels also contain valves (**Figure 22-3**). The valves are quite close together, and they produce noticeable bulges. As a result, some lymphatic vessels have a beaded appearance due to an irregular lumen (**Figure 22-3a**). The valves prevent the backflow of lymph within lymphatic vessels, especially in the limbs. Pressures within the lymphatic system are minimal, and the valves are essential to maintaining normal lymph flow toward the thoracic cavity. Contractions of skeletal muscles surrounding the lymphatic vessels aid lymph flow.

Lymphatic vessels are often associated with blood vessels (**Figure 22-3a**). Differences in size, general appearance, and branching pattern distinguish lymphatic vessels from arteries and veins. We can see characteristic color differences in living tissues. Most arteries are bright red, veins are dark red (although usually illustrated as blue to distinguish them from arteries), and lymphatic vessels are a pale golden color. In general, a tissue contains many more lymphatic vessels than veins, but the lymphatic vessels are much smaller.

Major Lymph-Collecting Vessels

Two sets of lymphatic vessels collect lymph from the lymphatic capillaries: superficial lymphatics and deep lymphatics. **Superficial lymphatics** are in the subcutaneous layer deep to the skin; in the areolar tissues of the mucous membranes lining the digestive, respiratory, urinary, and reproductive tracts; and in the areolar tissues of the serous membranes lining the pleural, pericardial, and peritoneal cavities. **Deep lymphatics** are larger lymphatic vessels that accompany deep arteries and veins supplying skeletal muscles and other organs of the neck, limbs, and trunk, and the walls of visceral organs.

Figure 22-3 Lymphatic Vessels and Valves.

What feature do lymphatic vessels share with veins that allows lymph to flow in only one direction?

Superficial and deep lymphatics converge to form even larger vessels called **lymphatic trunks**. The trunks in turn empty into two large collecting vessels: the thoracic duct and the right lymphatic duct. The **thoracic duct** collects lymph from the body inferior to the diaphragm and from the left side of the body superior to the diaphragm. The smaller **right lymphatic duct** collects lymph from the right side of the body superior to the diaphragm (**Figure 22-4a**).

The thoracic duct begins inferior to the diaphragm at the level of vertebra L₂ (**Figure 22-4b**). The base of the thoracic duct is an expanded, saclike chamber called the **cisterna chyli** (KĪ-lĪ; *chylos*, juice). The cisterna chyli receives lymph from the inferior part of the abdomen, the pelvis, and the lower limbs by way of the *right* and *left lumbar trunks* and the *intestinal trunk*.

The inferior segment of the thoracic duct lies anterior to the vertebral column. From the second lumbar vertebra, it passes posterior to the diaphragm alongside the aorta. It then ascends along the left side of the vertebral column to the level

of the left clavicle. It collects lymph from the *left bronchomediastinal trunk*, the *left subclavian trunk*, and the *left jugular trunk*, and then empties into the left subclavian vein near the left internal jugular vein (**Figure 22-4b**). In this way, lymph reenters the venous circulation from the left side of the head, neck, and thorax, as well as from the entire body inferior to the diaphragm.

The *right lymphatic duct* is formed by the merging of the *right jugular*, *right subclavian*, and *right bronchomediastinal trunks* in the area near the right clavicle. This duct empties into the right subclavian vein, delivering lymph from the right side of the body superior to the diaphragm.

Obstruction of lymphatic vessels produces **lymphedema** (limf-e-DE-muh), as large amounts of lymph accumulate in the affected region. This causes swelling, especially in subcutaneous tissues. If the condition persists, the connective tissues lose their elasticity and the swelling becomes permanent. Lymphedema by itself does not pose a major threat to life. The danger comes from

Figure 22-4 The Relationship between the Lymphatic Ducts and the Venous System.

the constant risk that an uncontrolled infection will develop in the affected area. Because the interstitial fluids are essentially stagnant, toxins and pathogens can accumulate and overwhelm local defenses without fully activating the immune system.

Lymphoid Cells

Lymphoid cells consist of immune system cells found in lymphoid tissues and the cells that support those tissues. Immune system cells that function in defense include phagocytes and lymphocytes. Phagocytes include cell types such as *macrophages* and *microphages*. These cells function as a general first line of defense against pathogens, such as bacteria or viruses.

Lymphocytes respond to specific invading pathogens, as well as to abnormal body cells (such as virus-infected cells or cancer cells) and foreign proteins (such as the toxins released by some bacteria). They eliminate these threats or render

them harmless through a combination of physical and chemical attacks. Lymphocytes account for 20–40% of circulating leukocytes. Three classes of lymphocytes circulate in blood: (1) *T* (thymus-dependent) *cells*, (2) *B* (bone marrow-derived) *cells*, and (3) *NK* (natural killer) *cells*. Each type has distinctive biochemical and functional properties. However, circulating lymphocytes are only a small fraction of the total lymphocyte population. The body contains about 1 trillion lymphocytes, with a combined weight of more than a kilogram (2.2 lb).

Lymphoid Tissues

Lymphoid tissues are connective tissues dominated by lymphocytes. In a **lymphoid nodule**, or *lymphatic nodule*, the lymphocytes are densely packed in an area of areolar tissue. In many areas, lymphoid nodules form large clusters. Lymphoid nodules occur in the connective tissue deep to the epithelia

Figure 22–5 Lymphoid Nodules.

lining the respiratory tract, where they are known as *tonsils*, and along the digestive, respiratory, urinary, and reproductive tracts (**Figure 22–5**). They are also found within more complex lymphoid organs, such as lymph nodes or the spleen.

A single nodule averages about a millimeter in diameter. Its boundaries are not distinct, because no fibrous capsule surrounds it. Each nodule often has a central zone called a **germinal center**, which contains dividing lymphocytes (**Figure 22–5**).

Tonsils

The **tonsils** are large lymphoid nodules in the walls of the pharynx (**Figure 22–5a**). Most people have five tonsils. A single **pharyngeal tonsil**, often called the *adenoid*, lies in the posterior superior wall of the nasopharynx. Left and right **palatine tonsils** are located at the posterior, inferior margin of the oral cavity, along the boundary of the pharynx. A pair of **lingual tonsils** lies deep to the mucous epithelium covering the base

(pharyngeal portion) of the tongue. Because of their location, the lingual tonsils are usually not visible unless they become infected and swollen. **Tonsillitis** is an inflammation of the tonsils (especially the palatine tonsils) although the other tonsils may also be affected. Tonsils reach their largest size by puberty and then begin to atrophy.

MALT

The collection of lymphoid tissues that protect the epithelia of the digestive, respiratory, urinary, and reproductive systems is called the **mucosa-associated lymphoid tissue (MALT)**. Clusters of lymphoid nodules deep to the epithelial lining of the intestine are known as **aggregated lymphoid nodules**, or *Peyer's patches* (**Figure 22–5b**). Other examples of MALT include the appendix and the tonsils.

The *appendix*, or *vermiform* (“worm-shaped”) *appendix*, is a tube-shaped sac opening into the junction between the small and large intestines. Its walls contain a mass of fused lymphoid nodules.

Figure 22-6 The Structure of a Lymph Node.

Lymphoid Organs

Lymphoid organs include the lymph nodes, thymus, and spleen. A fibrous connective tissue capsule separates these organs from surrounding tissues.

Lymph Nodes

Lymph nodes are small lymphoid organs ranging in diameter from 1 mm to 25 mm (to about 1 in.). Most lymph nodes are in the neck, axillae, and groin, where they defend us against bacteria and other invaders. The general pattern of lymph node distribution in the body is shown in **Figure 22-1**.

A dense connective tissue capsule covers each lymph node (**Figure 22-6**). Bundles of collagen fibers extend from the capsule into the interior of the node. These fibrous partitions are called **trabeculae** (*trabecula*, a beam).

The typical lymph node is shaped like a kidney bean. Blood vessels and nerves reach the lymph node at a shallow indentation called the **hilum**. Two sets of lymphatic

vessels, afferent lymphatics and efferent lymphatics, are connected to each lymph node. **Afferent** (*afferens*, bringing towards) **lymphatics** bring lymph to the lymph node from peripheral tissues. The afferent lymphatics penetrate the capsule of the lymph node on the side opposite the hilum. **Efferent** (*efferens*, carrying out) **lymphatics** exit the lymph node at the hilum. These vessels carry lymph away from the lymph node and toward the venous circulation (**Figure 22-6**).

Lymph Flow through Nodes. Lymph from the afferent lymphatics flows through the lymph node within a network of sinuses, open passageways with incomplete walls. The lymph node interior is divided into an outer cortex, an inner medulla, and a region between the two called the paracortex (**Figure 22-6**). Lymph first enters a *subcapsular space* that contains a meshwork of branching reticular fibers, macrophages, and dendritic cells. *Dendritic cells* are involved in starting an immune response. Lymph passes through the subcapsular space

and then flows through the **cortex** of the node. The periphery of the cortex contains B cells within germinal centers similar to those of lymphoid nodules.

Lymph then continues through lymph sinuses toward an ill-defined area known as the **paracortex**, which is dominated by T cells. Here lymphocytes leave the bloodstream and enter the lymph node by crossing the walls of blood vessels.

After flowing through the sinuses of the paracortex, lymph continues into the core, or **medulla**. The medulla contains B cells and macrophages. Elongated masses of dense lymphoid tissue between the sinuses in the medulla are known as **medullary cords**. Lymph passes through a network of sinuses in the medulla and then enters the efferent lymphatics at the hilum.

Lymph Node Function. A lymph node functions like a kitchen water filter: It purifies lymph before it reaches the veins. As lymph flows through a lymph node, at least 99% of the antigens (foreign substances) in the lymph are removed. Fixed macrophages in the walls of the lymphatic sinuses engulf debris or pathogens in lymph as it flows past.

In addition to filtering, lymph nodes function as an early-warning defense system. Any infection or other abnormality in a peripheral tissue puts antigens into the interstitial fluid, and thus into the lymph leaving the area. These antigens then stimulate macrophages and lymphocytes in nearby lymph nodes. Antigens are also carried by dendritic cells from peripheral tissues to lymph nodes.

To protect a house against intruders, you might guard all the entrances and exits or place locks on the windows and doors. The distribution of lymphoid tissues and lymph nodes follows such a pattern. The largest lymph nodes are located where peripheral lymphatics connect with the trunk, such as in the groin, the axillae, and the base of the neck. These nodes are often called *lymph glands*. Because lymph is monitored in these nodes, potential problems can be detected and dealt with before they affect the vital organs of the trunk. The mesenteries of the gut also have aggregations of lymph nodes, located near the trachea and passageways leading to the lungs, and in association with the thoracic duct. These lymph nodes protect against pathogens and other antigens within the digestive and respiratory systems.

A minor infection commonly produces a slight enlargement of the nodes along the lymphatic vessels draining the region. This sign is often called “swollen glands.” It typically indicates inflammation in peripheral structures. The enlargement generally results from an increase in the number of lymphocytes and phagocytes in the node. Inflammation of lymph nodes is termed *lymphadenitis*.

The Thymus

The thymus is a primary lymphoid organ. It is necessary in early life for immunity, but later in life it atrophies and becomes inactive. This section begins with a description of its anatomy.

+ Clinical Note Lymphadenopathy

There are approximately 600 lymph nodes scattered throughout the body. Some are superficial, but many are deep; few are *palpable* (able to be felt). Abnormal lymph nodes that are palpable may come to our attention during a physical examination. Any disease that affects lymph nodes is termed **lymphadenopathy** (lim-fad-e-NOP-a thē).

Most enlarged lymph nodes are benign and reflect an underlying localized infection. Think of *pharyngitis* (a sore throat) draining to nodes in the cervical region, or a sinus infection infiltrating submandibular nodes. An infected cut on the hand will localize to the axillary nodes, whereas a sexually transmitted disease localizes to the inguinal nodes.

Generalized lymphadenopathy should always be evaluated. It may be evidence of something more serious, such as *lymphoma* (a primary cancer of the lymph nodes) or metastatic cancer (cancerous nodes caused by cancer spreading from another site).

Anatomy of the Thymus. The **thymus** is a pink, grainy organ located in the mediastinum, generally just posterior to the sternum (**Figure 22-7a,b**). In newborn infants and young children, the thymus is relatively large. It commonly extends from the base of the neck to the superior border of the heart. The thymus reaches its greatest size relative to body size in the first year or two after birth. (The organ continues to increase in mass throughout childhood, but the body grows even faster, so the size of the thymus relative to that of the other organs in the mediastinum gradually decreases.)

The thymus reaches its maximum absolute size, at a weight of about 40 g (1.4 oz), just before puberty. After puberty, it gradually diminishes in size and becomes increasingly fibrous and fatty, a process called *involution*. By the time a person reaches age 50, the thymus may weigh less than 12 g (0.3 oz).

Figure 22-7 The Thymus.

The capsule that covers the thymus divides it into two thymic **lobes** (Figure 22-7b). Fibrous partitions called **septa** (singular, *septum*) originate at the capsule and divide the lobes into **lobules** averaging 2 mm in diameter (Figure 22-7b,c). Each lobule consists of an outer **cortex** densely packed with lymphocytes and a paler, central **medulla**.

Lymphocytes in the cortex are arranged in clusters that are surrounded by **epithelial reticular cells**. The epithelial reticular cells in the medulla cluster together in concentric layers, forming distinctive structures known as **thymic (Hassall's) corpuscles** (Figure 22-7d). Epithelial reticular cells also encircle the blood vessels of the cortex.

Function of the Thymus. The cortex contains actively dividing T cell lymphocytes (T lymphocytes). Epithelial reticular cells maintain the **blood-thymus barrier** around the blood vessels of the cortex, which separates developing T cells from the general circulation. These epithelial cells also regulate T cell development and function. Maturing T cells leave the cortex and enter the medulla of the thymus. The medulla has no blood-thymus barrier. After about 3 weeks, these T cells leave the thymus by entering one of the medullary blood vessels. T cells in the medulla can enter or leave the bloodstream across the walls of blood vessels in this region or within one of the efferent lymphatics that collect lymph from the thymus.

Figure 22–8 The Spleen.

What types of cells are found in the white pulp of the spleen and in the red pulp of the spleen?

Thymic Hormones. The thymus produces several hormones that are important to the development and maintenance of T cells for normal immunological defenses. *Thymosin* (THĪ-mō-sin) is the name originally given to an extract from the thymus that promotes the development and maturation of T cells. This extract contains several complementary hormones. They include *thymosin-a*, *thymosin-b*, *thymosin V*, *thymopoietin*, and *thymulin*. The plural term *thymosins* is sometimes used to refer to all thymic hormones.

The Spleen

The adult **spleen** contains the largest collection of lymphoid tissue in the body. In essence, the spleen performs the same

functions for blood that lymph nodes perform for lymph. Functions of the spleen can be summarized as (1) removing abnormal blood cells and other blood components by phagocytosis, (2) storing iron recycled from red blood cells, and (3) initiating immune responses by B cells and T cells in response to antigens in circulating blood.

Anatomy and Histology of the Spleen. The spleen is about 12 cm (5 in.) long and weighs, on average, nearly 160 g (5.6 oz). In gross dissection, the spleen is deep red, due to the blood it contains. The spleen lies along the curving lateral border of the stomach, extending between the 9th and 11th ribs on the left side. It is attached to the lateral border of the stomach by the **gastrosplenic ligament**, a broad band of mesentery (**Figure 22–8a**).

The spleen has a soft texture, so its shape reflects the shapes of the structures around it. The spleen is in contact with the muscular diaphragm, the stomach, and the left kidney. The *diaphragmatic surface* is smooth and convex, conforming to the shape of the diaphragm and body wall. The *visceral surface* contains indentations that conform to the shape of the stomach (the *gastric area*) and the kidney (the *renal area*) (**Figure 22-8b**). Splenic blood vessels (the *splenic artery* and *splenic vein*) and lymphatic vessels communicate with the spleen on the visceral surface at the **hilum**, a groove marking the border between the gastric and renal areas.

The spleen is surrounded by a capsule containing collagen and elastic fibers. The cellular components within make up the **pulp** of the spleen (**Figure 22-8c**). **Red pulp** contains large quantities of red blood cells, and **white pulp** resembles lymphoid nodules. Interestingly, the spleens of dogs, cats, and other mammals have extensive smooth muscle layers that contract to eject blood into the bloodstream. The human spleen lacks these muscles and therefore cannot contract.

The splenic artery enters at the hilum and branches to produce several arteries that radiate outward toward the capsule. These **trabecular arteries** in turn branch extensively, and their finer branches are surrounded by areas of white pulp. Capillaries then discharge the blood into the red pulp.

The cell population of the red pulp includes all the normal components of circulating blood, plus fixed and free macrophages. The structural framework of the red pulp consists of a network of reticular fibers. The blood passes through this meshwork and enters large sinusoids, also lined by fixed macrophages. The sinusoids empty into small veins, which ultimately collect into **trabecular veins** that continue toward the hilum.

This circulatory arrangement gives the phagocytes in the spleen an opportunity to identify and engulf damaged or infected cells in circulating blood. Macrophages are scattered throughout the red pulp, and the area surrounding the white pulp has a high concentration of lymphocytes and dendritic cells. For this reason, any microorganism or other antigen in the blood quickly triggers an immune response.

Rupture of the Spleen. The spleen tears so easily that a seemingly minor hit to the left side of the abdomen can rupture the capsule. The result is serious internal bleeding and eventual circulatory shock. Such an injury is a known risk of contact sports (such as football, hockey, and rugby) and of individual athletic activities, such as skiing and sledding.

Because the spleen is so fragile, it is very difficult to repair surgically. (Sutures typically tear out before they have been tensed enough to stop the bleeding.) A severely ruptured spleen is removed, a process called a **splenectomy** (splĒ-NEK-tō-mĒ). A person can survive without a spleen but lives with an increased risk of bacterial infection.

Checkpoint

1. Define pathogen.
2. List the components of the lymphatic system.
3. How would blockage of the thoracic duct affect lymph circulation?
4. If the thymus failed to produce thymic hormones, development of which population of lymphocytes would be affected?
5. Why do lymph nodes enlarge during some infections?

See the blue Answers tab at the back of the book.

22-2 Lymphocytes are important to innate (nonspecific) and adaptive (specific) immunity

Learning Outcome Distinguish between innate (nonspecific) and adaptive (specific) immunity and explain the role of lymphocytes in the immune response.

Immunity (i-MYŪ-ni-tĒ) is the body's ability to resist and defend against infectious organisms or other substances that could damage tissues and organs. The body's reaction to these infectious agents and other abnormal substances is known as the **immune** (*immune*, protected) **response**. The closely associated process is **resistance**, which is the ability of the body to maintain its immunity. There are two types of immunity that collaborate to protect the human body. These types are *innate (nonspecific) immunity* and *adaptive (specific) immunity*. Each has specific lymphocytes associated with their function, although, as we discover in this section, innate immunity uses other forms of defense as well. We also examine the origin, distribution, and general functions of the three classes of lymphocytes involved in the immune response.

Types of Immunity

Humans have two types of immunity: innate (natural and "one-size-fits all") and adaptive (acquired and specific). Both function to defend us against foreign organisms or substances.

1. **Innate (Nonspecific) Immunity.** The body has several physical barriers and internal defenses that either prevent or slow the entry of infectious organisms or attack them if they do enter. For example, the skin serves as a physical barrier, and phagocytes attack invading bacteria. This type of immunity is called *innate* because you are born with it, and *nonspecific* because it does not distinguish one potential threat from another. Therefore, this category of immunity is called **innate (nonspecific) immunity**, and it depends on a class of lymphocytes called NK cells.
2. **Adaptive (Specific) Immunity.** In this case, two classes of lymphocytes, T cells and B cells, respond to specific antigens. If a bacterial pathogen invades peripheral tissues, these

lymphocytes organize a defense against that particular bacterium, but not other bacteria and viruses. More importantly, this type of immunity also protects against further attacks by the same type of pathogen. For this reason, we say that T cells and B cells provide an *adaptive* defense. Many specific defenses develop after birth because of accidental or deliberate exposure to antigens. **Adaptive (specific) immunity** depends on the activities of specific lymphocytes—B cells and T cells.

Lymphocytes

In the previous section, we introduced the main classes of lymphocytes that circulate in blood. These are **B cells**, **T cells**, and **NK cells**. Most lymphocytes are T cells. These cells recognize various abnormal and foreign antigens, and produce a defensive, immune response. Let's look at the circulation and life span of these lymphocytes, as well as their production.

Circulation and Life Span of Lymphocytes

The various types of lymphocytes are not evenly distributed in the blood, red bone marrow, spleen, thymus, and peripheral lymphoid tissues. The ratio of B cells to T cells varies among tissues and organs. For example, B cells are seldom found in the thymus, and T cells outnumber B cells in blood by a ratio of 8:1.

The lymphocytes in these organs are visitors, not residents. All types of lymphocytes move throughout the body. They wander through tissues and then enter blood vessels or lymphatic vessels for transport.

T cells move quickly. For example, a wandering T cell may spend about 30 minutes in the blood, 5–6 hours in the spleen, and 15–20 hours in a lymph node. B cells move more slowly. A typical B cell spends about 30 hours in a lymph node before moving on.

Lymphocytes have relatively long life spans. About 80% survive 4 years, and some last 20 years or more. Throughout your life, you maintain normal lymphocyte populations by producing new lymphocytes in your red bone marrow and lymphoid tissues.

Lymphocyte Production

In Chapter 19, we discussed *hemopoiesis*—the formation of the formed elements of blood. In adults, red blood cell formation, or *erythropoiesis*, is normally confined to red bone marrow. In contrast, lymphocyte formation, or **lymphocytopoiesis** (lim-fō-SĪ-tō-poy-Ē-sis), involves the red bone marrow, thymus, and peripheral lymphoid tissues (**Figure 22–9**).

Red bone marrow plays the primary role in maintaining normal lymphocyte populations. Hemocytoblasts divide in the red bone marrow of adults to generate the lymphoid stem cells that produce all types of lymphocytes. The red bone marrow produces two distinct populations of lymphoid stem cells.

One group of lymphoid stem cells remains in the red bone marrow and the other group migrates to the thymus (**Figure 22–9**). Lymphoid stem cells in the red bone marrow divide to produce immature B cells and NK cells. B cell development involves intimate contact with large *stromal cells* (not shown) in the red bone marrow. Bone marrow stromal cells provide a specialized microenvironment to control hemopoiesis. The cytoplasmic extensions of stromal cells contact or even wrap around the developing B cells. Stromal cells of the red bone marrow produce a cytokine called *interleukin-7*, which promotes the differentiation of B cells.

As they mature, B cells and NK cells enter the bloodstream and migrate to peripheral tissues (**Figure 22–9**). Most of the B cells move into lymph nodes, the spleen, or other lymphoid tissues. The NK cells patrol the body, moving through peripheral tissues in search of abnormal cells.

The second group of lymphoid stem cells migrates to the thymus (**Figure 22–9**). These stem cells and their descendants develop and mature in an environment that is isolated from the general circulation by the blood-thymus barrier. Under the influence of thymic hormones, the lymphoid stem cells divide repeatedly, producing the various kinds of T cells. When the development of the T cells nears completion, they reenter the bloodstream and travel to peripheral tissues, including lymphoid tissues and organs, such as the spleen (**Figure 22–9**).

The T cells and B cells that migrate from their sites of origin retain the ability to divide, producing daughter cells of the same type. For example, a dividing B cell produces other B cells, not T cells or NK cells. As we will see, the ability of specific types of lymphocytes to increase in number is crucial to the success of the immune response.

Checkpoint

6. Compare immunity with resistance.
7. Explain the difference between innate immunity and adaptive immunity.

See the blue Answers tab at the back of the book.

22-3 Innate defenses respond the same regardless of the invader

Learning Outcome List the body's innate defenses, and describe the components, mechanisms, and functions of each.

Innate (nonspecific) defenses make up the first line of defense in immunity. They include physical barriers, phagocytes, immune surveillance, interferons, complement, inflammation, and fever. These innate defenses are summarized in **Figure 22–10**.

Physical Barriers

To initiate an immune response, a foreign substance or pathogen must enter body tissues. In other words, it must cross an

Figure 22–9 The Origin and Distribution of Lymphocytes.

Figure 22–10 Innate Defenses. Innate (nonspecific) defenses deny pathogens access to the body or destroy them without distinguishing among specific types of pathogens.

Innate Defenses	
Physical barriers keep hazardous organisms and materials outside the body.	
Phagocytes engulf pathogens and cell debris.	
Immune surveillance is the destruction of abnormal cells by NK cells in peripheral tissues.	
Interferons are chemical messengers that coordinate the defenses against viral infections.	
Complement is a system of circulating proteins that assist antibodies in the destruction of pathogens. It also lyses cells, and enhances phagocytosis and inflammation.	
Inflammation is a localized, tissue-level response that tends to limit the spread of an injury or infection.	
Fever is an elevation of body temperature that speeds up tissue metabolism and the activity of defenses.	

epithelium—either at the *skin* or across a *mucous membrane*. The epithelial covering of the skin has multiple layers, a keratin coating, and a network of desmosomes that lock adjacent cells together. These physical barriers are very effective in protecting

underlying tissues. Even along the delicate internal passageways of the respiratory, digestive, urinary, and reproductive tracts, epithelial cells are tied together by tight junctions. These cells generally are supported by a dense and fibrous basement membrane.

In addition, specialized accessory structures and secretions protect most epithelia. The hairs on most areas of the body protect against abrasion, especially on the scalp. They often prevent hazardous materials or insects from contacting your skin. The epidermal surface also receives the secretions of sebaceous and sweat glands. These secretions flush the surface and wash away microorganisms and chemicals. Such secretions may also contain chemicals that kill bacteria, destructive enzymes called *lysozymes*, and antibodies.

The epithelia lining the digestive, respiratory, urinary, and reproductive tracts are more delicate, but they are equally well defended. For example, mucus bathes most surfaces of your digestive and respiratory tracts, urine flushes the urinary tract, and glandular secretions do the same for the reproductive tract. Your stomach also contains a powerful acid that can destroy many pathogens.

Phagocytes

Phagocytes serve as janitors and police in peripheral tissues. They remove cellular debris and respond to invasion by foreign substances or pathogens. Many phagocytes attack and remove microorganisms even before lymphocytes detect them. The human body has two general classes of phagocytes: microphages and macrophages.

Microphages

22 Microphages are the neutrophils and eosinophils that normally circulate in the blood. These phagocytes leave the bloodstream and enter peripheral tissues that have been subjected to injury or infection. Neutrophils are abundant, mobile, and quick to phagocytize cellular debris or invading bacteria. Eosinophils are less abundant. They target foreign substances or pathogens that have been coated with antibodies.

Macrophages

Macrophages are large, active phagocytes. Your body has several types of macrophages. Most are derived from the monocytes in circulating blood. Typically, macrophages are either fixed in position or freely mobile. For this reason, they are usually classified as fixed macrophages or free macrophages, but the distinction is not absolute. During an infection, fixed macrophages may lose their attachments and roam around the damaged tissue.

No organs or tissues are dominated by phagocytes, but almost every tissue in the body shelters resident or visiting macrophages. This relatively diffuse collection of phagocytes is the **monocyte-macrophage system**, or the *reticuloendothelial system*.

How might an activated macrophage respond to a pathogen? It may:

- engulf a pathogen or other foreign object and destroy it with lysosomal enzymes.

- bind to or remove a pathogen from the interstitial fluid, but it may be unable to destroy the invader until other cells assist.
- destroy its target by releasing toxic chemicals, such as *tumor necrosis factor*, nitric oxide, or hydrogen peroxide, into the interstitial fluid.

These responses are considered further in a later section.

Fixed macrophages, or *histiocytes*, reside in specific tissues and organs. These cells are normally incapable of movement, so their targets must diffuse or otherwise move through the surrounding tissue until they are within range. Fixed macrophages are scattered among connective tissues, usually in close association with collagen or reticular fibers. They are found in the papillary and reticular layers of the dermis, in the subarachnoid space of the meninges, and in bone marrow. In some organs, the fixed macrophages have specific names. **Microglia** are macrophages in the central nervous system, and **stellate macrophages** (*Kupffer cells*) are macrophages located on the luminal surface of liver sinusoids.

Free macrophages, or *wandering macrophages*, travel throughout the body. They arrive at the site of an injury by migrating through adjacent tissues or by leaving the circulating blood. Some tissues contain free macrophages. For example, **alveolar macrophages**, also known as *dust cells*, monitor the epithelial surfaces of the lungs for respiratory pathogens.

Functions of Phagocytes

Microphages and free macrophages function in similar ways:

- Both can move through capillary walls by squeezing between adjacent endothelial cells. This process is known as *emigration*. The endothelial cells in an injured area develop membrane “markers” that signal passing blood cells that something is abnormal. The phagocytes then attach to the endothelial lining and migrate into the surrounding tissues.
- Both may be attracted to chemicals, or both may be repelled by chemicals in the surrounding fluids, a phenomenon called **chemotaxis**. They are particularly sensitive to chemicals known as *cytokines* that are released by other body cells and to chemicals released by pathogens.
- For both, phagocytosis begins with **adhesion**, the attachment of the phagocyte to its target. In adhesion, receptors on the plasma membrane of the phagocyte bind to the surface of the target. Adhesion is followed by the formation of a vesicle containing the bound target. The contents of the vesicle are digested once the vesicle fuses with lysosomes or peroxisomes.

All phagocytes function in much the same way, although their targets may differ. Phagocyte life span is regulated by the host and the pathogen because both have evolved strategies regulating immune function and cell death.

Figure 22–11 How Natural Killer Cells Kill Cellular Targets.

Immune Surveillance

The immune system generally ignores the body's own cells unless they become abnormal in some way. Natural killer (NK) cells, also known as *large granular lymphocytes*, are responsible for recognizing and destroying abnormal cells when they appear in peripheral tissues. Their continuous “policing” of peripheral tissues has been called **immune surveillance**.

The plasma membrane of an abnormal cell generally contains antigens that are not found on the membranes of normal cells. NK cells recognize an abnormal cell by detecting those antigens. NK cells are much less selective about their targets than are other lymphocytes: They respond to a *variety* of abnormal antigens that may appear anywhere on a plasma membrane. They also attack *any* membrane containing abnormal antigens. As a result, NK cells are highly versatile defenders. A single NK cell can attack bacteria in the interstitial fluid, body cells infected with viruses, or cancer cells.

NK cells respond much more rapidly than T cells or B cells. The activation of T cells and B cells involves a complex and time-consuming sequence of events. NK cells respond immediately on contact with an abnormal cell.

Activated NK cells react in a predictable way (**Figure 22–11**):

1 Recognition and Adhesion. If a cell has unusual components in its plasma membrane, an NK cell recognizes that cell as abnormal. This recognition activates the NK cell, which then adheres to its target cell.

2 Realignment of Golgi Apparatus. The Golgi apparatus moves around the nucleus until the maturing (*trans*) face points directly toward the abnormal cell. The process might be compared to the rotation of a tank turret to point the cannon toward the enemy. The Golgi apparatus then produces a flood of secretory vesicles that contain proteins called **perforins**. These vesicles move through the cytosol toward the abnormal cell's surface.

3 Secretion of Perforin. The perforins are released at the NK cell surface by exocytosis and diffuse across the narrow gap between the NK cell and its target.

4 Lysis of Abnormal Cell. When perforin molecules reach the opposing plasma membrane, the perforins interact with one another and create a network of pores in it. These pores are large enough to allow the free passage of ions, proteins, and other intracellular materials. As a result, the target cell can no longer maintain its internal environment, and it quickly disintegrates.

Tips

Perforin gets its name because it **perforates** the target cell.

Why doesn't perforin affect the plasma membrane of the NK cell? The answer is not clear, but NK cell membranes contain a second protein, called *protectin*. It may bind and inactivate perforin.

NK cells attack cancer cells and body cells infected with viruses. Cancer cells probably appear throughout life, but their plasma membranes generally contain unusual proteins called **tumor-specific antigens**, which NK cells recognize as abnormal. The NK cells then destroy the cancer cells, preserving the tissue. Unfortunately, some cancer cells avoid detection, perhaps because they lack tumor-specific antigens or because these antigens are covered in some way. Other cancer cells can destroy the NK cells that detect them. This process of avoiding detection or neutralizing body defenses is called **immunological escape**. Once immunological escape has occurred, cancer cells can multiply and spread without interference by NK cells.

In viral infections, the viruses replicate inside cells, beyond the reach of circulating antibodies. However, infected cells incorporate viral antigens into their plasma membranes, and NK cells recognize these infected cells as abnormal. By destroying them, NK cells can slow or prevent the spread of a viral infection.

Interferons

Interferons (in-ter-FĒR-onz) (**IFNs**) are small proteins released by activated lymphocytes and macrophages, and by tissue cells infected with viruses. An interferon binds to surface receptors on the membrane of a normal cell and, by second messengers, triggers the production of antiviral proteins in the cytoplasm. Antiviral proteins do not prevent viruses from entering the cell. Instead, they interfere with viral replication inside the cell. In addition to slowing the spread of viral infections, IFNs stimulate the activities of macrophages and NK cells.

At least three types of interferons exist: **interferon alpha** (α), **interferon beta** (β), and **interferon gamma** (γ) (**Figure 22-12**). Most cells other than lymphocytes and macrophages respond to viral infection by secreting interferon beta.

Interferons are examples of cytokines. **Cytokines** (SĪ-tō-kĭnz) are chemicals that tissue cells release to coordinate local activities. Cytokines include hormones and paracrine-like glycoproteins important to the immune response. Most cells produce cytokines only for paracrine communication—that is, cell-to-cell communication within one tissue. However, defense cells also release cytokines (discussed in Section 22-5).

22

Figure 22-12 Interferons.

Which type of interferon attracts and stimulates NK cells to enhance viral resistance to viral infection?

Complement System

Plasma contains over 30 special **complement proteins** that form the **complement system**. The term *complement* refers to the fact that this system complements, or enhances, the action of antibodies and phagocytes. The complement proteins interact with one another in chain reactions, or *cascades*, reminiscent of those of the clotting system.

The activation of complement can occur by three different routes: the *classical pathway*, the *lectin pathway*, and the *alternative pathway*. The **classical pathway** activates the complement system most rapidly and effectively. Its proteins are abbreviated “C” with a number that corresponds to its discovery. It begins with the binding of complement protein C1 to two nearby antibodies already attached to its specific antigen, such as a bacterial cell wall. The **lectin pathway** activates the complement system by the binding of the protein mannose-binding lectin (MBL) to carbohydrates on pathogen surfaces, such as bacterial cell walls. The **alternative pathway** also activates the complement system without antibody interactions. Its proteins are given specific names or called *factors*. The alternative pathway begins when several complement proteins—including **properdin** (*factor P*), *factor B*, and *factor D*—interact in the plasma. This interaction is triggered by exposure to foreign materials, such as the cell wall of a bacterium.

All three pathways involve the splitting of inactive C3 protein to activated C3b and C3a proteins. Complement activation brings about the following effects: killing of the pathogen by cell lysis, enhanced phagocytosis (**opsonization**), and enhanced inflammation (histamine release). **Figure 22-13** shows the three pathways of complement activation and its effects.

Inflammation

Inflammation is a localized tissue response to injury. Inflammation produces local *redness*, *swelling*, *heat*, and *pain*. These are known as the so-called *cardinal signs and symptoms of inflammation*. Sometimes a fifth is included: *lost function*.

Many stimuli can produce inflammation. They include impact, abrasion, distortion, chemical irritation, infection by pathogens, and extreme temperatures (hot or cold). Each stimulus kills cells, damages connective tissue fibers, or injures the tissue in some other way. The changes alter the chemical composition of the interstitial fluid. Damaged cells release prostaglandins, proteins, and potassium ions. The injury itself may have introduced foreign proteins or pathogens. These changes in the interstitial environment trigger the complex process of inflammation.

Inflammation has several effects:

- The injury is temporarily repaired, and additional pathogens are prevented from entering the wound.
- The spread of pathogens away from the injury is slowed.
- Local, regional, and systemic defenses are mobilized to overcome the pathogens and facilitate permanent repairs. This repair process is called *regeneration*.

Figure 22–13 Pathways of Complement Activation.

Mast cells play a pivotal role in inflammation. **Figure 22-14** summarizes the events of inflammation in the skin. Comparable events take place in almost any tissue subjected to physical damage or infection.

When stimulated by physical stress or chemical changes in the local environment, mast cells release histamine, heparin, prostaglandins, and other chemicals into interstitial fluid. The histamine makes capillaries more permeable and increases blood flow through the area. The combination of abnormal tissue conditions and chemicals released by mast cells stimulates local sensory neurons, producing pain. The person then may take steps to limit the damage, such as removing a splinter or cleaning a wound.

The increased blood flow reddens the area and raises the local temperature. These changes increase the rate of enzymatic reactions and accelerate the phagocyte activity. The rise in temperature may also denature foreign proteins or vital enzymes of invading microorganisms.

Because vessel permeability has increased, clotting factors and complement proteins can more readily leave the bloodstream and enter the injured or infected area. Clotting does not take place at the actual site of injury, due to the presence of heparin. However, a clot soon forms around the damaged area, both isolating the region and slowing the spread of the chemical or pathogen into healthy tissues. Meanwhile, complement activation through the alternative pathway breaks down bacterial cell walls and attracts phagocytes.

22 Neutrophils are drawn to the area by chemotaxis, where they attack cellular debris (organic waste from dead cells) and bacteria. As neutrophils circulate through a blood vessel in an injured area, they undergo *activation*. In this process (1) they stick to the side of the vessel and move into the tissue by emigration; (2) their metabolic rate goes up dramatically, and while this *respiratory burst* continues, they generate reactive compounds, such as nitric oxide and hydrogen peroxide, that can destroy engulfed pathogens; and (3) they secrete cytokines that attract other neutrophils and macrophages to the area. As inflammation proceeds, the foreign proteins, toxins, microorganisms, and active phagocytes in the area activate the body's specific defenses.

Fixed and free macrophages engulf pathogens and cell debris. At first, neutrophils outnumber these cells. Then, as the macrophages and neutrophils continue to secrete cytokines, the number of macrophages increases rapidly. Eosinophils may get involved if antibodies coat the foreign materials.

The cytokines released by active phagocytes stimulate fibroblasts in the area. The fibroblasts then begin forming scar tissue that reinforces the clot and slows the invasion of adjacent tissues. Over time, the clot is broken down and the injured tissues are either repaired or replaced by scar tissue. The process is essentially complete, although subsequent remodeling may take place over a period of years.

After an injury, tissue conditions generally become even more abnormal before they begin to improve. The tissue destruction that occurs after cells have been injured or destroyed is called **necrosis** (ne-KRŌ-sis). The destruction

Figure 22-14 Inflammation and the Steps in Tissue Repair.

begins several hours after the initial event, and the damage is due to lysosomal enzymes. Lysosomes break down by autolysis, releasing digestive enzymes that first destroy the injured cells and then attack surrounding tissues. As local inflammation continues, debris, fluid, dead and dying cells, and necrotic tissue components accumulate at the injury site. This viscous fluid mixture is known as **pus**. An accumulation of pus in an enclosed tissue space is called an **abscess**.

Fever

Fever is a body temperature greater than 37.2°C (99°F). Recall that the pre-optic area of the hypothalamus contains the temperature-regulating center. Fever-inducing agents called **pyrogens** (Pĭ-rō-jenz; *pyro-*, fever) can reset this thermostat and raise body temperature.

Bacteria, molds, viruses, and yeasts produce pyrogens and release them into the bloodstream. Several endogenous, or internally produced, pyrogens have been identified including interleukin-1, interferons, and tumor necrosis factor.

Within limits, a fever can be beneficial. High body temperatures may inhibit some viruses and bacteria. The most likely benefit is on body metabolism. For each 1°C rise in body temperature, metabolic rate increases by 10%. Cells can move faster, and enzymatic reactions take place more quickly. As a result, tissue defenses can be mobilized more rapidly and the repair process speeds up.

Checkpoint

8. What types of cells would be affected by a decrease in the number of monocyte-forming cells in red bone marrow?
9. A rise in the level of interferon in someone suggests what kind of infection?
10. What effects do pyrogens have in the body?

See the blue Answers tab at the back of the book.

22-4 Adaptive (specific) defenses respond to particular threats and are either cell mediated or antibody mediated

Learning Outcome Define adaptive (specific) defenses, identify the forms and properties of immunity, and distinguish between cell-mediated (cellular) immunity and antibody-mediated (humoral) immunity.

Lymphocytes of Adaptive Immunity

Adaptive (specific) defenses result from the coordinated activities of T lymphocytes and B lymphocytes, known as T cells and B cells. Under proper stimulation, T cells differentiate into several types of cells, which attack antigens and help to increase the immune response.

The primary types of T cells are as follows (**Figure 22-15**):

- **Cytotoxic T cells** are involved in direct cellular attack. These cells enter peripheral tissues and attack antigens physically and chemically.
- **Helper T cells** stimulate the responses of both T cells and B cells. Helper T cells are vital to the immune response because they must activate B cells before the B cells can produce antibodies. The reduction in the helper T cell population that occurs in AIDS is largely responsible for the loss of immunity.
- **Regulatory T cells** are a subset of T cells that moderate the immune response.
- **Memory T cells** respond to antigens they have already encountered by the cloning (producing identical cellular copies) of more lymphocytes to ward off the invader.

The interplay between helper T cells and regulatory T cells helps establish and control the sensitivity of the immune response. Other types of regulatory T cells also take part in the immune response. For example, *inflammatory T cells* stimulate regional inflammation and local defenses in an injured tissue. *Suppressor-inducer T cells* suppress B cell activity but stimulate other T cells.

When stimulated, B cells differentiate into *plasma cells* that secrete soluble proteins called *antibodies*. The binding of an antibody to its target antigen leads to the destruction of the target invader.

Types of Adaptive Immunity

Adaptive (specific) defenses result from the coordinated activities of T cells and B cells. Cytotoxic T cells provide **cell-mediated immunity**, or *cellular immunity*, which defends against abnormal cells and pathogens inside cells. B cells provide **antibody-mediated immunity**, which defends against antigens and pathogens in body fluids. Antibody-mediated immunity is also known as *humoral* (“liquid”) immunity because antibodies are found in body fluids.

Both kinds of immunity are important because they come into play under different circumstances. Both T and B cells respond to the presence of specific antigens. However, activated T cells do not respond to antigens in solution, and antibodies (produced by activated B cells) cannot cross plasma membranes. Moreover, helper T cells play a crucial role in antibody-mediated immunity by stimulating the activity of B cells.

An Introduction to Adaptive Immunity

Figure 22-16 provides an overview of adaptive immunity. When an antigen triggers an immune response, it usually activates both T cells and B cells. The activation of T cells generally occurs first, but only after phagocytes have been exposed to the antigen. Once activated, T cells attack the antigen and stimulate the activation of B cells. Activated B cells mature into cells that produce antibodies. Antibodies in the bloodstream then bind with the antigen and attack it.

Figure 22–15 Classes of Lymphocytes.

Antigens

Specific chemical targets called **antigens** stimulate the immune response. Most antigens are pathogens, parts or products of pathogens, or other foreign substances. Antigens are usually proteins, but some lipids, polysaccharides, and nucleic acids are also antigens.

Lymphocyte Activation and Clonal Selection

A lymphocyte becomes **activated** when it has contact with an appropriate antigen. When activated, a lymphocyte begins to divide, producing more lymphocytes with the same specificity. All the identical cells produced by these divisions make up a **clone**, and all the members of that clone are sensitive to the same specific antigen.

To understand how this system works, think about operating a commercial kitchen with only samples on display. The chef can display a wide selection because the samples don't take up much space, and she doesn't have to expend energy preparing food that might never be eaten. When a customer selects one of her samples and places an order for several dozen, she prepares them immediately.

The same principle applies to the lymphatic system. The body contains a small number of many kinds of lymphocytes. When an antigen arrives, it "selects" only those lymphocytes sensitive to it. These lymphocytes become activated and divide to generate many additional lymphocytes of the same type. This process of an antigen selecting specific lymphocytes for cloning is called **clonal selection**.

Forms of Adaptive Immunity

Adaptive immunity can be *active* or *passive* (**Figure 22–17**). These forms of immunity can be either naturally acquired or artificially acquired.

Active immunity develops after exposure to an antigen. It is a consequence of the immune response. In active immunity, the body responds to an antigen by making its own antibody. The immune system can defend against a huge number of antigens. However, the appropriate defenses are mounted only after encountering a particular antigen. Active immunity can result from natural exposure to an antigen in the environment (*naturally acquired active immunity*) or from deliberate exposure to an antigen (*artificially acquired active immunity*).

Figure 22–16 An Overview of Adaptive Immunity.

- **Naturally acquired active immunity** normally begins to develop after birth. It continues to build as “new” pathogens or other antigens are encountered. This process can be compared to the development of a child’s vocabulary: The child begins with a few basic common words and learns new ones as they are encountered.
- **Artificially acquired active immunity** stimulates the body to produce antibodies under controlled conditions so the body will be able to overcome natural exposure to the pathogen in the future. This is the basic principle behind *immunization*, or *vaccination*, to prevent disease. A **vaccine** is a preparation designed to induce an immune response. It contains either a dead or an inactive pathogen, or antigens derived from that pathogen.

Passive immunity is produced by transferring antibodies from another source.

- In **naturally acquired passive immunity**, a baby receives antibodies from the female, either during gestation (by crossing the placenta) or in early infancy (through breast milk).
- In **artificially acquired passive immunity**, a person receives antibodies to fight infection or prevent disease. For example, someone who has been bitten by a rabid animal gets injections containing antibodies against the rabies virus.

Properties of Adaptive Immunity

Regardless of the form, adaptive immunity has four general properties: (1) *specificity*, (2) *versatility*, (3) *memory*, and (4) *tolerance*.

Specificity

A specific defense is activated by a specific antigen, and the immune response targets that particular antigen and no others. **Specificity** results from the activation of appropriate lymphocytes and the production of antibodies with targeted effects. Specificity occurs because T cells and B cells respond to the molecular structure of an antigen. The shape and size of the antigen determine which lymphocytes will respond to it. Each T cell or B cell has receptors that will bind to one specific antigen, ignoring all others. The response of an activated T cell or B cell is equally specific. Either lymphocyte will destroy or inactivate that antigen without affecting other antigens or normal tissues.

Versatility

Millions of antigens in the environment can pose a threat to health. Over a lifetime, only a fraction of that number—perhaps tens of thousands of antigens—are encountered. The immune system, however, has no way of anticipating which antigens it will encounter. It must be ready to confront *any* antigen at *any* time. **Versatility** results in part from the large diversity of lymphocytes present in the body, and in part from variability in the structure of synthesized antibodies.

During development, cells in the lymphatic system differentiate to produce a huge number of lymphocytes with varied antigen sensitivities. The trillion or more T cells and B cells in the body include millions of different lymphocyte populations, distributed throughout the body. Each population contains several thousand cells with receptors in their membranes that differ from the receptors of other lymphocyte populations. As a result, each population of lymphocytes responds to a different antigen.

Figure 22–17 Forms of Immunity.

What type of immunity develops after receiving a vaccine?

Memory

During the initial response to an antigen, lymphocytes that are sensitive to that antigen undergo repeated cycles of cell division. **Memory** exists because those cell divisions produce two groups of cells. One group attacks the invader immediately. Another group remains inactive unless it meets the same antigen later. This inactive group is made up of *memory cells*. They enable the immune system to “remember” an antigen it has previously encountered, and to launch a faster, stronger, and longer-lasting counterattack if such an antigen appears again.

Tolerance

The immune system does not respond to all antigens. All the cells and tissues in the body, for example, contain antigens that normally do not stimulate an immune response. We say that the immune system exhibits **tolerance** toward such antigens, called *self-antigens*.

During their differentiation in the red bone marrow (B cells) and thymus (T cells), any cells that react to

self-antigens are destroyed. During this process up to 98% of developing T cells are deselected and undergo *apoptosis* (the process of genetically programmed cell death). As a result, mature B cells and T cells ignore self-antigens, but attack foreign antigens, or *non-self-antigens*. Tolerance can also develop over time in response to chronic exposure to an antigen in the environment. Such tolerance lasts only if the exposure continues.

Checkpoint

11. Explain the difference between cell-mediated (cellular) immunity and antibody-mediated (humoral) immunity.
12. Identify the four major types of T cells.
13. Identify the two forms of active immunity and the two forms of passive immunity.
14. List the four general properties of adaptive immunity.

See the blue Answers tab at the back of the book.

Clinical Note Types of Vaccines

Vaccines are substances that stimulate the production of antibodies to produce an immune response to specific pathogens, namely, bacteria and viruses. Their purpose is to prevent disease without inducing the actual disease. Pioneers in vaccine development include Edward Jenner, Louis Pasteur, Jonas Salk, and Maurice Hilleman, and vaccines can be dated back to as early as the 1700s.

The discovery and use of vaccines have resulted in the eradication of smallpox (officially declared in 1980) and near eradication (stopped the spread in many areas, yet requiring ongoing efforts) of polio, measles, tetanus, flu, hepatitis B, mumps, chickenpox, and malaria.

As science advances, our understanding of physiology, pathology, virology, and bacteriology deepens and becomes more specialized. The introduction of genetic engineering has rapidly advanced vaccine technology and resulted in products with more effective formulations and delivery methods.

Currently, we have several types of vaccines, and each “teaches” the immune system how to respond should the body encounter a particular pathogen for which a vaccine has been developed. Much goes into vaccine development; researchers consider factors such as immune system physiology, populations, and technology. Scientists work across the globe with other scientists because infectious diseases are world-wide issues.

To date, vaccines fall into several categories, and each functions a little differently. However, their developmental purposes are always consistent: ensuring that the vaccine is safe for the person receiving it (host) and that the vaccine is effective against the disease-causing organism (pathogen). Vaccines may be delivered orally (by mouth), intranasally (sniffed in the nose), subcutaneously (just below the skin with a needle), or intramuscularly (into a muscle with a needle). Today, those vaccine types include the following:

- **Inactivated vaccines:** These vaccines use killed forms of the pathogen; booster shots are needed for continuous immunity. These types are effective against hepatitis A, influenza, polio, and rabies.
- **Live-attenuated vaccines:** These vaccines use live or weakened (attenuated) forms of the pathogen; they provide long-lasting protection with one or two doses. These types are effective against chickenpox; measles, mumps, rubella (MMR combination vaccine); rotavirus; smallpox; and yellow fever.
- **Messenger RNA (mRNA) vaccines:** These vaccines make proteins that trigger an immune response and do not use live or attenuated pathogens. The mRNA is broken down by one's cells within a few days after vaccination. These types are effective against coronavirus disease (COVID-19).
- **Subunit, recombinant, polysaccharide, and conjugate vaccines:** These types use specific pieces of the pathogen and elicit a very strong immune response. People with weakened immune systems can also be given these vaccines, and booster shots are needed for continuous immunity. These types are effective against *Haemophilus influenzae* type b (Hib) disease, hepatitis B, human papillomavirus (HPV), meningococcal disease, pneumococcal disease, shingles, and whooping cough (part of the DTaP combined vaccine).
- **Toxoid vaccines:** These types use altered and weakened forms of a bacterial pathogen's toxin (harmful substance) to act as antigens. This induces an immune response to parts of the bacterial pathogen that cause the disease instead of the whole pathogen. Booster shots are needed for continuous immunity. These types are effective against diphtheria and tetanus.
- **Viral vector vaccines:** These types use modified versions of a different virus as the vector to deliver protection. For example, adenoviruses that cause the common cold have been modified to be harmless vectors in these vaccines. These types are effective against COVID-19.

Vaccines are a boon to personal and public health, preventing the spread of contagious, often deadly, diseases. While vaccine hesitancy (being unsure) and vaccine refusal (unwillingness) remain public health concerns, vaccines are safe and effective means for thwarting unnecessary illness and death.

22-5 In cell-mediated adaptive immunity, presented antigens activate T cells, which respond by producing cytotoxic and helper T cells

Learning Outcome Discuss the types of T cells and their roles in the adaptive immune response and describe the mechanisms of T cell activation and differentiation.

This section describes the mechanisms involved in antigen recognition by T cells and their subsequent activation, clonal selection, and mitotic divisions.

Activation and Clonal Selection of T Cells

Before an immune response can begin, T cells must be activated by exposure to an antigen. This activation seldom occurs through direct interaction between a T cell and the antigen. Foreign substances or pathogens entering a tissue commonly fail to stimulate an immediate immune response. T cells only recognize antigens when they are processed and “presented” by cells called *antigen-presenting cells*, most of which are phagocytes such as macrophages. This process—*antigen presentation*—is generally the first step in the activation of the

immune response (**Figure 22-16**). The next step is antigen recognition, followed by differentiation and production of clones of the various defensive cells, such as cytotoxic T cells and helper T cells.

Antigen Presentation with MHC Proteins

For a T cell to recognize an antigen, the antigen must be bound to glycoproteins in the plasma membrane of another cell, such as an antigen-presenting cell. Recall that glycoproteins are integral membrane components. The structure of these glycoproteins is genetically determined, and these proteins identify the cell as “self” rather than foreign. The genes controlling their synthesis are located along one portion of chromosome 6, in a region called the **major histocompatibility complex (MHC)**. These membrane glycoproteins are therefore called **MHC proteins**, or *human leukocyte antigens* (HLAs). **Antigen presentation** occurs when an antigen–MHC protein combination capable of activating T cells appears in a plasma membrane.

The amino acid sequences and the shapes of MHC proteins differ among individuals. Each MHC molecule has a distinct three-dimensional shape with a relatively narrow central groove. An antigen that fits into this groove can be held in position by hydrogen bonding.

Two major classes of MHC proteins are known: *class I* and *class II*. An antigen bound to a class I MHC protein acts like a red flag that in effect tells the immune system, “I’m an abnormal cell—kill me!” An antigen bound to a class II MHC protein tells the immune system, “This antigen is dangerous—get rid of it!”

Class I MHC Proteins. **Class I MHC proteins** are in the plasma membranes of all nucleated cells. These proteins are continuously synthesized and exported to the plasma membrane in vesicles formed by the Golgi apparatus. As they form, class I proteins pick up small peptides from the surrounding cytoplasm and carry them to the cell surface. If the cell is healthy and the peptides are normal, T cells ignore them. If the cytoplasm contains abnormal (non-self) peptides or viral proteins, they soon appear in the plasma membrane, and T cells will recognize them as foreign and be activated (**Figure 22-18a**). Ultimately, their activation leads to the destruction of the abnormal cells. This is the primary reason that donated organs are commonly rejected by the recipient. Despite preliminary tissue typing, the recipient’s T cells recognize the transplanted tissue as foreign.

Class II MHC Proteins and Antigen-Presenting Cells. **Class II MHC proteins** are present only in the plasma membranes of antigen-presenting cells and lymphocytes. **Antigen-presenting cells (APCs)** are specialized cells that activate T cell defenses against foreign cells (including bacteria) and foreign proteins. Antigen-presenting cells include all the phagocytes of the monocyte–macrophage group discussed in other chapters, including (1) free and fixed macrophages in connective tissues, (2) the stellate macrophages of the liver, and (3) the microglia

Clinical Note Lab Tests for Organ Donation

A successful match between an organ donor and a recipient depends on the results of three tests: (1) blood type, (2) tissue type, and (3) cross-matching. Each of these tests seeks evidence of an immune response to a foreign antigen. Immune rejection either disqualifies the match or requires the recipient to receive more medication to suppress his or her immune response.

Blood typing establishes whether an individual has type O, A, B, or AB blood. Type O blood is the universal donor (all blood types can receive type O⁻); type AB is the universal recipient (type AB⁺ can receive all blood types).

Tissue typing is performed by specialized laboratories. Also called histocompatibility testing, this test assesses HLAs, human leukocyte antigens. Out of more than 100 existing antigens, six have been determined to be the most important in organ donation, three inherited from each parent. Although it is rare to have a perfect six-antigen match between donor and recipient, the higher the match, the better the success rate of organ or tissue transplantation.

Cross-matching tests for incompatibility between donor and recipient blood to avoid hemolytic reactions. It is done by mixing a sample of donor red blood cells with plasma from the recipient and mixing recipient red blood cells with plasma from the donor. If clumping occurs, donation is not possible because the blood types are incompatible.

in the central nervous system. The **dendritic cells** of the skin (where they are also known as *Langerhans* cells) and those of the lymph nodes and spleen are APCs that are not phagocytic.

Antigen-presenting cells engulf and break down pathogens or foreign antigens. This **antigen processing** creates fragments of the antigen, which are then bound to class II MHC proteins and inserted into the plasma membrane (**Figure 22-18b,c**). Class II MHC proteins appear in the plasma membrane only when the cell is processing antigens. The APC then presents the combined class II MHC protein and processed antigen to appropriate T cells.

The dendritic cells remove antigenic materials from their surroundings by pinocytosis rather than phagocytosis. However, their plasma membranes still present antigens bound to class II MHC proteins. More important is that, unlike macrophages that do not migrate very far from an infection site, dendritic cells travel with their foreign antigens to lymphocyte-packed lymph nodes.

Antigen Recognition and CD Markers

How do T cells recognize antigens? Inactive T cells have receptors that can bind either class I or class II MHC proteins. These receptors also have binding sites for a specific target antigen. If an MHC protein contains any antigen other than the specific target of a particular kind of T cell, the T cell remains inactive. If the MHC protein contains the antigen that the T cell is

Figure 22–18 Antigens and MHC Proteins.

programmed to detect, binding occurs. This process is called **antigen recognition**, because the T cell recognizes that it has found an appropriate target.

Some T cells can recognize antigens bound to class I MHC proteins, whereas others can recognize antigens bound to class II MHC proteins. Whether a T cell responds to antigens held by one class or the other depends on a type of protein in the T cell's own plasma membrane. The membrane proteins involved are members of a larger group of proteins called **CD (cluster of differentiation) markers**.

More than 350 types of CD markers exist, and each type is designated by a number. All T cells have a **CD3 receptor complex** in their plasma membranes, and this complex ultimately activates the T cell. Either of two other CD markers

may be bound to the CD3 receptor complex, and these two CD markers are especially important in specific groups of T cells:

- **CD8** markers are found on cytotoxic T cells and regulatory T cells, which together are often called **CD8 T cells**. CD8 T cells respond to antigens presented by class I MHC proteins.
- **CD4** markers are found on helper T cells, often called **CD4 T cells**. CD4 T cells respond to antigens presented by class II MHC proteins.

T cells are not usually activated upon their first encounter with the antigen. Antigen recognition simply prepares the cell for activation.

Tips

You can remember that MHC class **I** and CD**8** go together, and MHC class **II** and CD**4** go together, because both pairs multiplied are 8 ($1 \times 8 = 8$ and $2 \times 4 = 8$).

Costimulation and Clonal Selection

To proceed from recognition to activation, a T cell must also bind to the stimulating cell at a second site. This vital secondary binding process, called *costimulation*, essentially confirms the initial activation signal.

Costimulation is like the safety on a gun: It helps prevent T cells from mistakenly attacking normal (self) tissues. If a cell displays an unusual antigen but does not display the “I am an active phagocyte” or “I am infected” signal, T cell activation will not occur. Costimulation is important only in determining whether a T cell will become activated.

Once activation has occurred, the “safety” is off and the T cell will undergo mitosis, producing clones of identical cells. The types of cells that are produced depend on the type of T cell that was activated.

Functions of Activated CD8 T Cells

Two different types of CD8 T cells are activated by exposure to antigens bound to class I MHC proteins. One type responds

quickly, giving rise to clones containing large numbers of active cytotoxic T cells and inactive *memory T cells* (Figure 22–19). The other type responds more slowly and produces relatively small numbers of regulatory T cells.

Cytotoxic T Cells (T_C)

Cytotoxic T (T_C) cells seek out and destroy abnormal and infected cells. They are highly mobile cells that roam throughout injured tissues. The constant monitoring of normal tissues by cytotoxic T cells and NK cells is called immune surveillance.

When a cytotoxic T cell encounters its target antigen bound to class I MHC proteins, it immediately destroys the target cell (Figure 22–19). The T cell may (1) release perforins to destroy the target cell’s plasma membrane, (2) release cytokines and activate genes in the target cell’s nucleus stimulating that cell to undergo apoptosis, or (3) secrete a poisonous **lymphotoxin** (lim-fō-TOK-sin) to kill the target cell.

The entire sequence of events, from the appearance of the antigen in a tissue to cell destruction by cytotoxic T cells, takes a significant amount of time. After the first exposure to an antigen, 2 days or more may pass before the population of cytotoxic T cells reaches an effective level at the site of injury

Figure 22–19 Antigen Recognition and Activation of Cytotoxic T Cells.

Clinical Note Organ Donation

Each day in the United States, 40 people receive an organ donation and 17 people die waiting for one. Every 9 minutes, a new name is added to the current roster of 106,093 people on the national transplant waiting list (2021). These names come from people with chronic disease, trauma, or birth defects. People need organs (kidneys, hearts, lungs, pancreases, livers) or tissues (such as bone marrow, bone, tendons, or corneas) to extend their life or improve its quality. Each donor organ or tissue must be scrupulously matched to the recipient to ensure the best chance of success.

Most living donors are female; most deceased donors are male, and most of these are accident victims. A single donor can save up to eight lives through the donation of multiple organs and tissues. In the case of a fatality, there is a window of 24 hours to initiate donation.

Individuals who are interested in becoming donors can sign up with a state registry or give their legal consent on their driver's license or in their living will. The U.S. Department of Health and Human Services (DHHS) sponsors the network for organ procurement and transplantation.

or infection. Over this period, the damage or infection may spread, making it more difficult to control.

Memory T_C Cells

The same cell divisions that produce cytotoxic T cells also produce thousands of **memory T_C cells**. These cells do not differentiate further the first time the antigen triggers an immune response. However, if the same antigen appears a second time, memory T_C cells *immediately* differentiate into cytotoxic T cells and undergo repeated mitotic divisions. They produce a prompt, effective cellular response that can overwhelm the invader before it becomes well established in the tissues.

Regulatory T Cells (T_{regs})

Regulatory T cells, referred to as T_{regs} , moderate the responses of other T cells and of B cells by secreting inhibitory cytokines called *suppression factors*. Suppression does not take place right away, because activation takes much longer for regulatory T cells than for other types of T cells. In addition, upon activation, most of the CD8 T cells in the bloodstream produce cytotoxic T cells rather than regulatory T cells. As a result, regulatory T cells act *after* the initial immune response. In effect, these cells limit the degree of immune system activation from a single stimulus.

Functions of Activated CD4 T Cells: Helper T (T_H) and Memory T_H Cells

Upon activation, helper T (T_H) cells with CD4 markers undergo a series of divisions that produce both active helper T cells and **memory T_H cells** (Figure 22–20). The memory T_H

Figure 22–20 Antigen Recognition and Activation of Helper T Cells. Inactive CD4 T cells (T_H cells) must be exposed to appropriate antigens bound to class II MHC proteins. The T_H cells then undergo activation, dividing to produce active T_H cells and memory T_H cells.

cells remain in reserve. The active helper T cells secrete a variety of cytokines, our next topic.

Tips

Helper T cells “help” translate the message from the antigen-presenting cells of the nonspecific response to the cells of the specific immune responses.

Cytokines of Adaptive Defenses

Lymphocytes and other defensive cells produce and secrete cytokines that act as hormones, affecting cells and tissues throughout the body. Interleukins and tumor necrosis factors are examples of cytokines used in adaptive defenses (**Spotlight Figure 22–21**).

Innate (nonspecific) immunity and adaptive (specific) immunity are coordinated by both physical interactions and the release of chemical messengers.

CYTOKINES

Many types of cells involved in the immune response secrete chemicals known as cytokines. Six major groups of cytokines are described here.

Interleukins

Interleukins may be the most diverse and important chemical messengers in the immune system. Currently, 33 interleukins have been identified. Lymphocytes and macrophages are the primary sources of interleukins, but endothelial cells, fibroblasts, and astrocytes also produce certain interleukins, such as interleukin-1 (IL-1).

The functions of interleukins include the following:

- 1. Increasing T Cell Sensitivity to Antigens Exposed on Macrophage Membranes.** Heightened sensitivity increases the production of cytotoxic and regulatory T cells.
- 2. Stimulating B Cell Activity, Plasma Cell Formation, and Antibody Production.** These events promote the production of antibodies and the development of antibody-mediated immunity.
- 3. Enhancing Innate (Nonspecific) Immunity.** Known effects of interleukin production include (a) stimulating inflammation, (b) forming scar tissue by fibroblasts, (c) increasing body temperature by the pre-optic nucleus of the hypothalamus, (d) stimulating mast cell formation, and (e) promoting adrenocorticotrophic hormone (ACTH) secretion by the anterior lobe of the pituitary gland.
- 4. Moderating the Immune Response.** Some interleukins help suppress immune function and shorten the immune response.

Two interleukins, IL-1 and IL-2, are important in stimulating and maintaining the immune response. When released by activated macrophages and lymphocytes, these cytokines stimulate other immune cells and the secreting cell. The result is a positive feedback loop that helps to recruit additional immune cells.

Although mechanisms exist to control the degree of stimulation, the regulatory process sometimes breaks down. Massive production of interleukins can cause problems at least as severe as those of the primary infection. For example, in *Lyme disease*, activated macrophages release IL-1 in response to a localized bacterial infection. This release produces fever, pain, skin rash, and arthritis throughout the entire body.

Some interleukins enhance the immune response, while others suppress it. The quantities secreted at any moment affect the nature and intensity of the response to an antigen. During a typical infection, the pattern of interleukin secretion changes constantly. Whether stimulatory interleukins or suppressive interleukins predominate plays a part in determining whether the individual overcomes the infection. For this reason, interleukins and their interactions are now the focus of intensive research.

Interferons

Interferons (IFNs) make the cell that synthesizes them, and that cell's neighbors, resistant to viral infection. In this way, IFNs slow the spread of a virus. They may have other beneficial effects. For example, interferon alpha (α) and interferon gamma (γ) attract and stimulate NK cells. Interferon beta (β) slows the progress of inflammation associated with viral infection. Interferon gamma also stimulates macrophages, making them more effective at killing bacterial or fungal pathogens.

Because they stimulate NK cell activity, interferons can be used to fight some cancers. For example, interferon alpha has been used to treat malignant melanoma, bladder cancer, ovarian cancer, and some forms of leukemia. Interferon alpha or gamma may be used to treat Kaposi's sarcoma, a cancer that typically develops in patients with AIDS.

Phagocyte-Activating Chemicals

Several cytokines coordinate immune defenses by adjusting the activities of phagocytic cells. These cytokines include factors that attract free macrophages and microphages and prevent their premature departure from the injury site.

Colony-Stimulating Factors

Colony-stimulating factors (CSFs) were introduced in Chapter 19. These factors are produced by active T cells, cells of the monocyte-macrophage system, endothelial cells, and fibroblasts. CSFs stimulate the production of blood cells in red bone marrow and lymphocytes in lymphoid tissues and organs.

Tumor Necrosis Factors

Tumor necrosis factors (TNFs) slow the growth of a tumor and kill sensitive tumor cells. Activated macrophages secrete one type of TNF and carry the molecules in their plasma membranes. Cytotoxic T cells produce a different type of TNF. In addition to their effects on tumor cells, TNFs stimulate granular leukocyte production, promote eosinophil activity, act as pyrogens and cause fever, and increase T cell sensitivity to interleukins.

Miscellaneous Cytokines

This general category includes many chemicals discussed in earlier chapters. Examples include leukotrienes, lymphotoxins, perforin, and suppression factors.

NOTE: Cytokines are often classified according to their origins. For example, *lymphokines* are produced by lymphocytes. *Monokines* are secreted by active monocytes, macrophages, and other antigen-presenting cells. These terms are misleading, however, because lymphocytes and macrophages may secrete the same cytokines. In addition, cells involved in adaptive immunity and tissue repair can also secrete cytokines.

Figure 22–22 A Summary of the Pathways of T Cell Activation.

Cytokines Produced by Helper T Cells

Helper T cells produce cytokines that coordinate specific and nonspecific defenses and stimulate cell-mediated and antibody-mediated immunities. These cytokines do the following:

- Stimulate the T cell divisions that produce memory T cells and speed the maturation of cytotoxic T cells.
- Enhance nonspecific defenses by attracting macrophages to the affected area, preventing their departure, and stimulating their phagocytic activity and effectiveness.
- Attract and stimulate the activity of cytotoxic T cells, providing another means of destroying abnormal cells and pathogens.
- Promote the activation of B cells, leading ultimately to antibody production.

Summary of Cell-Mediated Adaptive Immunity

Figure 22–22 provides a review of the alternate pathways of antigen presentation and T cell stimulation. The plasma membranes of infected or otherwise abnormal cells trigger an immune response when CD8 T cells recognize antigens bound to class I MHC proteins. Extracellular pathogens or foreign proteins trigger an immune response when CD4 T cells recognize antigens displayed by class II MHC proteins. In the next section, we look at how the helper T cells derived from activated CD4 T cells in turn activate B cells that are sensitive to the same specific antigen.

Checkpoint

15. How can the presence of an abnormal peptide in the cytoplasm of a cell initiate an immune response?
16. A decrease in the number of cytotoxic T cells would affect which type of immunity?

See the blue Answers tab at the back of the book.

22-6 In antibody-mediated adaptive immunity, sensitized B cells respond to antigens by producing specific antibodies

Learning Outcome Discuss the mechanisms of B cell activation and differentiation, describe the structure and function of antibodies, and explain the primary and secondary responses to antigen exposure.

B cells are responsible for launching a chemical attack on antigens. They produce appropriate specific antibodies that eliminate the antigens. If the same antigens eliminated in the *primary response* reappear, a rapid *secondary response* is initiated by memory cells.

B Cell Sensitization and Activation

The human body has millions of B cell populations. Each B cell carries thousands of its own particular type of antibody molecules bound to its plasma membrane. If corresponding antigens appear in the interstitial fluid, they interact with

Figure 22–23 The Sensitization and Activation of B Cells. A B cell is sensitized by exposure to antigens. Once antigens are bound to antibodies in the B cell plasma membrane, the B cell displays those antigens on class II MHC proteins in its plasma membrane. Activated helper T cells encountering the antigens release cytokines that costimulate the sensitized B cell and trigger its activation. The activated B cell then divides, producing memory B cells and plasma cells that secrete antibodies.

these membrane-bound antibodies. When binding occurs, the B cell prepares to undergo activation. This preparatory process is called **sensitization** (Figure 22–23). Because B cells migrate throughout the body, pausing briefly in one lymphoid tissue or another, sensitization typically takes place within the lymph node nearest the site of infection or injury.

Recall that B cell plasma membranes contain class II MHC proteins. During sensitization, antigens are brought into the cell by endocytosis. The antigens subsequently appear on the surface of the B cell, bound to class II MHC proteins. The sensitized B cell is then on “standby” but generally does not undergo activation unless it receives the “OK” from a helper T cell. The need for activation by a helper T cell helps prevent inappropriate activation, the same way that costimulation acts as a “safety” in cell-mediated immunity.

What happens when a sensitized B cell meets a helper T cell that has already been activated by antigen presentation? The helper T cell binds to the B cell’s MHC complex, recognizes the antigen, and begins secreting cytokines that promote B cell activation (Figure 22–23).

Production of Plasma Cells, Antibodies, and Memory B Cells

The activated B cell typically divides several times, producing daughter cells that differentiate into **plasma cells** and **memory B cells** (Figure 22–23). The plasma cells begin synthesizing and secreting large quantities of antibodies into the interstitial fluid. These antibodies have the same target as the membrane-bound antibodies on the surface of the sensitized B cell. After activation of the B cell, helper T cells secrete cytokines that stimulate B cell division, speed plasma cell formation, and enhance antibody production. A plasma cell can secrete up to 100 million antibody molecules each hour.

Memory B cells perform the same role in antibody-mediated immunity that memory T cells perform in cell-mediated immunity. Memory B cells do not respond to a threat on first exposure. Instead, they remain in reserve to deal with subsequent injuries or infections that involve the same antigens. On subsequent exposure, the memory B cells divide and differentiate into plasma cells that secrete antibodies in massive quantities.

Antibody Structure and Function

As noted earlier, **antibodies** are soluble proteins. The binding of an antibody to its target antigen starts a chain reaction that leads to the destruction of the target compound or organism.

Structure and Classes of Antibodies

A Y-shaped antibody molecule consists of two pairs of polypeptide chains: one pair of **heavy chains** and one pair of **light chains** (Figure 22-24). Each chain contains both *constant segments* and *variable segments*.

The constant segments of the heavy chains form the base of the antibody molecule (Figure 22-24a,b). B cells produce only five types of constant segments. These are the basis of a scheme that identifies five classes of antibodies, or **immunoglobulins (Igs)**: IgG, IgE, IgD, IgM, and IgA (Table 22-1). The structure of the constant segments of the heavy chains determines the way the antibody is secreted and how it is distributed within the body. For example, antibodies in one class

circulate in body fluids, whereas those of another class bind to the membranes of basophils and mast cells.

Tips

The classes of immunoglobulins—Ig**M**, Ig**A**, Ig**D**, Ig**G**, Ig**E**—spell **MADGE**.

The heavy-chain constant segments, which are bound to constant segments of the light chains, also contain binding sites that can activate the complement system. These binding sites are covered when the antibody is secreted but become exposed when the antibody binds to an antigen.

The specificity of an antibody molecule depends on the amino acid sequence of the variable segments of the light and heavy chains. The free tips of the two variable segments form the **antigen-binding sites** of the antibody molecule (Figure 22-24a). The heavy-chain constant segments have no effect on the antibody's specificity, which is determined by the antigen-binding sites.

Figure 22-24 Antibody Structure and Function.

Table 22-1 Classes of Antibodies

 IgG is the largest and most diverse class of antibodies. IgG antibodies account for 80% of all antibodies. They are responsible for resistance against many viruses, bacteria, and bacterial toxins. These antibodies can cross the placenta, and maternal IgG provides passive immunity to the fetus during embryonic development. However, the anti-Rh antibodies produced by Rh-negative mothers are also IgG antibodies and produce <i>hemolytic disease of the newborn</i>.	 IgE attaches as an individual molecule to the exposed surfaces of basophils and mast cells. When a suitable antigen is bound by IgE molecules, the cell is stimulated to release histamine and other chemicals that accelerate inflammation in the immediate area. IgE is also important in the allergic response.	 IgD is an individual molecule on the surfaces of B cells, where it can bind antigens in the extracellular fluid. This binding can play a role in the sensitization of the B cell involved.	 IgM is the first class of antibody secreted after an antigen is encountered. IgM concentration declines as IgG production accelerates. Although plasma cells secrete individual IgM molecules, IgM circulates as a five-antibody starburst. The anti-A and anti-B antibodies responsible for the agglutination of incompatible blood types are IgM antibodies. IgM antibodies may also attack bacteria that are insensitive to IgG.	 IgA is found primarily in glandular secretions such as mucus, tears, saliva, and semen. These antibodies attack pathogens before they gain access to internal tissues. IgA antibodies circulate in blood as individual molecules or in pairs. Epithelial cells absorb them from the blood and attach a <i>secretory piece</i>, before secreting the IgA molecules onto the epithelial surface.
--	--	--	---	--

Small differences in the structure of the variable segments affect the precise shape of the antigen-binding site. These differences make antibodies specific for different antigens. The distinctions are the result of minor genetic variations that occur during the production, division, and differentiation of B cells. An adult body contains approximately 10 trillion B cells, which can produce an estimated 100 million types of antibodies, each with a different specificity.

The Antigen–Antibody Complex

When an antigen-binding site on an antibody molecule binds to its corresponding antigen molecule, an **antigen–antibody complex** is formed. Once the two molecules are in position, hydrogen bonding and other weak chemical forces lock them together. Antigen-binding sites interact with an antigen in the same way that the active site of an enzyme interacts with a substrate molecule.

Antibodies do not bind to the entire antigen. Instead, they bind to specific portions of its exposed surface—regions called **antigenic determinant sites**, or **epitopes** (Figure 22-24c). The specificity of the binding depends initially on the three-dimensional “fit” between the variable segments of the antibody molecule and the corresponding antigenic determinant sites. A **complete antigen** has at least two antigenic determinant sites, one for each of the antigen-binding sites on an antibody molecule. Exposure to a complete antigen can lead to B cell sensitization and a subsequent immune response. Most environmental antigens have multiple antigenic determinant sites, and entire microorganisms may have thousands.

Haptens, or *partial antigens*, do not ordinarily cause B cell activation and antibody production. Haptens include short peptide chains, steroids and other lipids, and several drugs, including antibiotics such as *penicillin*. However, haptens may become attached to carrier molecules, forming combinations that can function as complete antigens (Figure 22-24d). In some cases, the carrier contributes an antigenic determinant site. Antibodies will then attack both the hapten and the carrier molecule. If the carrier molecule is normally present in the tissues, the antibodies may begin attacking and destroying normal cells. This process is the basis for several drug reactions, including allergies to penicillin.

Actions of Antibodies

The formation of an antigen–antibody complex may cause the elimination of the antigen in the following ways:

- **Neutralization.** Both viruses and bacterial toxins have specific sites that must bind to target regions on body cells before they can enter or injure those cells. Antibodies may bind to those sites, making the virus or toxin incapable of attaching itself to a cell. This mechanism is known as **neutralization**.
- **Precipitation and Agglutination.** Each antibody molecule has two antigen-binding sites, and most antigens have many antigenic determinant sites. If individual antigens (such as macromolecules or bacterial cells) are far apart, an antibody molecule will necessarily bind to two antigenic sites on the same antigen. However, if antigens are close together, an antibody can bind to antigenic

determinant sites on two separate antigens. In this way, antibodies can link large numbers of antigens together. The three-dimensional structure created by such binding is known as an **immune complex**. When the antigen is a soluble molecule, such as a toxin, this process may create complexes that are too large to remain in solution. The formation of insoluble immune complexes is called **precipitation**. When the target antigen is on the surface of a cell or virus, the formation of large complexes is called **agglutination**. We discussed an example of agglutination with the clumping of erythrocytes that occurs when incompatible blood types are mixed.

- **Activation of the Complement System.** When an antibody molecule binds to an antigen, portions of the antibody molecule change shape. This change exposes areas that bind complement proteins. The bound complement molecules then activate the complement system, which destroys the antigen (as discussed previously).
- **Attraction of Phagocytes.** Antigens covered with antibodies attract eosinophils, neutrophils, and macrophages. These cells phagocytize pathogens and destroy foreign or abnormal plasma membranes.
- **Opsonization.** A coating of antibodies and complement proteins increases the effectiveness of phagocytosis. This effect is called *opsonization*. Some bacteria have slick plasma membranes or capsules, but opsonization makes it easier for phagocytes to hold onto their prey before they engulf it. Phagocytes can bind more easily to antibodies and complement proteins than they can to the bare surface of a pathogen.
- **Stimulation of Inflammation.** Antibodies may promote inflammation by stimulating basophils and mast cells.
- **Prevention of Bacterial and Viral Adhesion.** Antibodies dissolved in saliva, mucus, and perspiration coat epithelia, adding an additional layer of defense. A covering of antibodies makes it difficult for pathogens to attach to and penetrate body surfaces.

Primary and Secondary Responses to Antigen Exposure

The initial immune response to an antigen is called the **primary response**. When the antigen appears again, it triggers a more extensive and prolonged **secondary response**. This response is due to the presence of large numbers of memory cells that are primed for the arrival of the antigen. Let's consider the pattern of antibody production over time to see the differences between the primary and secondary responses.

The Primary Response

The primary response takes time to develop because the antigen must activate the appropriate B cells. These cells must then differentiate into plasma cells. As plasma cells differentiate and

begin secreting, the concentration of circulating antibodies makes a gradual, sustained increase (**Figure 22-25a**).

During the primary response, the **antibody titer**, or level of antibodies in the plasma, does not peak until 1 to 2 weeks after the initial exposure. If the person is no longer exposed to the antigen, the antibody concentration then decreases. The antibody titer decreases because (1) plasma cells have very high metabolic rates and survive for only a short time, and (2) regulatory T cells release suppression factors that inhibit further plasma cell production. However, regulatory T cell activity does not begin immediately after exposure to the antigen. Also, under normal conditions helper T cells outnumber regulatory T cells by more than 3 to 1. As a result, many B cells are activated before regulatory T cell activity has a noticeable effect.

Activated B cells start dividing immediately. At each cycle of division, some of the daughter cells differentiate into plasma cells, while others continue to divide. Molecules of *immunoglobulin M*, or *IgM*, are the first to appear in the bloodstream. The plasma cells that produce IgM differentiate after only a few cycles of B cell division. Levels of *immunoglobulin G*, or *IgG*, rise more slowly, because the plasma cells responsible differentiate only after repeated cell divisions that also generate large numbers of memory B cells. In general, IgM is less effective as a defense than IgG. However, IgM provides an immediate defense that can fight the infection until massive quantities of IgG can be produced.

The Secondary Response

Unless memory B cells are exposed to the same antigen a second time, they do not differentiate into plasma cells. If that exposure occurs, the memory B cells respond immediately—faster than the B cells stimulated during the initial exposure. This response is immediate in part because memory B cells are activated at relatively low antigen concentrations. In addition, these cells synthesize more effective and destructive antibodies. Activated memory B cells divide and differentiate into plasma cells that secrete these antibodies in massive quantities. This secretion is the secondary response to antigen exposure.

During the secondary response, antibody concentrations and titers increase more rapidly and reach levels many times higher than they did in the primary response (**Figure 22-25b**). The secondary response appears even if the second exposure occurs years after the first. The reason is that memory cells may survive for 20 years or more.

The primary response develops slowly and does not produce antibodies in massive quantities. For these reasons, it may not prevent an infection the first time a pathogen appears in the body. However, a person who survives the first infection will probably be resistant to that pathogen in the future, thanks to a rapid and overwhelming secondary response. The effectiveness of the secondary response is one of the basic principles behind the use of immunization to prevent disease.

Figure 22–25 The Primary and Secondary Responses in Antibody-Mediated Immunity.

a The primary response takes about 2 weeks to develop peak antibody levels (titers). IgM and IgG antibody levels do not remain elevated.

b The secondary response has a very rapid increase in IgG antibody concentration and rises to levels much higher than those of the primary response. Antibody levels remain elevated for an extended period after the second exposure to the antigen.

During the primary response, which antibody peaks sooner? During the secondary response, which antibody level is higher?

Tips

The antibody response is like ordering a custom suit. The first suit (the primary antibody response) takes time to make because the tailor (an activated B cell) must first make a pattern (a clone of memory cells). Subsequent suits (secondary responses) are made much more quickly because the pattern already exists.

Checkpoint

17. How would a lack of helper T cells affect the antibody-mediated immune response?
18. Define sensitization.
19. A sample of lymph contains an elevated number of plasma cells. Would the number of antibodies in the blood be increasing or decreasing? Why?
20. Describe the structure of an antibody.
21. Which would be more negatively affected—the primary response or the secondary response—by a lack of memory B cells for a particular antigen?

See the blue Answers tab at the back of the book.

22-7 Immunocompetence enables a normal immune response; abnormal responses result in immune disorders

Learning Outcome Describe the development of immunocompetence, discuss the effects of stress on immune function, and list and explain examples of immune disorders and allergies.

This section begins by summarizing the normal immune response. Next, we explore **immunocompetence**, the ability to

produce an immune response after exposure to an antigen. Then we examine the role of stress in immune responses. Finally, we consider some of the disorders that result when immune responses go wrong.

Summary of Innate and Adaptive Immunity

We have examined the basic cellular and chemical interactions that proceed after a foreign antigen appears in the body. **Table 22–2** reviews the cells that participate in tissue defenses, and **Figure 22–26** shows a time line for their appearance at the site of a bacterial infection.

In the early stages of infection, neutrophils and NK cells migrate into the threatened area and destroy bacteria. Over time, cytokines draw increasing numbers of phagocytes into the region. Cytotoxic T cells appear as arriving T cells are activated by antigen presentation. Last of all, the population of plasma cells rises as activated B cells differentiate. This rise is followed by a gradual, sustained increase in the level of circulating antibodies.

Figure 22–27 provides an integrated review of the relationship between innate and adaptive immunity. The basic sequence of events is similar when a viral infection occurs. The initial steps are different, however, because cytotoxic T cells provide an adaptive defense and NK cells provide an innate defense. **Figure 22–28** contrasts the events involved in defending against bacterial infection with those against viral infection.

The Development of Immunocompetence

Cell-mediated immunity can be demonstrated as early as the third month of fetal development. Active antibody-mediated immunity follows about 1 month later.

Table 22-2 Cells That Participate in Tissue Defenses

Cell	Functions
Neutrophils	Phagocytosis; stimulation of inflammation
Eosinophils	Phagocytosis of antigen–antibody complexes; suppression of inflammation; participation in allergic response
Mast cells and basophils	Stimulation and coordination of inflammation by release of histamine, heparin, leukotrienes, prostaglandins
ANTIGEN-PRESENTING CELLS	
Macrophages (free and fixed macrophages, stellate macrophages, and microglia)	Phagocytosis; antigen processing; antigen presentation with class II MHC proteins; secretion of cytokines, especially interleukins and interferons
Dendritic cells	Pinocytosis; antigen processing; antigen presentation bound to class II MHC proteins
LYMPHOCYTES	
NK cells	Destruction of plasma membranes containing abnormal antigens
Cytotoxic T cells (CD8 marker)	Lysis of plasma membranes containing antigens bound to class I MHC proteins; secretion of perforins, defensins, lymphotoxins, and other cytokines
Helper T cells (CD4 marker)	Secretion of cytokines that stimulate cell-mediated and antibody-mediated immunity; activation of sensitized B cells
B cells	Differentiation into plasma cells, which secrete antibodies and provide antibody-mediated immunity
Regulatory T cells (CD8 marker)	Secretion of suppression factors that inhibit the immune response
Memory cells (T cells, B cells)	Produced during the activation of T cells and B cells; remain in tissues awaiting antigen reappearance

The first cells that leave the fetal thymus migrate to the skin and into the epithelia lining the mouth, the digestive tract, and, in females, the uterus and vagina. These cells take up residence in these tissues as antigen-presenting cells, such as the dendritic cells of the skin, whose primary function will be to help activate T cells. T cells that leave the thymus later in development populate lymphoid organs throughout the body.

The plasma membranes of the first B cells produced in the liver and bone marrow carry IgM antibodies. Sometime after the fourth month the fetus may produce IgM antibodies if exposed to specific pathogens. The developing fetus usually does not produce antibodies, however, because it has naturally acquired passive immunity due to IgG antibodies from the maternal bloodstream. These are the only antibodies that can cross the placenta. They include the antibodies responsible for the clinical problems due to Rh incompatibility, discussed in Chapter 19. Problems with incompatibilities involving the ABO blood groups rarely occur. The reason is that anti-A and anti-B antibodies are IgM antibodies, which cannot cross the placenta.

The natural immunity provided by maternal IgG may not be enough to protect the fetus if the female's defenses are overwhelmed by a bacterial or viral infection. For example, the microorganisms responsible for syphilis and rubella ("German measles") can cross from the maternal bloodstream to the fetal bloodstream, producing a congenital infection that leads to the production of fetal antibodies. IgM provides only a partial defense, and these infections can result in severe developmental problems for the fetus.

Delivery eliminates the maternal supply of IgG. Although IgA antibodies are found in breast milk, the infant gradually loses its passive immunity. The amount of maternal IgG in the infant's bloodstream declines rapidly over the first 2 months after birth. During this period, the infant becomes vulnerable to infection by bacteria or viruses that were previously overcome by maternal antibodies. The infant's immune system begins to respond to infections, environmental antigens, and

Figure 22-26 The Course of the Body's Response to a Bacterial Infection. The basic sequence of events begins with the appearance of bacteria in peripheral tissues at time 0.

After the appearance of bacteria in the body, which immune cell is present for the shortest amount of time?

Figure 22–27 An Integrated Summary of the Immune Response.

vaccinations. As a result, the infant begins producing its own IgG. From birth to age 12, children encounter a “new” antigen on average every 6 weeks. (This fact explains why most

parents, who were exposed to the same antigens when they were children, remain healthy while their children develop runny noses and colds.) Over this period, the concentration

Figure 22–28 Defenses against Bacterial and Viral Pathogens.**a** Defenses against bacteria involve phagocytosis and antigen presentation by APCs.**b** Defenses against viruses involve direct contact with virus-infected cells and antigen presentation by APCs.

of circulating antibodies gradually rises toward normal adult levels. Populations of memory B cells and T cells also increase.

Skin tests are sometimes used to determine whether an individual has been exposed to a particular antigen. In these procedures, small quantities of antigen are injected into the

skin, generally on the anterior surface of the forearm. If resistance has developed, the region becomes inflamed over the next 2 to 4 days. Many states require a tuberculosis test, called a *tuberculin skin test*, before children enter public school. If the test is positive, further tests must then be done to determine

whether an infection is currently under way. Skin tests are also used to check for allergies to environmental antigens.

Stress and the Immune Response

One of the normal effects of interleukin-1 secretion is the stimulation of adrenocorticotrophic hormone (ACTH) production by the anterior lobe of the pituitary gland. This hormone, in turn, prompts the secretion of glucocorticoids by the adrenal cortex. The anti-inflammatory effects of the glucocorticoids may help control the extent of the immune response.

However, chronic stress depresses the immune system and can be a serious threat to health. The long-term secretion of glucocorticoids, as in the resistance phase of the *stress response*, can inhibit the immune response and lower a person's resistance to disease. The effects of glucocorticoids that alter the effectiveness of innate and adaptive defenses include the following:

- *Depression of Inflammation.* Glucocorticoids inhibit mast cells and make capillaries less permeable. Inflammation becomes less likely. When it does occur, the reduced permeability of the capillaries slows the entry of fibrinogen, complement proteins, and cellular defenders into tissues.
- *Reduction in the Abundance and Activity of Phagocytes in Peripheral Tissues.* This reduction further impairs innate defense mechanisms. It also interferes with the processing and presentation of antigens to lymphocytes.
- *Inhibition of Interleukin Secretion.* A reduction in interleukin production depresses the response of lymphocytes, even to antigens bound to MHC proteins.

The mechanisms that bring about these changes are still under investigation.

Immune Disorders

Because the immune response is so complex, many opportunities exist for things to go wrong. A variety of clinical conditions result from disorders of the immune function. A common class of immune disorders is *allergies*, also called *hypersensitivities*. *Autoimmune disorders* develop when the immune response inappropriately targets normal body cells and tissues. In an *immunodeficiency disease*, either the immune system fails to develop normally or the immune response is blocked in some way. Autoimmune disorders and immunodeficiency diseases are rare—clear evidence of the effectiveness of the immune system's control mechanisms.

Hypersensitivities

Hypersensitivities, commonly called allergies, are excessive immune responses to antigens. The sudden increase in cellular activity or antibody level (titer) can have several unpleasant side effects. For example, neutrophils or cytotoxic T cells may destroy normal cells while they are attacking an antigen. Or the

antigen–antibody complex may trigger massive inflammation. Antigens that set off allergic reactions are often called **allergens**.

Four types of hypersensitivities exist. These four classification categories include *immediate hypersensitivity* (type I), *cytotoxic reactions* (type II), *immune complex disorders* (type III), and *delayed hypersensitivity* (type IV). In Chapter 19 we discussed one example of a cytotoxic (type II) reaction: the cross-reaction that follows the transfusion of an incompatible blood type. Here we focus on immediate hypersensitivity (type I). It is probably the most common type of allergy.

Immediate hypersensitivity is a rapid and especially severe response to an antigen. One form, *allergic rhinitis*, includes hay fever and environmental allergies. This form may affect 15% of the U.S. population. Sensitization to an allergen during the initial exposure leads to the production of large quantities of IgE. Genes may determine a person's tendency to produce IgE in response to allergens.

Due to the lag time needed to activate B cells, produce plasma cells, and synthesize antibodies, the first exposure to an allergen does not produce signs and symptoms. Instead, it sets the stage for the next encounter. After sensitization, the IgE molecules become attached to basophils and mast cells throughout the body. When the individual meets the same allergen again, the bound antibodies stimulate these cells to release histamine, heparin, several cytokines, prostaglandins, and other chemicals into the surrounding tissues. This results in a sudden, massive inflammation of the affected tissues.

The cytokines and other mast cell secretions draw basophils, eosinophils, T cells, and macrophages into the area. These cells release their own chemicals, extending and intensifying the responses initiated by mast cells. The severity of the allergic reaction depends on the individual's sensitivity and on the location involved. If allergen exposure occurs at the body surface, the response may be restricted to that area. If the allergen enters the bloodstream, the response could be lethal.

In **anaphylaxis** (an-uh-fuh-LAK-sis; *ana-*, again + *phylaxis*, protection), a circulating allergen affects mast cells throughout the body (**Figure 22–29**). In drug reactions, such as allergies to penicillin, IgE antibodies are produced in response to a hapten (partial antigen) bound to a larger molecule that is widely distributed within the body because the combination acts as an allergen. A wide range of signs and symptoms can develop within minutes. Changes in capillary permeabilities produce swelling and edema in the dermis, and raised welts, or *hives*, appear on the skin. Smooth muscles along the respiratory passageways contract, and the narrowed passages make breathing extremely difficult. In severe cases, an extensive peripheral vasodilation occurs, producing a drop in blood pressure that can lead to a circulatory collapse. This response is **anaphylactic shock**.

The prompt administration of drugs that block the action of histamine, known as **antihistamines** (an-tē-HIS-ta-mēnz), can prevent many of the signs and symptoms of immediate

Figure 22–29 The Mechanism of Anaphylaxis.

hypersensitivity. *Benadryl* (*diphenhydramine hydrochloride*) is a popular antihistamine that is available over the counter. Severe anaphylaxis is treated with injections of antihistamines, corticosteroids, and epinephrine.

Autoimmune Disorders

Autoimmune disorders affect an estimated five percent of adults in North America and Europe. In previous chapters we have cited many examples of the effects of autoimmune disorders on the function of major systems.

The immune system usually recognizes, yet ignores, antigens normally found in the body—self-antigens. When

the recognition system does not work correctly, however, activated B cells make antibodies against other body cells and tissues. These “misguided” antibodies are called **autoantibodies**. The trigger may be a reduction in suppressor T cell activity, the excessive stimulation of helper T cells, tissue damage that releases large quantities of antigenic fragments, haptens bound to compounds normally ignored, viral or bacterial toxins, or a combination of factors.

The resulting condition depends on the antigen that the autoantibodies attack. For example:

- The inflammation of *thyroiditis* is due to autoantibodies against thyroglobulin.
- *Rheumatoid arthritis* occurs when autoantibodies form immune complexes in connective tissues around the joints.
- Type 1 diabetes develops when autoantibodies attack cells in the pancreatic islets.

Many autoimmune disorders appear to be cases of mistaken identity. For example, proteins associated with the measles, Epstein–Barr, influenza, and other viruses contain amino acid sequences that are similar to those of myelin proteins. As a result, antibodies that target these viruses may also attack myelin sheaths. This accounts for the neurological complications that sometimes follow a vaccination or a viral infection. It also may be responsible for *multiple sclerosis*.

For unknown reasons, the risk of autoimmune problems increases if an individual has an unusual type of MHC protein. At least 50 clinical conditions have been linked to specific variations in MHC structure.

Immunodeficiency Diseases

Immunodeficiency diseases result from (1) problems with the embryonic development of lymphoid organs and tissues; (2) an infection with a virus, such as HIV, that depresses immune function; or (3) treatment with, or exposure to, immunosuppressive agents, such as radiation or drugs.

Individuals born with **severe combined immunodeficiency disease (SCID)** fail to develop either cell-mediated or antibody-mediated immunity. Their lymphocyte populations are low, and normal B cells and T cells are absent. Such infants cannot produce an immune response, so even a mild infection can prove fatal. Total isolation offers protection but at great cost—extreme restrictions on lifestyle. Bone marrow transplants from a compatible donor, normally a close relative, have been used to colonize lymphoid tissues with functional lymphocytes. Gene-splicing techniques have led to therapies that can treat at least one form of SCID. **AIDS** is an immunodeficiency disease that results from a viral infection that targets helper T cells.

Immunosuppressive drugs have been used for many years to prevent graft rejection after transplant surgery.

Unfortunately, immunosuppressive drugs can destroy stem cells and lymphocytes and lead to a complete failure of the immune response.

✓ Checkpoint

22. Which kind of immunity protects a developing fetus, and how is that immunity produced?
23. How does increased stress reduce the effectiveness of the immune response?
24. Define autoimmune disorder.

See the blue Answers tab at the back of the book.

22-8 The immune response diminishes as we age

Learning Outcome Describe the effects of aging on the lymphatic system and the immune response.

As we age, the immune system becomes less effective at combating disease. T cells become less responsive to antigens, so fewer cytotoxic T cells respond to an infection. This effect may be due to the gradual decrease in the size of functional tissue and secretory abilities of the thymus and to lower circulating levels of thymic hormones. Because the number of helper T cells is also reduced, B cells are less responsive, so antibody levels do not rise as quickly after antigen exposure. The net result is an increased susceptibility to viral and bacterial infections. For this reason, vaccinations for acute viral diseases such as the flu (influenza) and for pneumococcal pneumonia are strongly recommended for older individuals. The increased incidence of cancer in older people reflects the fact that immune surveillance diminishes, so tumor cells are not eliminated as effectively.

✓ Checkpoint

25. Why are older people more susceptible to viral and bacterial infections?
26. What may account for the increased incidence of cancer among older people?

See the blue Answers tab at the back of the book.

22-9 The nervous and endocrine systems influence the immune response

Learning Outcome Give examples of interactions between the lymphatic system and other organ systems we have studied so far and explain how the nervous and endocrine systems influence the immune response.

Build Your Knowledge **Figure 22-30** summarizes the interactions between the lymphatic system and other body systems we have studied so far. Interactions among elements of the immune response and the nervous and endocrine systems are now the focus of intense research. For example:

- The thymus secretes oxytocin, ADH, and endorphins as well as thymic hormones. The effects on the CNS are not known, but removal of the thymus lowers brain endorphin levels.
- Both thymic hormones and cytokines help establish the normal levels of CRH and TRH produced by the hypothalamus.
- Other thymic hormones affect the anterior lobe of the pituitary gland directly, stimulating the secretion of prolactin and GH.

Conversely, the nervous system can apparently adjust the sensitivity of the immune response:

- The PNS innervates dendritic cells in the lymph nodes, spleen, skin, and other antigen-presenting cells. The nerve endings release neurotransmitters that heighten local immune responses. For this reason, some skin conditions, such as *psoriasis*, worsen when a person is under stress.
- Neuroglia in the CNS produce cytokines that promote an immune response.
- A sudden decline in immune function can occur after even a brief period of emotional distress.

27. What is the relationship between the endocrine system and the lymphatic system?
28. Identify the role of the lymphatic system for all body systems.

See the blue Answers tab at the back of the book.

Build Your Knowledge

Figure 22–30 Integration of the LYMPHATIC system with the other body systems presented so far.

22 Chapter Review

Study Outline

An Introduction to the Lymphatic System and Immunity

1. The cells, tissues, and organs of the **lymphatic system** play a central role in the body's defenses against a variety of **pathogens**, or disease-causing organisms.
2. **Immunity** is the ability to resist infection and disease. All the cells and tissues involved in producing immunity make up a functional **immune system**.

22-1 The vessels, tissues, and organs of the lymphatic system maintain fluid volume and function in body defenses

3. An array of **lymphoid tissues** and **lymphoid organs** is connected to lymphatics. **Primary lymphoid tissues and organs** are sites where lymphocytes are formed and mature. **Secondary lymphoid tissues and organs** are where lymphocytes are activated and cloned. The lymphatic system includes a network of **lymphatic vessels**, or *lymphatics*, that carry **lymph** (interstitial fluid that has entered lymphatic vessels). (Figure 22-1)
4. The lymphatic system produces, maintains, and distributes lymphocytes (which attack invading organisms, abnormal cells, and foreign proteins); it also helps maintain blood volume and eliminate local variations in the composition of interstitial fluid.
5. Lymph flows along a network of lymphatic vessels, the smallest of which are the **lymphatic capillaries**. The lymphatic vessels empty into the **thoracic duct** and the **right lymphatic duct**. (Figures 22-2 to 22-4)
6. **Lymphoid cells** are immune system cells found in lymphoid tissues and the cells that support those tissues. Immune system cells that function in defense include phagocytes and lymphocytes. **Lymphocytes** respond to specific invading pathogens, abnormal body cells, and foreign proteins. The three classes of lymphocytes are T (thymus-dependent) cells, B (bone marrow-derived) cells, and NK (natural killer) cells.
7. **Lymphoid tissues** are connective tissues dominated by lymphocytes. In a **lymphoid nodule**, the lymphocytes are densely packed in an area of areolar tissue. The lymphoid tissue that protects the epithelia of the digestive, respiratory, urinary, and reproductive tracts is called **mucosa-associated lymphoid tissue (MALT)**. (Figure 22-5)
8. Important lymphoid organs include the **lymph nodes**, the **thymus**, and the **spleen**. Lymphoid tissues and organs are distributed in areas that are especially vulnerable to injury or invasion.
9. Lymph nodes are encapsulated masses of lymphoid tissue. The **paracortex** is dominated by T cells; the **cortex** and **medulla** contain B cells. (Figure 22-6)
10. The thymus lies behind the sternum, in the anterior mediastinum. **Epithelial reticular cells** regulate T cell development and function. (Figure 22-7)
11. The adult spleen contains the largest mass of lymphoid tissue in the body. The cellular components form the **pulp**

Media Resources:

- PhysioEx

of the spleen. **Red pulp** contains large numbers of red blood cells, and **white pulp** resembles lymphoid nodules. (Figure 22-8)

22-2 Lymphocytes are important to innate (nonspecific) and adaptive (specific) immunity

12. The lymphatic system is a major component of the body's defenses, which are classified as either **innate (nonspecific) immunity**, which protects without distinguishing one threat from another, or **adaptive (specific) immunity**, which protects against particular threats only. The body's reaction to infectious agents and other abnormal substances is known as the **immune response**.
13. Lymphocytes continuously migrate into and out of the blood through the lymphoid tissues and organs. **Lymphocytopoiesis** (lymphocyte production) involves the red bone marrow, thymus, and peripheral lymphoid tissues. (Figure 22-9)

22-3 Innate defenses respond the same regardless of the invader

14. Innate (nonspecific) defenses prevent the approach, deny the entry, or limit the spread of living or nonliving hazards. (Figure 22-10)
15. Physical barriers include skin, mucous membranes, hair, epithelia, and various secretions of the integumentary and digestive systems.
16. The two types of phagocytes are **microphages** and **macrophages** (cells of the **monocyte-macrophage system**). Microphages are neutrophils and eosinophils in circulating blood.
17. **Phagocytes** leave the bloodstream by *emigration* (migration between adjacent endothelial cells) and exhibit **chemotaxis** (sensitivity and orientation to chemical stimuli).
18. NK cells (also called **large granular lymphocytes**) attack foreign cells, normal cells infected with viruses, and cancer cells. NK cells provide *immune surveillance*.
19. **Immune surveillance** involves constant monitoring of normal tissues by NK cells that are sensitive to abnormal antigens on the surfaces of otherwise normal cells. NK cells kill cancer cells that have **tumor-specific antigens** on their surfaces. (Figure 22-11)
20. **Interferons (IFNs)**—small proteins released by cells infected with viruses—trigger the production of **antiviral proteins**, which interfere with viral replication inside the cell. IFNs are **cytokines**, which are chemical messengers released by tissue cells to coordinate local activities. (Figure 22-12)
21. At least 30 **complement proteins** make up the **complement system**. These proteins interact with each other in cascades to destroy target cell walls, enhance phagocytosis

(opsonization), or stimulate inflammation. The complement system can be activated by the **classical pathway**, the **lectin pathway**, or the **alternative pathway**. (Figure 22–13)

22. Inflammation is a localized tissue response to injury.

(Figure 22–14)

23. Fever is a body temperature greater than 37.2°C (99°F). Fevers can inhibit pathogens and accelerate metabolic processes. **Pyrogens** can reset the body's thermostat and raise the temperature.

22-4 Adaptive (specific) defenses respond to particular threats and are either cell mediated or antibody mediated

24. T cells are responsible for **cell-mediated (cellular) immunity**. The primary types of T cells are **cytotoxic T cells**, **helper T cells**, **regulatory T cells**, and **memory T cells**. (Figure 22–15)

25. B cells provide **antibody-mediated (humoral) immunity**. B cells differentiate into plasma cells, which secrete antibodies. (Figure 22–15)

26. The **immune response** is triggered by the presence of specific antigens and includes cell-mediated and antibody-mediated defenses. (Figure 22–16)

27. Forms of immunity include **innate immunity** (genetically determined and present at birth) or **adaptive immunity** (produced by prior exposure to an antigen or antibody production). The two types of adaptive immunity are **active immunity** (which appears after exposure to an antigen) and **passive immunity** (produced by the transfer of antibodies from another source). (Figure 22–17)

28. Immunity exhibits four general properties: **specificity**, **versatility**, **memory**, and **tolerance**. Specificity occurs because T cells and B cells respond to the molecular structure of specific antigens. Versatility is based on the large diversity of lymphocytes in the body and from variability in the structure of synthesized antibodies. *Memory cells* enable the immune system to “remember” previous target antigens. Tolerance is the ability of the immune system to ignore some antigens, such as those of normal body cells.

22-5 In cell-mediated adaptive immunity, presented antigens activate T cells, which respond by producing cytotoxic and helper T cells

29. Antigen presentation occurs when an antigen–glycoprotein combination appears in the plasma membrane of an antigen-presenting cell (typically of a macrophage or dendritic cell). T cells sensitive to this combination are activated if they contact the membrane of the antigen-presenting cell.

30. All body cells have plasma membrane glycoproteins. The genes controlling their synthesis make up a chromosomal region called the **major histocompatibility complex (MHC)**. The membrane glycoproteins are called **MHC proteins**. **APCs (antigen-presenting cells)** are involved in antigen stimulation.

31. Lymphocytes are not activated by free antigens, but they instead respond to an antigen bound to either a **class I** or a **class II** MHC protein in a process called **antigen recognition**. (Figure 22–18)

32. Class I MHC proteins are in all nucleated body cells. Class II MHC proteins are only in antigen-presenting cells (APCs) and lymphocytes.

33. Whether a T cell responds to antigens held in class I or class II MHC proteins depends on the structure of the T cell plasma membrane. T cell plasma membranes contain proteins called **CD (cluster of differentiation) markers**. **CD3 markers** are present on all T cells. **CD8 markers** are on cytotoxic and regulatory T cells. **CD4 markers** are on all helper T cells.

34. One type of CD8 cell responds quickly to a class I MHC-bound antigen, giving rise to large numbers of cytotoxic T cells and memory T cells. The other type of CD8 cell responds more slowly, giving rise to small numbers of regulatory T cells.

35. Cytotoxic T cells seek out and destroy abnormal and infected cells, using three different methods, including the secretion of **lymphotoxin**. (Figure 22–19)

36. Cell-mediated immunity (cellular immunity) results from the activation of CD8 cells by antigens bound to class I MHCs. When activated, most of these T cells divide to generate cytotoxic T cells and **memory T cells**, which remain in reserve to guard against future such attacks. Regulatory T cells moderate the responses of other T cells and of B cells. (Figures 22–19, 22–22)

37. Helper T cells, or CD4 cells, respond to antigens presented by class II MHC proteins. When activated, helper T cells secrete cytokines that aid in coordinating adaptive and innate defenses and also regulate cell-mediated and antibody-mediated immunity. (Figure 22–20, Spotlight Figure 22–21)

38. Cytokines are chemical messengers coordinated by the immune system. **Interleukins** increase T cell sensitivity to antigens exposed on macrophage membranes; stimulate B cell activity, plasma cell formation, and antibody production; enhance innate defenses; and moderate the immune response. (Spotlight Figure 22–21)

39. Interferons (IFNs) slow the spread of a virus by making the synthesizing cell and its neighbors resistant to viral infections. (Spotlight Figure 22–21)

40. Tumor necrosis factors (TNFs) slow tumor growth and kill tumor cells, and act as pyrogens. (Spotlight Figure 22–21)

41. Several cytokines adjust the activities of phagocytes to coordinate innate and adaptive defenses. (Spotlight Figure 22–21)

42. Colony-stimulating factors (CSFs) are factors produced by active T cells, cells of the monocyte–macrophage group, endothelial cells, and fibroblasts. (Spotlight Figure 22–21)

22-6 In antibody-mediated adaptive immunity, sensitized B cells respond to antigens by producing specific antibodies

43. B cells become **sensitized** when antibody molecules in their plasma membranes bind antigens. The antigens are then displayed on the class II MHC proteins of the B cells, which become activated by helper T cells activated by the same antigen. (Figure 22–23)

44. An active B cell may differentiate into a plasma cell or produce daughter cells that differentiate into plasma cells and memory B cells. Antibodies are produced by plasma cells. (Figure 22–23)

45. A Y-shaped antibody molecule consists of two parallel pairs of polypeptide chains containing *constant* and *variable segments*. (Figure 22–24)

46. The five classes of antibodies (**immunoglobulins, Ig**) in body fluids are (1) **IgG**, responsible for resistance against many

viruses, bacteria, and bacterial toxins; (2) **IgE**, which releases chemicals that accelerate local inflammation; (3) **IgD**, located on the surfaces of B cells; (4) **IgM**, the first type of antibody secreted after an antigen arrives; and (5) **IgA**, found in glandular secretions. (Table 22–1)

47. When antibody molecules bind to an antigen, they form an **antigen–antibody complex**. Effects that appear after binding include **neutralization** (antibody binding that prevents viruses or bacterial toxins from binding to body cells); **precipitation** (formation of an insoluble **immune complex**) and **agglutination** (formation of large complexes); **opsonization** (coating of pathogens with antibodies and complement proteins to enhance phagocytosis); stimulation of inflammation; and prevention of bacterial or viral adhesion. (Figure 22–24)
48. In humoral immunity, the antibodies first produced by plasma cells are the agents of the **primary response**. The maximum antibody level appears during the **secondary response** to antigen exposure. (Figure 22–25)
49. The initial steps in the immune responses to viral and bacterial infections differ. (Figures 22–26 to 22–28; Table 22–2)

22-7 Immunocompetence enables a normal immune response; abnormal responses result in immune disorders

50. **Immunocompetence** is the ability to produce an immune response after exposure to an antigen. A developing fetus acquires passive immunity from antibodies in the maternal bloodstream. After delivery, the infant begins developing

active immunity following exposure to environmental antigens.

51. During periods of stress, interleukin-1 released by active macrophages triggers the release of ACTH by the anterior lobe of the pituitary gland. Glucocorticoids produced by the adrenal cortex moderate the immune response, but their long-term secretion can lower a person's resistance to disease.
52. **Hypersensitivities** (allergies) are inappropriate or excessive immune responses to **allergens** (antigens that trigger allergic reactions). The four types of allergies are *immediate hypersensitivity* (type I), *cytotoxic reactions* (type II), *immune complex disorders* (type III), and *delayed hypersensitivity* (type IV).
53. In **anaphylaxis**, a circulating allergen affects mast cells throughout the body. (Figure 22–29)
54. **Autoimmune disorders** develop when the immune response inappropriately targets normal body cells and tissues.
55. In an **immunodeficiency disease**, either the immune system does not develop normally or the immune response is blocked.

22-8 The immune response diminishes as we age

56. With aging, the immune system becomes less effective at combating disease.

22-9 The nervous and endocrine systems influence the immune response

57. The lymphatic system has extensive interactions with the nervous and endocrine systems. (Figure 22–30).

Review Questions

See the blue Answers tab at the back of the book.

22

LEVEL 1 Reviewing Facts and Terms

1. Identify the structures of the lymphatic system in the following diagram.

- (a) _____
(b) _____
(c) _____
(d) _____
(e) _____
(f) _____
(g) _____
(h) _____
(i) _____
(j) _____
(k) _____
(l) _____
(m) _____
(n) _____
(o) _____
(p) _____
(q) _____

2. Lymph from the body inferior to the diaphragm and from the left side of the body superior to the diaphragm is collected by the (a) left subclavian trunk, (b) right lymphatic duct, (c) left jugular trunk, (d) thoracic duct.

3. Structure(s) belonging to the primary lymphoid tissues and organs is/are the (a) spleen, (b) thymus, (c) tonsils, (d) MALT, (e) lymph nodes.
4. Stellate macrophages are fixed macrophages located (a) in the central nervous system, (b) in the papillary layer of the dermis, (c) in the reticular layer of the dermis, (d) on the luminal surface of liver sinusoids, (e) in the bone marrow.
5. The major histocompatibility complex (MHC) (a) is responsible for forming lymphocytes, (b) produces antibodies in lymph glands, (c) is a group of genes that codes for human leukocyte antigens, (d) is a membrane protein that can recognize foreign antigens, (e) is the antigen found on bacteria that stimulates an immune response.
6. Lymphocytes in the cortex are arranged in clusters that are surrounded by (a) red pulp, (b) white pulp, (c) medullary cords, (d) thymic corpuscles.
7. Lymphocytopoiesis involves all of the following *except* the (a) red bone marrow, (b) thymus, (c) spleen, (d) peripheral lymphoid tissues.
8. Cells involved in suppression of inflammation are (a) eosinophils, (b) basophils, (c) neutrophils, (d) mast cells.
9. Macrophages in the central nervous system are known as (a) stellate cells, (b) microglia, (c) dust cells, (d) mast cells.
10. The most beneficial effect of fever is that it (a) inhibits the spread of some bacteria and viruses, (b) increases the metabolic rate by up to 10%, (c) stimulates the release of pyrogens, (d) achieves a and b.
11. CD4 markers are associated with (a) cytotoxic T cells, (b) regulatory T cells, (c) helper T cells, (d) all of these.
12. List the specific functions of each of the body's primary and secondary lymphoid tissues and organs.
13. Give a function for each of the following: (a) cytotoxic T cells, (b) helper T cells, (c) regulatory T cells, (d) plasma cells, (e) NK cells, (f) stromal cells, (g) epithelial reticular cells, (h) interferons, (i) pyrogens, (j) T cells, (k) B cells, (l) interleukins, (m) tumor necrosis factor, (n) colony-stimulating factors.

860 UNIT 4 Fluids and Transport

14. What are the three classes of lymphocytes, and where does each class originate?
15. What seven defenses, present at birth, provide the body with the defensive capability known as innate (nonspecific) immunity?

LEVEL 2 Reviewing Concepts

16. In inflammation, mast cells are responsible for all of the following *except* **(a)** increasing blood flow, **(b)** activating complement, **(c)** increasing regional temperature, **(d)** decreasing capillary permeability, **(e)** stimulating regional clotting reaction.
17. The absence of which type of lymphocyte would result in the lack of antibody production and secretion? **(a)** NK cells, **(b)** regulatory T cells, **(c)** helper T cells, **(d)** memory T cells, **(e)** plasma cells.
18. Which of the following statements about IgG antibodies is correct? **(a)** They can cross the placenta. **(b)** They are important in allergic responses. **(c)** They circulate as five-antibody starbursts. **(d)** They are found primarily in glandular secretions.
19. Skin tests are used to determine if a person **(a)** has an active infection, **(b)** has been exposed to a particular antigen, **(c)** carries a particular antigen, **(d)** has measles, **(e)** can produce antibodies.
20. Compare and contrast the effects of complement with those of interferon.
21. How does a cytotoxic T cell destroy another cell displaying antigens bound to class I MHC proteins?
22. How does the formation of an antigen–antibody complex cause the elimination of an antigen?
23. Give one example of each type of immunity: innate immunity, naturally acquired active immunity, artificially acquired active immunity, artificially acquired passive immunity, and naturally acquired passive immunity.

24. The coronavirus COVID-19 pandemic in the 21st century led to the need for new and effective vaccines. In an unusually short time, several different types of vaccine were developed. Which ones proved to be the most effective?

LEVEL 3 Critical Thinking and Clinical Applications

25. An investigator at a crime scene discovers some body fluid on the victim's clothing. The investigator carefully takes a sample and sends it to the crime lab for analysis. Based on the analysis of antibodies, could the crime lab determine whether the sample is blood plasma or semen? Explain.
26. Santiago finds out that he has been exposed to measles. He is concerned that he might have contracted the disease and goes to see his physician. The physician takes a blood sample and sends it to a lab for antibody levels (titers). The results show an elevated level and activity of IgM antibodies to rubella (measles) virus but very few IgG antibodies to the virus. Has Santiago contracted the disease?
27. You and your friend see a woman whose left arm appears to be swollen to several times its normal size. Your friend wonders aloud what its cause might be. You say that it may be likely that the woman had a radical mastectomy (the removal of a breast because of cancer). Explain the rationale behind your answer.
28. Kailani's grandfather is diagnosed as having lung cancer. His physician takes biopsies of several lymph nodes from neighboring regions of the body, and Kailani wonders why, since his cancer is in the lungs. What would you tell her?
29. Jared has developed AIDS as a result of sharing contaminated needles with other intravenous drug users. Explain how HIV works and how it has affected Jared's body.

CLINICAL CASE Wrap-up? Isn't There a Vaccine For That?

Vaccinations against infectious diseases are one of the most successful medical advancements in the history of public health. There are several types of vaccines, and each type “teaches” the immune system how to combat the pathogen. For example, a vaccine, containing weakened or dead forms of the infecting microbe (antigen), is administered orally, intranasally, subcutaneously, or intramuscularly. The antigens are not virulent enough to cause the disease, but they provoke the adaptive immune response in the body. This immune response involves B cells that differentiate into plasma cells and make antibodies. It also involves cytotoxic T cells and helper T cells. Regulatory T cells moderate the immune response. Memory T cells and memory B cells help the body remember the antigen so when the protected person is exposed to the real disease, a strong secondary immune response occurs.

Vaccinations are as varied as the diseases they protect against. Some are given as attenuated (greatly weakened) forms of a virus. Others are given as inactivated antigens, made from the cellular debris of killed bacteria. Vaccines can also be messenger

RNA (mRNA) vaccines, toxoid vaccines, or viral vector vaccines. Some vaccines require repeat doses (booster shots) to boost the secondary immune response and keep immune memory alive.

Baby Ruthie is due for her chickenpox vaccination next month, at her 12-month checkup. She is not yet immune to the varicella-zoster virus that causes chickenpox. Disease control in babies not yet immunized depends on the rest of the population being immunized. This is known as “herd” immunity. Ruthie's daycare classmate, Bukenya, had never been vaccinated and was spreading chickenpox to other unprotected children in the class.

1. Is immunity to chickenpox, developed after vaccination, innate immunity, or adaptive immunity? Why?
2. Does baby Ruthie still need her chickenpox vaccine at her 12-month checkup?

See the blue Answers tab at the back of the book.

Related Clinical Terms

adenitis: Inflammation of a gland or lymph node.

allograft: Transplant between compatible recipient and donor of the same species.

anamnesic response: An immune response that is initiated by memory cells.

autograft: A transplant of tissue that is taken from the same person.

Burkitt lymphoma: A malignant cancer of B lymphocytes.

chronic fatigue syndrome: A complicated disorder most often characterized by extreme fatigue that does not improve with rest, and which may worsen with physical activity.

congenital thymic aplasia: Congenital (present at birth) absence of the thymus and parathyroid glands and a deficiency of immunity.

Coombs test: A medical test to detect antibodies or complement in the blood.

dermatomyositis: An autoimmune disease characterized by inflammation of the skin and muscles.

eczema: A genetic inflammatory skin disorder, often with crusts, papules, and leaky eruptions.

Hodgkin lymphoma: A malignant lymphoma affecting lymph nodes and lymph organs.

host versus graft disease: A pathological condition in which cells from the transplanted tissue of a donor initiate an immune response, attacking the cells and tissue of the recipient.

hybridoma: A tissue culture composed of cancer cells fused to lymphocytes to mass produce a specific antibody.

immunology: Branch of biomedicine concerned with the structure and function of the immune system.

infectious mononucleosis: An acute disease caused by the Epstein–Barr virus, producing fever, swelling of the lymph nodes, sore throat, and increased lymphocytes in the bloodstream.

latex allergy: Hypersensitivity to products made of the sap of the rubber plant.

polymyositis: An autoimmune disease characterized by inflammation and atrophy of muscles.

sentinel node: The first lymph node to receive drainage from a tumor. It is used to determine if there is lymphatic metastasis in some types of cancer.

splenomegaly: Enlargement of the spleen.

systemic lupus erythematosus (SLE): An autoimmune disease in which a person's immune system attacks and injures its own organs and tissues in virtually every system of the body.

xenograft: A transplant that is made between two different species.

23

The Respiratory System

Learning Outcomes

These Learning Outcomes correspond by number to this chapter's sections and indicate what you should be able to do after completing the chapter.

- 23-1 ■ Describe the primary functions and organization of the respiratory system and explain how the thin respiratory exchange surfaces are protected from pathogens, debris, and other hazards.
- 23-2 ■ Identify the organs of the upper respiratory system and describe their functions.
- 23-3 ■ Describe the structure of the larynx, discuss its roles in normal breathing and in sound production, and identify the structures of the airways.
- 23-4 ■ Describe the functional anatomy of alveoli.
- 23-5 ■ Describe the superficial anatomy of the lungs and the structure of a pulmonary lobule.
- 23-6 ■ Define and compare the processes of external respiration and internal respiration.
- 23-7 ■ Summarize the physical principles controlling the movement of air into and out of the lungs and describe the actions of the respiratory muscles.
- 23-8 ■ Summarize the physical principles governing the diffusion of gases into and out of the blood and body tissues.
- 23-9 ■ Describe the structure and function of hemoglobin and the transport of oxygen and carbon dioxide in the blood.
- 23-10 ■ List the factors that influence respiration rate and discuss reflex respiratory activity and the brain centers involved in the control of respiration.
- 23-11 ■ Describe age-related changes in the respiratory system.
- 23-12 ■ Give examples of interactions between the respiratory system and other organ systems studied so far.

CLINICAL CASE

No Rest for the Weary

Leonard reads the boss's e-mail for the third time. It's 3 p.m. at the office and he's had trouble concentrating all day. The commute home gets downright dangerous when he catches himself nodding off behind the wheel.

Leonard is 30 pounds overweight. He enjoys snacking on potato chips and a few beers after dinner every night. When he goes to bed, he's exhausted. After a couple of hours his wife nudges him. "Leonard, turn over. You're snoring and keeping me awake!" she says. She lies awake and notices that now he's quiet. Too quiet. Finally, he takes another rattling breath. This is their sleep pattern during

most nights. In the morning, Leonard wakes up with a headache, and neither one of them feels rested.

Leonard's doctor refers him to an ear, nose, and throat (ENT) specialist, also called an *otorhinolaryngologist*, who finds that Leonard has a lengthened soft palate with a prominent uvula. During an overnight sleep study, it's noted that Leonard sleeps on his back. The sleep technician documents several episodes of *apnea* (cessation of breathing). **What is causing Leonard's nighttime drama? To find out, turn to the Case Study Wrap-Up at the end of the chapter.**

An Introduction to the Respiratory System

When we think of the respiratory system, we generally think of breathing—the movement of air into and out of our bodies. However, an efficient respiratory system must do more than merely move air. Cells need energy for maintenance, growth, defense, and division. Our cells obtain that energy mainly through aerobic mechanisms that require oxygen and produce carbon dioxide.

Our cells obtain oxygen and release carbon dioxide when these gases diffuse across the thin respiratory exchange surfaces within the *lungs*. In their warm, moist, protected environment, diffusion takes place between the air and the blood. Circulating blood then carries oxygen from the lungs to peripheral tissues. The blood also transports the carbon dioxide generated by those tissues, delivering it to the lungs. The cardiovascular system is the link between interstitial fluids and the exchange surfaces of the lungs. In this chapter we describe how air enters and exits the lungs by the actions of respiratory muscles, and how oxygen and carbon dioxide are exchanged within the lungs.

23-1 The respiratory system, organized into an upper respiratory system and a lower respiratory system, functions primarily to aid gas exchange

Learning Outcome Describe the primary functions and organization of the respiratory system and explain how the thin respiratory exchange surfaces are protected from pathogens, debris, and other hazards.

The **respiratory system** is composed of structures involved in *ventilation* (providing air) and *gas exchange*. In this section we consider its functions and structures.

Functions of the Respiratory System

The basic functions of the respiratory system include:

- Providing an extensive surface area for gas exchange between air and circulating blood.
- Moving air to and from the exchange surfaces of the lungs along the respiratory passageways.
- Protecting respiratory surfaces from dehydration, temperature changes, and pathogens.
- Producing sounds for speaking, singing, and other forms of communication.
- Detecting odors by olfactory receptors in the superior portions of the nasal cavity.

Organization of the Respiratory System

We can view the respiratory system from either an anatomical or a functional perspective. Anatomically, we can divide the system into an upper respiratory system and a lower respiratory system (**Figure 23–1**). The **upper respiratory system** consists of the *nose*, *nasal cavity*, *paranasal sinuses*, and *pharynx* (throat). The **lower respiratory system** includes the *larynx* (voice box), *trachea* (windpipe), *bronchi* and *bronchioles* (air-conducting passageways), and *alveoli* (air-filled pockets within the lungs).

Tips

To recall the boundary between the upper and lower respiratory systems, remember that the lower respiratory system begins at the larynx.

From a functional perspective, the term **respiratory tract** refers to the passageways that carry air to and from the lung exchange surfaces. The *conducting portion* of the respiratory tract begins at the entrance to the nasal cavity and extends

Figure 23–1 The Structures of the Respiratory System.

through the pharynx, larynx, trachea, bronchi, and larger bronchioles. The *respiratory portion* of the tract includes the narrowest *respiratory bronchioles* and their associated thin-walled **alveoli** (al-VĒ-ō-lī), where all gas exchange between air and blood takes place. The following sections combine these two methods of organization, so keep in mind that the upper respiratory system contains the upper part of the conducting portion, while the lower respiratory system includes the rest of the conducting portion and all the respiratory portion of the respiratory system.

The passageways of the conducting portion of the upper respiratory system filter, warm, and humidify inhaled air, protecting the more delicate surfaces of the lower respiratory system. By the time air reaches the alveoli, most foreign particles and pathogens have been removed, and the humidity and temperature are within acceptable limits. The success of this “conditioning process” is due to the respiratory mucosa.

The Respiratory Mucosa and the Respiratory Defense System

The **respiratory mucosa** (myū-KŌ-suh) lines the conducting portion of the respiratory system. A *mucosa* is a *mucous membrane*, one of the four types of membranes introduced in Chapter 4. This mucosa, which changes along the length of the conducting portion, provides a series of filtration mechanisms that make up the **respiratory defense system**. This defense system reduces the amount of debris or pathogens in inhaled air, which can severely damage the exchange surfaces of the respiratory system.

The Respiratory Mucosa

The respiratory mucosa consists of an epithelium and an underlying layer of areolar tissue. The **lamina propria** (LAM-ih-nuh PRŌ-prē-uh) is the underlying layer of areolar

Figure 23–2 The Respiratory Epithelium of the Nasal Cavity and Conducting Portion of the Respiratory Tract.

What type of epithelium lines the conducting portion of the respiratory tract?

tissue that supports the respiratory epithelium. In the upper respiratory system, trachea, and bronchi, the lamina propria contains mucous glands that discharge their secretions onto the epithelial surface (**Figure 23–2**). The respiratory mucosa of the trachea consists of a mucosa, submucosa, hyaline cartilage, and an adventitial layer. The lamina propria in the conducting

portions of the lower respiratory system contains bundles of smooth muscle cells. In the bronchioles, the smooth muscles form thick bands that encircle or spiral around the lumen.

A pseudostratified ciliated columnar epithelium with numerous mucous cells lines the nasal cavity and the superior portion of the pharynx. The epithelium lining inferior portions of the

pharynx is a stratified squamous epithelium similar to that of the oral cavity. These portions of the pharynx conduct air to the larynx, and they also carry food to the esophagus. The pharyngeal epithelium must therefore protect against abrasion and chemicals.

A pseudostratified ciliated columnar epithelium, comparable to that of the nasal cavity, lines the superior portion of the lower respiratory system. The smaller bronchioles have a cuboidal epithelium with scattered cilia. The exchange surfaces of the alveoli are made up of a simple squamous epithelium. Other, more specialized cells are scattered among the squamous cells, and together they form the *alveolar epithelium*.

The Respiratory Defense System

Along much of the respiratory tract, mucous cells in the epithelium and mucous glands in the lamina propria produce a sticky mucus that bathes exposed surfaces. In the nasal cavity, cilia sweep that mucus and any trapped debris or microorganisms toward the pharynx. There it is swallowed and exposed to the acids and enzymes in the stomach. In the lower respiratory system, the cilia beat toward the pharynx, moving a carpet of mucus in that direction and cleaning the respiratory surfaces. This mechanism is the *mucociliary escalator* (Figure 23–2b,c).

Tips

The mucus in the respiratory mucosa functions like sticky flypaper, but instead of flies, it traps particles and debris from the passing air.

Filtration in the nasal cavity removes virtually all particles larger than about 10 μm from the inhaled air. Smaller particles may be trapped by the mucus of the nasopharynx or by secretions of the pharynx. The rate of mucus production in the nasal cavity and paranasal sinuses speeds up when exposed to unpleasant stimuli, such as noxious vapors, large quantities of dust and debris, allergens, or pathogens. (The familiar signs and symptoms of the “common cold” appear when any of more than 200 types of viruses invades the respiratory epithelium.)

Most particles 1–5 μm in diameter are trapped in the mucus coating the respiratory bronchioles or in the liquid covering the alveolar surfaces. These areas are outside of the mucociliary escalator, but the foreign particles can be engulfed by alveolar macrophages. Most particles smaller than about 0.5 μm remain suspended in the air.

Checkpoint

1. Identify several functions of the respiratory system.
2. List the two anatomical divisions of the respiratory system.
3. What membrane lines the conducting portion of the respiratory tract?

See the blue Answers tab at the back of the book.

Clinical Note Breakdown of the Respiratory Defense System

Large quantities of airborne particles may overload the respiratory defenses and produce a variety of illnesses. For example, irritants in the lining of the conducting passageways can provoke the formation of mucous plugs that block airflow and reduce pulmonary function. Damage to the epithelium in the affected area may allow irritants to enter the surrounding tissues of the lung. The irritants then produce local inflammation. Airborne irritants—such as those in cigarette smoke—are known to promote the development of lung cancer.

Aggressive pathogens can also overwhelm respiratory defenses. **Tuberculosis** (tū-ber-kyū-LŌ-sis), or **TB**, results from an infection of the lungs by the bacterium *Mycobacterium tuberculosis*. Bacteria may colonize the respiratory passageways, the interstitial spaces, the alveoli, or a combination of the three. Signs and symptoms generally include coughing and chest pain, plus fever, night sweats, fatigue, and weight loss. In 1900, TB, then known as *consumption*, was the leading cause of death. An estimated one-third of the world’s population is still infected with TB today.

The respiratory defense system can also fail due to inherited congenital defects. For example, **cystic fibrosis (CF)** affects mucus-producing cells, leading to thick, sticky mucus. The respiratory mucosa produces such a dense, viscous mucus that it cannot be transported by the respiratory defense system. The mucociliary escalator stops working, leading to frequent infections. Mucus also blocks the smaller respiratory passageways, making breathing difficult.

23

23-2 The conducting portion of the upper respiratory system filters, warms, and humidifies air

Learning Outcome Identify the organs of the upper respiratory system and describe their functions.

Recall that the upper respiratory system consists of the nose, nasal cavity, paranasal sinuses, and pharynx (Figure 23–1).

The Nose and Nasal Cavity

The nose not only provides an airway for breathing, it also moistens and warms entering air, filters and cleans inhaled air, serves as a resonating chamber for speech, and houses olfactory receptors. The nasal cavity filters coarse particles from inspired air and is lined with an olfactory mucosa.

The Nose

The **nose** is the primary passageway for air entering the respiratory system. Air normally enters through the paired **nostrils**, or **nares** (NĀ-res), which open into the *nasal cavity* (Figure 23-3a). The **nasal vestibule** is the space contained within the flexible tissues of the nose (Figure 23-3c). The epithelium of the vestibule contains coarse hairs that extend across the nostrils. Large airborne particles, such as sand, sawdust, or even insects, are trapped in these hairs and prevented from entering the nasal cavity.

The Nasal Cavity and Paranasal Sinuses

The **nasal cavity** is divided into left and right sides by the **nasal septum** (Figure 23-3b). The bony portion of the nasal septum is formed by the fusion of the perpendicular plate of the ethmoid and the vomer (see Figure 7-3d). The anterior portion of the nasal septum is formed of hyaline cartilage. This cartilaginous plate supports the **dorsum of nose** (bridge) and the **apex of nose** (tip).

The maxillae, nasal bone, frontal bone, ethmoid, and sphenoid form the lateral and superior walls of the nasal cavity. The mucus produced in the *paranasal sinuses* (sinuses of the frontal bone, sphenoid, ethmoid, and paired maxillae and palatine bones) helps keep the surfaces of the nasal cavity moist and clean (see Figure 7-15). Tears draining through the nasolacrimal ducts do so as well.

The *olfactory region* is the superior portion of the nasal cavity. It includes the areas lined by olfactory epithelium: (1) the inferior surface of the cribriform plate, (2) the superior portion of the nasal septum, and (3) the superior nasal conchae. Receptors in the olfactory epithelium provide the sense of smell. The *superior*, *middle*, and *inferior nasal conchae* project toward the nasal septum from the lateral walls of the nasal cavity. (Some anatomical references use the terms *superior*, *middle*, and *inferior turbinates*.) To pass from the vestibule to the **choanae** (KŌ-an-ē)—openings of the nasal cavity—air flows between adjacent conchae, through the **superior**, **middle**, and **inferior nasal meatuses** (mē-Ā-tus-ez;) (Figure 23-3b). These are narrow grooves rather than open passageways. The incoming air bounces off the superior, middle, and inferior nasal conchal surfaces and churns like a stream flowing over rocks. This turbulence serves several purposes. As the air swirls, small airborne particles are likely to contact the mucus coating the nasal cavity. In addition, the turbulence provides extra time for warming and humidifying incoming air. It also creates circular air currents that bring olfactory stimuli to the olfactory receptors.

The bony **hard palate** is made up of portions of the paired maxillae and palatine bones. The hard palate forms the floor of the nasal cavity and separates it from the oral cavity. A fleshy **soft palate** extends posterior to the hard palate, marking the boundary between the superior *nasopharynx* (nā-zō-FAR-ingks) and the rest of the pharynx. The nasal cavity opens into the nasopharynx at the choanae.

Functions of the Nasal Mucosa

The mucosa of the nasal cavity prepares inhaled air for arrival at the lower respiratory system. Throughout much of the nasal cavity, the lamina propria contains an abundance of arteries, veins, and capillaries that bring nutrients and water to the secretory cells. The lamina propria of the nasal conchae also contains an extensive network of highly expandable veins. This vascularization warms and humidifies the incoming air (and dehumidifies and absorbs the heat of the outgoing air as well). As cool, dry air passes inward over the exposed surfaces of the nasal cavity, the warm epithelium radiates heat, and water in the mucus evaporates. In this way, air moving from the nasal cavity to the lungs is heated nearly to body temperature. It is also nearly saturated with water vapor. These changes protect more delicate respiratory surfaces from chilling or drying out—two potentially disastrous events. Mouth breathing eliminates many of these preliminary events. To avoid alveolar damage, patients breathing on a respirator (mechanical ventilator), which uses a tube to conduct air directly into the trachea, must receive air that has been externally filtered and humidified.

As air moves out of the respiratory tract, it again passes over the epithelium of the nasal cavity. This air is warmer and more humid than the air that enters. It warms the nasal mucosa, and moisture condenses on the epithelial surfaces. In this way, breathing through the nose helps prevent heat loss and water loss.

The extensive vascularization of the nasal cavity and the vulnerable position of the nose make a **nosebleed**, or *epistaxis* (ep-ih-STAK-sis), a fairly common event. (The leading cause of epistaxis in children is nose-picking.) This bleeding generally involves vessels of the mucosa covering the cartilaginous portion of the septum. Possible causes include trauma (such as a punch in the nose), drying, infections, allergies, or clotting disorders. Hypertension can also bring on a nosebleed by rupturing small vessels of the lamina propria.

The Pharynx

The **pharynx** (FAR-ingks), or throat, is a chamber shared by the digestive and respiratory systems. It extends between the choanae and the entrances to the larynx and esophagus. The curving superior and posterior walls of the pharynx are closely bound to the axial skeleton, but the lateral walls are flexible and muscular.

The pharynx is divided into three parts: the *nasopharynx*, the *oropharynx*, and the *laryngopharynx* (Figure 23-3c).

1. The **nasopharynx** is the superior portion of the pharynx. It is connected to the posterior portion of the nasal cavity through the choanae. The soft palate separates it from the oral cavity. The nasopharynx is lined by the same pseudostratified ciliated columnar epithelium as in the nasal cavity. The *pharyngeal tonsil* is located on the posterior

Figure 23-3 The Structures of the Upper Respiratory System.

wall of the nasopharynx. Each auditory tube opens into the nasopharynx at the **pharyngeal opening of auditory tube** on each side of the pharyngeal tonsil.

- The **oropharynx** (*oris*, mouth) extends between the soft palate and the base of the tongue at the level of the hyoid bone. The posterior portion of the oral cavity connects directly with the oropharynx, as does the posterior inferior portion of the nasopharynx. At the boundary between the nasopharynx and the oropharynx, the epithelium changes from pseudostratified columnar epithelium to stratified squamous epithelium.
- The narrow **laryngopharynx** (la-rin-gō-FAR-ingks) is the inferior part of the pharynx. It includes that portion of the pharynx between the hyoid bone and the entrance to the larynx and esophagus. Like the oropharynx, the laryngopharynx is lined with a stratified squamous epithelium that resists abrasion, chemicals, and pathogens.

✓ Checkpoint

- Name the structures of the upper respiratory system.
- Why is the vascularization of the nasal cavity important?
- Why is the lining of the nasopharynx different from that of the oropharynx and the laryngopharynx?

See the blue Answers tab at the back of the book.

23-3 The conducting portion of the lower respiratory system conducts air to the respiratory portion and produces sound

Learning Outcome Describe the structure of the larynx, discuss its roles in normal breathing and in sound production, and identify the structures of the airways.

In this section we cover the conducting portion of the lower respiratory system. These structures include the larynx, which also allows us to produce sound. The trachea is a large air passageway that leads to the bronchi. The bronchi and their branching vessels form the *bronchial tree* that leads air into the lungs.

The Larynx

Inhaled air leaves the pharynx and enters the larynx through the *glottis*, a slit-like opening between the vocal cords. The glottis is the “voice box,” of the larynx. The **larynx** (LAR-ingks) is a cartilaginous tube that surrounds and protects the glottis. The larynx begins at the level of vertebra C₄ or C₅ and ends at the level of vertebra C₆. Essentially a cylinder, the larynx has incomplete cartilages that are stabilized by ligaments and laryngeal muscles (**Figure 23–4**).

Figure 23–4 The Anatomy of the Larynx.

Media resource available for this topic: Practice Anatomy Lab: Respiratory System: Human Cadaver and Anatomical Models

Figure 23-5 The Glottis and Surrounding Structures.

Cartilages and Ligaments of the Larynx

Three large, unpaired cartilages form the larynx: (1) the thyroid cartilage, (2) the cricoid cartilage, and (3) the epiglottis (**Figure 23-4**). Made of hyaline cartilage, the **thyroid cartilage** is the largest laryngeal cartilage. It forms most of the anterior and lateral walls of the larynx. In section, this cartilage is U-shaped, and posteriorly, it is incomplete. Practitioners can easily see and feel the prominent anterior surface of the thyroid cartilage, called the *laryngeal prominence*, or *Adam's apple*. The inferior surface articulates with the cricoid cartilage. The superior surface has ligamentous attachments to the hyoid bone and to the epiglottis and smaller laryngeal cartilages.

Also made of hyaline cartilage, the **cricoid** (KRĪ-koyd) **cartilage** is the most inferior of the laryngeal cartilages. The posterior portion of the cricoid cartilage is expanded to provide support where there is no thyroid cartilage. The cricoid and thyroid cartilages protect the glottis and the entrance to the trachea. Their broad surfaces provide sites for the attachment of important laryngeal muscles and ligaments. Ligaments attach the inferior surface of the cricoid cartilage to the first tracheal cartilage. The superior surface of the cricoid cartilage articulates with the small, paired *arytenoid cartilages*.

Made of elastic cartilage, the shoehorn-shaped **epiglottis** (ep-ih-GLOT-is) projects superior to the glottis and forms a lid over it. It has ligamentous attachments to the anterior and superior borders of the thyroid cartilage and the hyoid bone. During swallowing, the larynx is elevated and the epiglottis folds back over the glottis, preventing both liquids and solid food from entering the respiratory tract.

The larynx also contains three pairs of smaller hyaline cartilages: (1) The **arytenoid** (ar-ih-TĒ-noyd; ladle shaped) **cartilage** articulates with the superior border of the enlarged portion of the cricoid cartilage. (2) The **corniculate** (kor-NIK-yū-lāt; horn

shaped) **cartilage** articulates with the arytenoid cartilage. The corniculate and arytenoid cartilages function in the opening and closing of the glottis and the production of sound. (3) An elongated, curving **cuneiform** (kyū-NĒ-ih-form; wedge-shaped) **cartilage** is within the *ary-epiglottic folds*, tissue that extends between the lateral surface of each arytenoid cartilage and the epiglottis.

Ligaments bind together the various laryngeal cartilages. Additional ligaments attach the thyroid cartilage to the hyoid bone, and the cricoid cartilage to the trachea (cricotracheal ligament) (**Figure 23-4a,b**). The *median cricothyroid ligament* attaches the thyroid cartilage to the cricoid cartilage. Because it has easily identifiable landmarks and is clear of the thyroid gland, this ligament is a common placement site for an emergency tracheostomy, a tracheal incision to bypass an airway obstruction. The **vestibular ligaments** and the **vocal ligaments** extend between the thyroid cartilage and the arytenoid cartilages.

The vestibular and vocal ligaments are covered by folds of laryngeal epithelium. The vestibular ligaments lie within the superior pair of folds, known as the **vestibular folds** (**Figure 23-5**). These folds are fairly inelastic and lie laterally to the glottis. The **glottis** (GLOT-is) is made up of the **vocal folds** and the gap between them, called the *rima glottidis*. The vestibular folds help prevent foreign objects from entering the open glottis. They also protect the more inferior, delicate vocal folds of the glottis.

The vocal folds are highly elastic, because the vocal ligaments consist of elastic tissue. The vocal folds are involved with sound production and are known as the **vocal cords**.

Muscles of the Larynx

The larynx is associated with two sets of muscles: (1) muscles of the neck and pharynx, which position and stabilize

the larynx, and (2) smaller intrinsic muscles that control tension in the glottal vocal folds or that open and close the glottis. These smaller muscles insert on the thyroid, arytenoid, and corniculate cartilages. The opening or closing of the glottis involves rotational movements of the arytenoid cartilages.

When swallowing, both sets of muscles work together to prevent food or drink from entering the glottis. Food is crushed and chewed into a pasty mass, known as a *bolus*, before being swallowed. Muscles of the neck and pharynx then elevate the larynx, bending the epiglottis over the glottis, so that the bolus can glide across the epiglottis rather than falling into the larynx. While this movement is under way, the glottis is closed.

Foods or liquids that touch the vestibular folds or glottis trigger the *coughing reflex*. In a cough, the glottis is kept closed while the chest and abdominal muscles contract, compressing the lungs. When the glottis is opened suddenly, a blast of air from the trachea ejects material that blocks the entrance to the glottis.

Sound Production

How is sound produced? Air passing through the open glottis vibrates its vocal folds and produces sound waves. The pitch of the sound depends on the diameter, length, and tension in the vocal folds. The diameter and length are directly related to the size of the larynx. Tension is controlled by contracting voluntary muscles that reposition the arytenoid cartilages relative to the thyroid cartilage. When the distance increases, the vocal folds tense and the pitch rises. When the distance decreases, the vocal folds relax and the pitch falls.

Children have slender, short vocal folds, so their voices tend to be high pitched. At puberty, the larynx of males enlarges much more than that of females. The vocal cords of an adult male are thicker and longer, so they produce lower tones than those of an adult female.

Sound production at the larynx is called *phonation* (fō-NĀ-shun; *phone*, voice). Phonation is one part of speech production. Clear speech also requires *articulation*, the modification of those sounds by voluntary movements of other structures, such as the tongue, teeth, and lips to form words. In a stringed instrument, such as a guitar, the quality of the sound produced does not depend solely on the nature of the vibrating string. Rather, the entire instrument becomes involved as the walls vibrate and the composite sound echoes within the hollow body. Similar amplification and resonance take place within the pharynx, oral cavity, nasal cavity, and paranasal sinuses. The combination produces the particular and distinctive sound of one's voice. That sound changes with a sinus infection and when the nasal cavity and paranasal sinuses are filled with mucus rather than air.

Tips

Intelligible sound requires both phonation and articulation. Saying “ahhhh” while the tongue is depressed during a tonsil examination is an example of phonation. Saying “hot” adds articulation to that sound.

An infection or inflammation of the larynx is known as *laryngitis* (lar-in-JĪ-tis). It commonly affects the vibrational qualities of the vocal folds. Hoarseness is the most familiar result. Mild cases are temporary and seldom serious. However, bacterial or viral infections of the epiglottis can be very dangerous. The resulting swelling may close the glottis and cause suffocation. This condition, *acute epiglottitis* (ep-ih-glot-TĪ-tis), can develop rapidly after a bacterial infection of the throat. Young children are most likely to be affected.

The Trachea

The **trachea** (TRĀ-kē-uh), or windpipe, is a tough, flexible tube with a diameter of about 2.5 cm (1 in.) and a length of about 11 cm (4.33 in.) (**Figure 23-6**). The trachea begins anterior to vertebra C₆ in a ligamentous attachment to the cricoid cartilage. It ends in the mediastinum, at the level of vertebra T₅, where it branches to form the *right* and *left main bronchi*.

The epithelium of the trachea is continuous with that of the larynx (**Figure 23-2a**). The mucosa of the trachea resembles that of the nasal cavity and nasopharynx. The **submucosa** (sub-mū-KŌ-suh), a thick layer of connective tissue, surrounds the mucosa. The submucosa contains **tracheal glands** whose mucous secretions reach the tracheal lumen through several short ducts. The trachea contains 15–20 **tracheal cartilages** that stiffen the tracheal walls and protect the airway (**Figure 23-6a**). They also prevent it from collapsing or overexpanding as pressure changes in the respiratory system.

Each tracheal cartilage is C-shaped. The continuous portion of the C protects the anterior and lateral surfaces of the trachea. The open ends of the C face posteriorly, toward the esophagus (**Figure 23-6b**). Because these cartilages are not continuous, the posterior tracheal wall can easily distort when swallowing, allowing large masses of food to pass through the esophagus.

An elastic **anular ligament** and a band of smooth muscle, the **trachealis**, connect the ends of each tracheal cartilage (**Figure 23-6b**). Contraction of the trachealis reduces the diameter of the trachea. This narrowing increases the tube's resistance to airflow. The normal diameter of the trachea changes from moment to moment, primarily under the control of the sympathetic division of the ANS. Sympathetic stimulation increases the diameter of the trachea and makes it easier to move large volumes of air along the respiratory passageways.

Figure 23-6 The Anatomy of the Trachea.**a** A diagrammatic anterior view showing the plane of section for part (b)**b** A cross-sectional view of the trachea and esophagus

The lungs are paired organs within the pulmonary cavities of the thorax. The right lung is slightly larger than the left and is divided into three lobes: superior, middle, and inferior. The left lung has two lobes: superior and inferior. Each main bronchus divides to form **lobar bronchi**, which supply the lobes of the lungs. Because the right lung has three lobes, it has three lobar bronchi; because the left lung has two lobes, it has two lobar bronchi. Each lobe is further divided internally into pulmonary lobules.

Figure 23-7a,b depicts the branching pattern of the left main bronchus as it enters the lung. (The number of branches has been reduced for clarity.) In each lung, the lobar bronchi branch to form **segmental bronchi**. The branching pattern differs between the two lungs, but each segmental bronchus ultimately supplies air to a single **bronchopulmonary segment**, a specific region of one lung (**Figure 23-7a**). The right lung has 10 bronchopulmonary segments. During development, the left lung also has 10 segments, but adjacent segmental bronchi fuse, generally reducing the number to 8 or 9.

The walls of the main, lobar, and segmental bronchi contain progressively less cartilage. In the lobar and segmental bronchi, the cartilages form plates arranged around the lumen. These cartilages serve the same structural purpose as the rings of cartilage in the trachea and primary bronchi. As the amount of cartilage decreases, the amount of smooth muscle increases. With less cartilaginous support, the degree of tension in those smooth muscles exerts a proportionally greater effect on bronchial diameter and the resistance to airflow. During a respiratory

The Bronchial Tree

The trachea branches within the mediastinum into the **right main bronchus** and **left main bronchus** (BRONG-kus; plural, *bronchi*). These main bronchi enter the right and left lungs, respectively, and divide to form smaller passageways, the **lobar bronchi** (**Figure 23-6a**). Together, the main and lobar bronchi and their branches form the **bronchial tree**.

The Bronchi

The **carina** (kah-RĪ-nuh) **of trachea** is a ridge that separates the openings of the right and left main bronchi at their junction with the trachea (**Figure 23-6a**). Like the trachea, the main bronchi have C-shaped rings, but the ends of the C overlap. The right main bronchus supplies the right lung, and the left supplies the left lung. The right main bronchus is larger in diameter than the left, and it descends toward the lung at a steeper angle. For these reasons, most foreign objects that enter the trachea find their way into the right bronchus rather than the left.

Figure 23-7 The Bronchi, Lobules, and Alveoli of the Lung.

infection, the bronchi and bronchioles can become inflamed and constricted, increasing resistance. In this condition, called **bronchitis**, the person has difficulty breathing.

The Bronchioles

Each segmental bronchus branches several times within a bronchopulmonary segment, forming many **bronchioles**. These bronchioles then branch into the finest conducting branches, called **terminal bronchioles**. Nearly 6500 terminal bronchioles arise from each segmental bronchus. The lumen of each terminal bronchiole has a diameter of 0.3–0.5 mm.

The walls of bronchioles lack cartilage and are dominated by smooth muscle tissue (**Figure 23-7c**). In functional terms, bronchioles are to the respiratory system what arterioles are to the cardiovascular system. Changes in the diameter of the bronchioles control the resistance to airflow and the distribution of air in the lungs.

The autonomic nervous system controls the luminal diameter of the bronchioles by regulating the smooth muscle layer. Sympathetic activation leads to **bronchodilation**, the enlargement of the luminal diameter of the airway. Parasympathetic stimulation leads to **bronchoconstriction**, a reduction in the luminal diameter of the airway. Tension in the smooth muscles commonly causes the bronchiole mucosa to form a series of folds that limits airflow. Excessive stimulation, as in **asthma** (AZ-muh), can almost completely prevent airflow along the terminal bronchioles. Bronchoconstriction also takes place during allergic reactions such as anaphylaxis, in response to histamine released by activated mast cells and basophils.

23-4 The respiratory portion of the lower respiratory system is where gas exchange occurs

Learning Outcome Describe the functional anatomy of alveoli.

This section considers the structures of the respiratory portion of the lower respiratory system, including the respiratory bronchioles, the alveoli, and the blood-air barrier. The function of these structures is presented in the following sections.

The Respiratory Bronchioles

Each terminal bronchiole delivers air to a single *pulmonary lobule*. Within the lobule, the terminal bronchiole branches to form several **respiratory bronchioles** (**Figure 23-7c**). The respiratory bronchioles are the thinnest branches of the bronchial tree. They deliver air to the gas-exchange surfaces of the lungs.

Before incoming air moves beyond the terminal bronchioles, it has been filtered and humidified. Cuboidal epithelium lines the terminal bronchioles and respiratory bronchioles. There are only scattered cilia and no mucous cells or underlying mucous glands. If particulates or pathogens reach this part of the respiratory tract, there is little to prevent them from damaging the lung's air exchange surfaces.

Alveolar Ducts and Alveoli

Respiratory bronchioles are connected to individual alveoli and to multiple alveoli along regions called **alveolar ducts**. Alveolar ducts end at **alveolar sacs** (*alveolar saccules*), common chambers connected to multiple individual alveoli (**Figure 23-7d** and **Figure 23-8a**). Each lung contains about 150 million alveoli. They give the lungs an open, spongy appearance (**Figure 23-8b**).

Each alveolus is associated with an extensive network of capillaries (**Figure 23-8a**). A network of elastic fibers surrounds the capillaries. These fibers help maintain the relative positions of the alveoli and respiratory bronchioles. When these fibers recoil during exhalation, they reduce the size of the alveoli and help push air out of the lungs.

The alveolar cell layer consists mainly of simple squamous epithelium (**Figure 23-8c**). The squamous epithelial cells, called **pneumocytes type I** (*type I alveolar cells*), are the sites of gas diffusion. Roaming **alveolar macrophages** patrol the epithelial surface. They engulf any particles that have eluded other defenses. Large **pneumocytes type II** (*type II alveolar cells*) are scattered among the squamous cells. Pneumocytes type II produce **surfactant** (sur-FAK-tant), an oily secretion containing phospholipids and proteins. Surfactant plays a key role in keeping the alveoli open.

Surfactant reduces surface tension in the thin layer of water coating the alveolar surface. (Recall that *surface tension* results from the attraction between water molecules at an air–water boundary.) Surface tension not only keeps small objects from entering the water, but also tends to collapse small air bubbles. Without surfactant, surface tension would collapse the alveoli in much the same way. Surfactant interacts with the water molecules, reducing surface tension and preventing the collapse of the alveoli.

If pneumocytes type II produce inadequate amounts of surfactant due to injury or genetic abnormalities, the alveoli collapse after each exhalation. Respiration then becomes difficult. With each breath, the inhalation must be forceful enough

Figure 23–8 Alveolar Organization and the Blood–Air Barrier.

What type of muscle wraps around a respiratory bronchiole and can change the diameter of the airway?

to open the alveoli. A person without enough surfactant is soon exhausted by the effort of inflating and deflating the lungs. This condition is called *respiratory distress syndrome*.

The Blood-Air Barrier

Gas exchange occurs across the three-layered **blood-air barrier** of the alveoli (**Figure 23-8d**). This barrier is made up of (1) the alveolar cell layer, (2) the capillary endothelial layer, and (3) the fused basement membrane between them.

Gas exchange can take place quickly and efficiently at the blood-air barrier because only a very short distance separates alveolar air from blood. Diffusion proceeds very rapidly because the distance is short and both oxygen and carbon dioxide are small, lipid-soluble molecules. In addition, the surface area of the blood-air barrier is very large.

Certain diseases can compromise the function of the blood-air barrier. **Pneumonia** (nū-MŌ-nē-uh) develops from an infection or any particle that causes inflammation within the lung. As inflammation occurs, fluids leak into the alveoli. The respiratory bronchioles swell, narrowing passageways and restricting the passage of air. Respiratory function deteriorates as a result. When bacteria are involved, they are generally types that normally inhabit the mouth and pharynx but have managed to evade the respiratory defenses.

Pneumonia becomes more likely when the respiratory defenses have already been compromised by other factors. Such factors include epithelial damage from smoking and the breakdown of the immune system in AIDS. The respiratory defenses of healthy individuals prevent infection and tissue damage, but the breakdown of those defenses in AIDS can lead to a massive, potentially fatal lung infection. The most common pneumonia that develops in individuals with AIDS results from infection by the fungus *Pneumocystis jiroveci* (formerly known as *Pneumocystis carinii*).

23-5 Enclosed by pleural cavities, the lungs are paired organs made up of multiple lobes

Learning Outcome Describe the superficial anatomy of the lungs and the structure of a pulmonary lobule.

The lungs contain both the bronchial tree and the respiratory portion of the lower respiratory system. The left and right **lungs**

are surrounded by the left and right *pleural cavities*, respectively (**Figure 23-9a**). In this section we look at the anatomy of the lungs, including their blood supply.

Anatomy of the Lungs

Each lung is a blunt cone. Its tip, or apex, points superiorly. The apex on each side extends superior to the first rib. The broad concave inferior portion, or base, of each lung rests on the superior surface of the diaphragm.

Lobes and Surfaces of the Lungs

The lungs have distinct **lobes** that are separated by deep fissures (**Figure 23-9b,c**). The right lung has three lobes—*superior*, *middle*, and *inferior*—separated by the *horizontal* and *oblique fissures*. The left lung has only two lobes—*superior* and *inferior*—separated by the *oblique fissure*. The right lung is broader than the left because most of the heart and great vessels project into the left thoracic cavity. However, the left lung is longer than the right lung because the diaphragm rises on the right side to accommodate the liver.

The heart is located to the left of the midline, so its corresponding impression is larger in the left lung than in the right. In the lateral view, the medial edge of the right lung forms a vertical line, but the medial margin of the left lung is indented at the **cardiac notch** (**Figure 23-9b**). The relationship between the lungs and the heart is shown in **Figure 23-10**.

Along the mediastinal surface of each lung is a groove called the **hilum**. Each main bronchus travels along this groove. The hilum also provides access for entry to pulmonary vessels, nerves, and lymphatics (**Figure 23-9c**). The entire array is firmly anchored in a meshwork of dense connective tissue. This complex is the **root of the lung** (**Figure 23-6a**). The root attaches to the mediastinum and fixes the positions of the major nerves, blood vessels, and lymphatic vessels. The roots of the lungs are anterior to vertebrae T₅ (right) and T₆ (left).

Pulmonary Lobules

The connective tissues of the root of each lung extend into the lung's *parenchyma*, or functional cells. These fibrous partitions, or *trabeculae*, contain elastic fibers, smooth muscles, and lymphatic vessels. The partitions branch repeatedly, dividing the lobes into ever-smaller compartments. The branches of the conducting passageways, pulmonary vessels, and nerves of the lungs follow these trabeculae.

The finest partitions, or **interlobular septa** (*septum*, a wall), divide the lung into **pulmonary lobules** (LOB-yūlz). Branches of the pulmonary arteries, pulmonary veins, and respiratory passageways supply each lobule. The connective tissues of the septa are, in turn, continuous with those of the *visceral pleura*, the serous membrane covering the lungs (**Figure 23-7**).

Figure 23–9 The Gross Anatomy of the Lungs.**b Lateral Views**

The curving anterior and inferior borders follow the contours of the rib cage.

**c Medial Views**

The mediastinal surface, which contains the hilum, has an irregular shape. Both lungs have grooves that mark the position of the great vessels and the heart.

How many lobes does each lung have, and which lung has a cardiac notch?

Blood Supply to the Lungs

Two circuits nourish lung tissue. One supplies the *respiratory* portion of the lungs. The other perfuses the *conducting* portion.

The respiratory exchange surfaces receive blood from arteries of the pulmonary circuit. The pulmonary arteries carry deoxygenated blood. They enter the lungs at the hilum and branch with the bronchi as they approach the lobules. Each lobule receives an arteriole and a venule, and a network of capillaries surrounds each alveolus as part of the blood-air barrier. Oxygen-rich blood from the alveolar capillaries passes through the pulmonary venules and then enters the pulmonary veins, which deliver the blood to the left atrium.

In addition to providing for gas exchange, the endothelial cells of the alveolar capillaries are the primary source of *angiotensin-converting enzyme* (ACE), which converts circulating angiotensin I to angiotensin II. This enzyme plays an important role in regulating blood volume and blood pressure.

The conducting passageways receive oxygen and nutrients from bronchial capillaries supplied by the bronchial arteries, which branch from the thoracic aorta. The venous blood from these bronchial capillaries may return to the heart by either the systemic circuit or pulmonary circuit. About one-eighth of the venous blood drains into bronchial veins, passes through the azygos, hemi-azygos, or highest intercostal vein, and enters the superior vena cava. The larger fraction of the venous blood enters anastomoses and drains into the pulmonary veins. This venous blood dilutes the oxygenated alveolar blood within the pulmonary veins.

Blood pressure in the pulmonary circuit is lower than that in the systemic circuit, so pulmonary vessels can easily become blocked by small blood clots, fat masses, or air bubbles in the pulmonary arteries. Because the lungs receive the entire cardiac output, any drifting objects in blood are likely to be trapped in the pulmonary arterial or capillary networks. Very small blood clots occasionally form in the venous system. These are usually trapped in the pulmonary (alveolar) capillary network, where they soon dissolve. Larger emboli are much more dangerous. Blocking a branch of a pulmonary artery stops blood flow to a group of lobules or alveoli. This condition is called a **pulmonary embolism**. If a pulmonary embolism is in place for several hours, the alveoli will permanently collapse. If the blockage occurs in a major pulmonary vessel rather than a minor branch, pulmonary resistance increases. The resistance places extra strain on the heart's right ventricle, which may be unable to maintain cardiac output, and congestive heart failure can result.

Pleural Cavities and Pleural Membranes

The thoracic cavity has the shape of a broad cone. Its walls are the rib cage, and the muscular diaphragm forms its floor. The two **pleural cavities** are separated by the mediastinum (**Figure 23–10**). Each lung is surrounded by a single pleural cavity, which is lined by a serous membrane called the **pleura** (PLOOR-uh; plural, *pleurae*). The pleura consists of two layers: the parietal pleura and the visceral pleura. The **parietal pleura** covers the inner surface of the thoracic wall and extends over

Figure 23–10 The Relationship between the Lungs and Heart. This transverse section was taken at the level of the cardiac notch.

the diaphragm and mediastinum. The **visceral pleura** covers the outer surfaces of the lungs, extending into the fissures between the lobes. Each pleural cavity represents a potential space rather than an open chamber, because the parietal and visceral pleurae are usually in close contact.

Both pleurae secrete a small amount of **pleural fluid**, a moist, slippery coating. This lubricating fluid reduces friction between the parietal and visceral surfaces during breathing. Samples of pleural fluid, obtained through a long needle inserted between the ribs, are sometimes needed for diagnostic purposes. This sampling procedure is called *thoracentesis* (thōr-a-sen-TĒ-sis; *thora-*, thoracic + *centesis*, puncture). The extracted fluid is examined for bacteria, blood cells, or other abnormal components.

In some diseases, the normal coating of pleural fluid does not prevent friction between the pleural surfaces. The result is pain and pleural inflammation, a condition called *pleurisy*. When pleurisy develops, pleural fluid secretion may be excessive, or the inflamed pleurae may adhere to one another, limiting movement. In either case, breathing becomes difficult, and prompt medical attention is required.

23-6 External respiration and internal respiration allow gas exchange within the body

Learning Outcome Define and compare the processes of external respiration and internal respiration.

The general term **respiration** includes two integrated processes: *external respiration* and *internal respiration*. The definitions of these terms vary among references. In our discussion, **external respiration** includes all the processes involved in the exchange of oxygen and carbon dioxide between the body's interstitial fluids and the external environment. The purpose of external respiration—and the primary function of the respiratory system—is to meet the respiratory demands of cells. **Internal respiration** is the absorption of oxygen and the release of carbon dioxide by those cells. We consider the biochemical pathways responsible for oxygen consumption and for the generation of carbon dioxide by mitochondria—pathways known collectively as *cellular respiration*—in Chapter 25.

Our discussion here focuses on three integrated steps in external respiration (**Figure 23-11**):

- *Pulmonary ventilation* (breathing) physically moves air into and out of the lungs
- *Gas diffusion* across the blood-air barrier between alveolar air spaces and alveolar capillaries, and across capillary walls between blood and other tissues
- *Transport of oxygen and carbon dioxide* between alveolar capillaries and capillary beds in other tissues.

Figure 23-11 An Overview of the Key Steps in Respiration.

Abnormalities affecting any of the steps involved in external respiration ultimately affect the concentration of gases in interstitial fluids and thus cellular activities. If the oxygen level decreases, the affected tissues will become starved for oxygen. **Hypoxia**, or a low tissue oxygen level, places severe limits on the metabolic activities of the affected area. For example, the effects of coronary ischemia result from chronic hypoxia affecting cardiac muscle cells. If the oxygen supply is cut off completely, the condition called **anoxia** (an-OK-sē-uh; *an-*, without + *oxy-*, oxygen) results. Anoxia kills cells very quickly. Much of the damage from strokes and heart attacks results from local anoxia.

In the sections that follow, we examine each of the processes involved in external respiration in greater detail.

23-7 Pulmonary ventilation—air exchange between the atmosphere and the lungs—involves muscle actions and volume changes that cause pressure changes

Learning Outcome Summarize the physical principles controlling the movement of air into and out of the lungs and describe the actions of the respiratory muscles.

Pulmonary ventilation (breathing) is the physical movement of air into and out of the respiratory tract. Its primary function is to maintain adequate *alveolar ventilation*—movement of air into and out of the alveoli. Alveolar ventilation prevents the buildup of carbon dioxide in the alveoli. It also ensures a continuous supply of oxygen that keeps pace with absorption by the bloodstream.

An Introduction to Airflow

Some basic physical principles govern the movement of air. One of the most basic is that the weight of Earth's atmosphere, the **atmospheric pressure**, compresses our bodies and everything around us. The role of atmospheric pressure on breathing is discussed next.

Airflow and Pressure Gradients

The presence of atmospheric pressure has several important physiological effects. For example, air moves into and out of the respiratory tract due to pressure gradients, as the air pressure in the lungs cycles between below atmospheric pressure and above atmospheric pressure. In other words, air flows from an area of higher pressure to an area of lower pressure.

The Relationship between Gas Pressure and Volume (Boyle's Law)

The primary differences between liquids and gases reflect the interactions among individual molecules. The molecules in a liquid are in constant motion, but they are held closely together by weak interactions, such as the hydrogen bonding between adjacent water molecules. Yet because the electrons of adjacent atoms tend to repel one another, liquids tend to resist compression. Squeezing a balloon filled with water will change it into a different shape, but the volumes of the two shapes will be the same.

In a gas, such as air, the molecules bounce around as independent objects. At normal atmospheric pressures, gas molecules are much farther apart than the molecules in a liquid. The forces acting between gas molecules are minimal because the molecules are too far apart for weak interactions to take place, so an applied pressure can push them closer together. Consider a sealed container of air at atmospheric pressure. The pressure exerted by the gas inside results from gas molecules bumping into the walls of the container. The greater the number of collisions, the higher the pressure.

The gas pressure within a sealed container can be changed by changing the volume of the container, giving the gas molecules more space or less space to bounce around. Decreasing the volume of the container increases the pressure (**Figure 23-12a**).

Figure 23-12 The Relationship between Gas Pressure and Volume.

Increasing the volume of the container decreases the pressure (**Figure 23–12b**).

For a gas in a closed container and at a constant temperature, pressure (P) is inversely proportional to volume (V). That is, *decreasing the volume of a gas increases its pressure. Increasing the volume of a gas decreases its pressure.* In particular, the relationship between pressure and volume is reciprocal: If the external pressure on a flexible container is doubled, its volume will drop by half, and if the external pressure is reduced by half, the volume of the container will double. This relationship, $P = 1/V$, is called **Boyle's law** because it was first recognized by Robert Boyle in the 1600s.

Overview of Pulmonary Ventilation: Volume Changes and Pressure Gradients

The tendency of air to flow in response to pressure gradients, plus the pressure–volume relationship of Boyle's law, provides the basis for pulmonary ventilation. A single **respiratory cycle** consists of an *inspiration*, or inhalation, and an *expiration*, or exhalation. Inhalation and exhalation involve changes in the volume of the lungs. These volume changes create pressure gradients that move air into or out of the respiratory tract.

Each lung is surrounded by a pleural cavity. The parietal and visceral pleurae are separated by only a thin film of pleural fluid. The two membranes can slide across one another, but they are held together by that fluid film. This principle can be demonstrated by placing a wet glass on a smooth tabletop. The glass can slide easily, but when trying to lift it there will be considerable resistance. As the glass is pulled away from the tabletop, a powerful suction is created. The only way to overcome the resistance is to tilt the glass so that air is pulled between the glass and the table, breaking the fluid bond.

A comparable fluid bond exists between the parietal pleura and the visceral pleura covering the lungs. For this reason, the surface of each lung sticks to the inner wall of the chest and to the superior surface of the diaphragm. Movements of the diaphragm or rib cage that change the volume of the thoracic cavity also change the volume of the lungs (**Spotlight Figure 23–13**):

- The diaphragm forms the floor of the thoracic cavity. The relaxed diaphragm has the shape of a dome that projects superiorly into the thoracic cavity. When the diaphragm contracts, it tenses and moves inferiorly. This movement increases the volume of the thoracic cavity, decreasing the pressure within it. When the diaphragm relaxes, it returns to its original position, and the volume of the thoracic cavity decreases.
- Due to the nature of the articulations between the sternum and ribs and between the ribs and vertebrae, raising the rib cage involves both superior and anterior movements. These movements increase both the depth and width of the thoracic cavity, increasing its volume. Return of the rib cage to its original position reverses the process, decreasing the volume of the thoracic cavity.

At rest just prior to inhalation, pressures inside and outside the thoracic cavity are identical, and no air moves into or out of the lungs (**Spotlight Figure 23–13**). When the thoracic cavity enlarges, the lungs expand to fill the additional space. This increase in volume decreases the pressure inside the lungs. Air then enters the respiratory passageways, because the pressure inside the lungs (P_{inside}) is lower than atmospheric pressure (P_{outside}). Air continues to enter the lungs until their volume stops increasing and the internal pressure is the same as that outside. When the thoracic cavity decreases in volume, pressures increase inside the lungs, forcing air out of the respiratory tract.

Actions of the Respiratory Muscles

The most important muscles involved in breathing are the *diaphragm* and the *external intercostals*. These muscles are the **primary respiratory muscles** and are active during normal breathing at rest. The **accessory respiratory muscles** become active when the depth and frequency of breathing must be greatly increased (**Figure 23–14**).

Muscles Used in Inhalation

Inhalation is an active process. It involves one or more of the following actions:

- Contraction of the diaphragm flattens the floor of the thoracic cavity, increasing its volume and drawing air into the lungs. Contraction of the diaphragm contributes about 75% of the volume of air in the lungs at rest.
- Contraction of the external intercostal muscles assists in inhalation by raising the ribs. This action contributes approximately 25% of the volume of air in the lungs at rest.
- Contraction of accessory muscles, including the sternocleidomastoid, scalenes of the neck, pectoralis minor, and serratus anterior, can assist the external intercostal muscles in elevating the ribs. These muscles increase the speed and amount of rib movement.

Muscles Used in Exhalation

Exhalation is either passive or active, depending on the level of respiratory activity. When exhalation is active, it may involve one or more of the following actions:

- The internal intercostal muscles and transversus thoracis depress the ribs. This action reduces the width and depth of the thoracic cavity.
- The abdominal muscles, including the external and internal oblique, transversus abdominis, and rectus abdominis, can assist the internal intercostal muscles in exhalation by compressing the abdomen. This action forces the diaphragm upward.

Pulmonary ventilation, or breathing, is the movement of air into and out of the respiratory system. It occurs by changing the volume of the lungs. Changes in lung volume take place through the contraction of skeletal muscles. The most important respiratory muscles are the diaphragm and the external intercostal muscles.

AT REST

When the rib cage and diaphragm are at rest, the pressures inside and outside the lungs are equal, and no air movement occurs.

INHALATION

Elevation of the rib cage and contraction of the diaphragm increase the volume of the thoracic cavity. Pressure within the lungs decreases, and air flows in.

Thoracic cavity volume increases

$$P_{\text{outside}} > P_{\text{inside}}$$

EXHALATION

When the rib cage returns to its original position and the diaphragm relaxes, the volume of the thoracic cavity decreases. Pressure within the lungs increases, and air moves out.

Thoracic cavity volume decreases

$$P_{\text{outside}} < P_{\text{inside}}$$

Figure 23–14 Primary and Accessory Respiratory Muscles.

Name the primary muscles of respiration.

Volume Changes in Pulmonary Ventilation

During pulmonary ventilation, we use the respiratory muscles in various combinations, depending on the volume of air that must be moved into or out of the system. We usually classify respiratory movements as *quiet breathing* or *forced breathing* according to the pattern of muscle activity during a single respiratory cycle.

Volume Changes in Quiet Breathing

In **quiet breathing**, or **eupnea** (YŪP-nē-uh; *eu-*, normal + *-pnea*, breath), inhalation involves muscular contractions, but exhalation is a passive process. Inhalation usually involves contracting both the diaphragm and the external intercostal muscles. The relative contributions of these muscles can vary:

- During **diaphragmatic breathing**, or **deep breathing**, contraction of the diaphragm provides the necessary change in thoracic volume. Air is drawn into the lungs as the diaphragm contracts. Air is exhaled passively when the diaphragm relaxes.
- In **costal breathing**, or **shallow breathing**, the thoracic volume changes because the rib cage alters its shape. Inhalation takes place when contractions of the external intercostal muscles raise the ribs and enlarge the thoracic cavity. Exhalation takes place passively when these muscles relax.

During quiet breathing, expansion of the lungs stretches their elastic fibers. In addition, elevation of the rib cage stretches opposing skeletal muscles and elastic fibers in the connective tissues of the body wall. When the muscles of inhalation relax, these elastic components recoil, returning the diaphragm, the rib cage, or both to their original positions. This action is called **elastic rebound**.

We typically use diaphragmatic breathing at minimal levels of activity. As we need increased volumes of air, our inspiratory movements become larger and the contribution of rib cage movement increases. Even when we are at rest, costal breathing can predominate when abdominal pressures, fluids, or masses restrict diaphragmatic movements. For example, pregnant individuals rely more and more on costal breathing as the enlarging uterus pushes the abdominal organs against the diaphragm.

Volume Changes in Forced Breathing

Forced breathing, or **hyperpnea** (hī-PERP-nē-uh), involves active inspiratory and expiratory movements. In forced breathing, our accessory muscles assist with inhalation, and exhalation involves contraction of the internal intercostal muscles.

At an absolute maximum level of forced breathing, our abdominal muscles take part in exhalation. Their contraction compresses the abdominal contents, pushing them up against the diaphragm. This action further reduces the volume of the thoracic cavity.

Pressure Gradients in Pulmonary Ventilation

Let's look more closely at the pressures inside and outside the respiratory tract. We know the pressure outside is made up only of atmospheric pressure, but the pressure inside the lungs has several different components. We use units of millimeters of mercury (mm Hg) to measure these pressures, as we did for blood pressure. Atmospheric pressure is also measured in *atmospheres*. At sea level, 1 atmosphere (atm) of pressure is equivalent to 760 mm Hg.

Intrapulmonary Pressure

The direction of airflow is determined by the relationship between atmospheric pressure and intrapulmonary pressure. **Intrapulmonary** (in-tra-PUL-mo-nār-ē) **pressure**, or **intra-alveolar** (in-tra-al-VĒ-ō-lar) **pressure**, is the pressure inside the respiratory tract, at the alveoli.

When relaxed and breathing quietly, the difference between atmospheric pressure and intrapulmonary pressure is relatively small. During inhalation, the lungs expand, and the intrapulmonary pressure decreases to about 759 mm Hg. Because the intrapulmonary pressure is 1 mm Hg below atmospheric pressure, it is generally reported as -1 mm Hg. During exhalation, the lungs recoil, and intrapulmonary pressure increases to 761 mm Hg, or $+1$ mm Hg (**Figure 23–15a**).

The size of the pressure gradient increases during heavy breathing. When a trained athlete breathes at maximum

Figure 23–15 Pressure and Volume Changes during Inhalation and Exhalation. One sequence of inhalation and exhalation makes up a single respiratory cycle.

capacity, the pressure differentials can reach -30 mm Hg during inhalation and $+100$ mm Hg if the individual is straining with the glottis kept closed. This is one reason to exhale while lifting weights. Exhaling keeps the intrapulmonary pressures and peritoneal pressure from increasing so high that an alveolar rupture or hernia could occur.

Intrapleural Pressure

Intrapleural pressure is the pressure in the pleural cavity, between the parietal and visceral pleurae. Intrapleural pressure averages about -4 mm Hg (Figure 23–15b). During a powerful inhalation, it can reach -18 mm Hg. This pressure is below atmospheric pressure, due to the relationship between the lungs and the body wall.

Earlier, we noted that the lungs are highly elastic. In fact, they would collapse to about five percent of their normal resting volume if their elastic fibers could recoil completely. The elastic fibers cannot recoil much, however. The reason is that they are not strong enough to overcome the fluid bond between the parietal and visceral pleurae. The elastic fibers continuously oppose that fluid bond and pull the lungs away from the chest wall and diaphragm, lowering the intrapleural

pressure slightly. The elastic fibers remain stretched even after a full exhalation. For this reason, intrapleural pressure remains below atmospheric pressure throughout normal cycles of inhalation and exhalation. The cyclical changes in the intrapleural pressure create the *respiratory pump* that assists the venous return to the heart.

Clinical Note Pneumothorax

Air can enter the pleural cavity due to an injury to the chest wall that penetrates the parietal pleura, or a rupture of the alveoli that breaks through the visceral pleura. This condition, called **pneumothorax** (nū-mō-THOR-aks; pneumo-, air), breaks the fluid bond between the pleurae and allows the elastic fibers to recoil, resulting in a “collapsed lung,” or **atelectasis** (at-e-LEK-tuh-sis; *ateles*, incomplete + *ektasis*, extension). The other lung is not affected because it is enclosed by a separate pleura. The treatment for a collapsed lung involves putting a needle into the cavity and drawing out the air. This treatment lowers the intrapleural pressure and reinflates the lung.

Summary of Volume Changes and Pressure Gradients during a Respiratory Cycle

As shown, air is moved into and out of the respiratory system by changing the volume of the lungs. Those changes alter the pressure relationships, producing air movement. The curves in **Figure 23–15a,b** show the intrapulmonary and intrapleural pressures during a single respiratory cycle of an individual at rest. The graph in **Figure 23–15c** plots the *tidal volume*, the amount of air moved into or out of the lungs during a single respiratory cycle.

Tips

Tidal volume floods and ebbs like the ocean tides.

At the start of the respiratory cycle, the intrapulmonary and atmospheric pressures are equal, and no air is moving. Inhalation begins when the thoracic cavity expands, causing a fall of intrapleural pressure. This pressure gradually falls to approximately -6 mm Hg. Over this period, intrapulmonary pressure drops to just under -1 mm Hg. It then begins to rise as air flows into the lungs.

When exhalation begins, intrapleural and intrapulmonary pressures rise rapidly, forcing air out of the lungs. At the end of exhalation, air again stops moving when the difference between intrapulmonary and atmospheric pressures has been eliminated. The amount of air moved into the lungs during inhalation—the tidal volume—equals the amount moved out of the lungs during exhalation.

Physical Factors Affecting Pulmonary Ventilation

Bronchodilation and bronchoconstriction are ways of adjusting the **resistance** to airflow. These actions direct airflow toward or away from specific portions of the respiratory exchange surfaces.

Recall that pneumocytes type II secrete surfactant onto the alveolar surfaces to reduce surface tension. Surface tension is the reason that small air bubbles in water collapse. Without surfactant, alveoli collapse in much the same way. The thin surface layer of surfactant interacts with the water molecules, keeping the alveoli open.

Tips

The term **surfactant** is derived from its purpose as a **surface active agent**.

The **compliance** of the lungs is a measure of their expandability, or how easily the lungs expand in response to applied pressure. The lower the compliance, the greater the force required to fill the lungs. The greater the compliance, the easier it is to fill the lungs. Factors affecting compliance include the following:

- *The Connective Tissue of the Lungs.* The loss of supporting tissues due to alveolar damage, as in *emphysema*, increases

compliance. This loss results in the alveoli increasing beyond their normal size, making the lungs easier to fill.

- *The Level of Surfactant Production.* On exhalation, the collapse of alveoli due to inadequate surfactant, as in respiratory distress syndrome, reduces compliance.
- *The Mobility of the Thoracic Cage.* Arthritis or other skeletal disorders that affect the articulations of the ribs or spinal column also reduce compliance.

At rest, the muscular activity involved in pulmonary ventilation accounts for 3–5% of the resting energy demand. If compliance is reduced, that figure climbs dramatically. An individual may become exhausted simply trying to continue breathing.

Measuring Respiratory Rates and Volumes

The respiratory system is extremely adaptable. Breathing can be slow and quiet one moment, and rapid and deep the next. The respiratory system adapts to meet the oxygen demands of the body by varying both the number of breaths per minute and the amount of air moved per breath. When exercising at peak levels, the amount of air moving into and out of the respiratory tract can be 50 times the amount moved while resting.

Respiratory Rate

The **respiratory rate**, symbolized (f), is the number of breaths taken each minute. The normal respiratory rate of a resting adult ranges from 12 to 18 breaths each minute, roughly one for every four heartbeats. Children breathe more rapidly, at rates of about 18–20 breaths per minute.

Respiratory Volumes

Recall that the **tidal volume**, symbolized **TV**, is the amount of air moved into or out of the lungs during a single respiratory cycle. Let's look at the volumes that make up the tidal volume.

The Respiratory Minute Volume ($\dot{V}$). We can calculate the amount of air moved each minute, symbolized $\dot{V}$, by multiplying the respiratory rate (f) by the tidal volume (TV). The dot over the V indicates that it is a timed volume. This value is called the **respiratory minute volume**. The respiratory rate at rest averages 12 breaths per minute, and the tidal volume at rest averages around 500 mL per breath. On that basis, we calculate the respiratory minute volume as follows:

$$\begin{aligned}\dot{V} &= f \times TV \\ \left(\begin{array}{c} \text{Volume of air moved} \\ \text{each minute} \end{array} \right) &= \left(\begin{array}{c} \text{breaths per} \\ \text{minute} \end{array} \right) \times \left(\begin{array}{c} \text{tidal} \\ \text{volume} \end{array} \right) \\ &= 12 \text{ per minute} \times 500 \text{ mL} \\ &= 6000 \text{ mL per minute} \\ &= 6.0 \text{ liters per minute}\end{aligned}$$

In other words, the respiratory minute volume at rest is approximately 6 liters per minute.

Alveolar Ventilation (V_A). The respiratory minute volume measures pulmonary ventilation. It provides an indication of how much air is moving into and out of the respiratory tract. However, only some of the inhaled air reaches the alveolar exchange surfaces. A typical inhalation pulls about 500 mL of air into the respiratory system. The first 350 mL of inhaled air travels along the conducting passageways and enters the alveolar spaces. The last 150 mL of inhaled air never gets that far. It stays in the conducting passageways and thus does not participate in gas exchange with blood. This “lagging” volume of air in the conducting passages is known as the **anatomic dead space**, denoted V_D . To calculate the anatomic dead space, multiply the tidal volume by 0.3. The example calculation below shows that with a tidal volume of 500 mL, anatomic dead space equals 150 mL.

$$V_D = TV \times 0.3$$

$$V_D = 500 \text{ mL} \times 0.3 = 150 \text{ mL}$$

Alveolar ventilation, symbolized V_A , is the amount of air reaching the alveoli each minute. The alveolar ventilation is less than the respiratory minute volume because some of the air never reaches the alveoli; it instead remains in the dead space of the lungs. We can calculate alveolar ventilation by subtracting the dead space from the tidal volume:

$$V_A = f \times (TV - V_D)$$

$$\left(\begin{array}{c} \text{Alveolar} \\ \text{ventilation} \end{array} \right) = \left(\begin{array}{c} \text{breaths} \\ \text{per minute} \end{array} \right) \times \left(\begin{array}{cc} \text{tidal} & - & \text{anatomic} \\ \text{volume} & & \text{dead space} \end{array} \right)$$

23 At rest, alveolar ventilation rates are approximately 4.2 liters per minute (12 per minute $\times$ 350 mL). However, the gas arriving in the alveoli is significantly different from the surrounding atmosphere. The reason is that inhaled air always mixes with “used” air in the conducting passageways on its way in. The air in alveoli thus contains less oxygen and more carbon dioxide than does atmospheric air.

Relationships among Tidal Volume (TV), ($\dot{V}$), and (V_A).

The respiratory minute volume can be increased by increasing either the tidal volume or the respiratory rate. In other words, one can breathe more deeply or more quickly or both. Under maximum stimulation, the tidal volume can increase to roughly 4800 mL, or 4.8 L. At peak respiratory rates of 40–50 breaths per minute and maximum cycles of inhalation and exhalation, the respiratory minute volume can approach 200 L per minute.

In functional terms, the alveolar ventilation rate is more important than the respiratory minute volume, because it determines the rate of delivery of oxygen to the alveoli. The

respiratory rate and the tidal volume together determine the alveolar ventilation rate:

- For a given respiratory rate, increasing the tidal volume (breathing more deeply) increases the alveolar ventilation rate.
- For a given tidal volume, increasing the respiratory rate (breathing more quickly) increases the alveolar ventilation rate.

The alveolar ventilation rate can change independently of the respiratory minute volume. In our previous example, the respiratory minute volume at rest was 6 liters and the alveolar ventilation rate was 4.2 L/min. If the respiratory rate rises to 20 breaths per minute, but the tidal volume drops to 300 mL, the respiratory minute volume remains the same ($20 \times 300 = 6000$). However, the alveolar ventilation rate decreases to only 3 L/min ($20 \times [300 - 150] = 3000$). For this reason, whenever the demand for oxygen increases, both the tidal volume *and* the respiratory rate must be regulated closely. (We focus on the mechanisms involved in a later section.)

Respiratory Performance and Volume Relationships

Pulmonary function tests monitor several aspects of respiratory function by measuring rates and volumes of air movement. A person exchanges only a small proportion of the air in their lungs during a single quiet respiratory cycle. Tidal volume can be increased by inhaling more vigorously and exhaling more completely.

We can divide the total volume of the lungs into a series of *volumes* and *capacities* (each the sum of various volumes), as indicated in **Figure 23-16**. These measurements are obtained by an instrument called a **spirometer**. Spirometry values are useful in diagnosing problems with pulmonary ventilation. Adult females, on average, have smaller bodies and thus smaller lung volumes than do males. As a result, there are sex-related differences in respiratory volumes and capacities. The table in the figure shows representative values for males and females.

Pulmonary volumes include the following:

- The **tidal volume (TV)** is the amount of air moved into or out of the lungs during a single respiratory cycle. The tidal volume averages about 500 mL in both males and females.
- The **inspiratory reserve volume (IRV)** is the amount of air that can be taken in over and above the tidal volume. On average, the lungs of males are larger than those of females. For this reason, the inspiratory reserve volume in males averages 3300 mL, compared with 1900 mL in females.
- The **expiratory reserve volume (ERV)** is the amount of air that can be voluntarily expelled after completing a normal, quiet respiratory cycle. As an example, with maximum use of the accessory muscles, males can expel an additional 1000 mL of air, on average. Female expiratory reserve volume averages 700 mL.

Figure 23–16 Pulmonary Volumes and Capacities. The red line indicates the volume of air within the lungs during breathing.

The inspiratory capacity is a total of what two pulmonary volumes?

- The **residual volume** is the amount of air that remains in the lungs even after a maximal exhalation—typically about 1200 mL in males and 1100 mL in females. The **minimal volume**, a component of the residual volume, is the amount of air that would remain in the lungs if they were allowed to collapse. The minimal volume ranges from 30 to 120 mL. Unlike other volumes, it cannot be measured in a healthy person. The minimal volume and the residual volume are very different, because the fluid bond between the lungs and the chest wall normally prevents the recoil of the elastic fibers in the lungs. Some air remains in the lungs, even at minimal volume, because the surfactant coating the alveolar surfaces prevents their collapse.

We can calculate respiratory capacities by adding the values of various volumes. Examples include the following:

- The **inspiratory capacity** is the amount of air that can be drawn into the lungs after the completion of a quiet respiratory cycle. The inspiratory capacity is the sum of the tidal volume and the inspiratory reserve volume.
- The **vital capacity** is the maximum amount of air that can be moved into or out of the lungs in a single respiratory cycle. The vital capacity is the sum of the expiratory

reserve volume, the tidal volume, and the inspiratory reserve volume. It averages around 4800 mL in males and 3400 mL in females.

- The **total lung capacity** is the total volume of a person's lungs. It is calculated by adding the vital capacity and the residual volume. The total lung capacity averages around 6000 mL in males and 4200 mL in females.
- The **functional residual capacity (FRC)** is the amount of air remaining in the lungs after the completion of a quiet respiratory cycle. The FRC is the sum of the expiratory reserve volume and the residual volume.

23-8 Gas exchange depends on the partial pressures of gases and the diffusion of gas molecules

Learning Outcome Summarize the physical principles governing the diffusion of gases into and out of the blood and body tissues.

Pulmonary ventilation ensures that alveoli are supplied with oxygen and that the carbon dioxide arriving from the blood-stream is removed. The actual process of gas exchange takes place between blood and alveolar air across the blood-air barrier. To understand these events, let's first consider (1) the *partial pressures* of the gases involved and (2) the diffusion of molecules between a gas and a liquid. Then we can discuss the movement of oxygen and carbon dioxide across the blood-air barrier.

An Introduction to the Diffusion of Gases

Gases are exchanged between the alveolar air and the blood through diffusion, which takes place in response to concentration gradients. As we saw in Chapter 3, the rate of diffusion varies in response to a variety of factors, including the concentration gradient and the temperature. The principles that govern the movement and diffusion of gas molecules, such as those in the atmosphere, are relatively straightforward. These principles, known as *gas laws*, have been understood for some 250 years. Boyle's law, which determines the direction of air movement in pulmonary ventilation, has already been presented. In this section, we consider other gas laws and factors that determine the rate of oxygen and carbon dioxide diffusion across the blood-air barrier.

Partial Pressures (Dalton's Law)

The air we breathe is a mixture of gases. Nitrogen molecules (N_2) are the most abundant, accounting for 78.6% of atmospheric gas molecules. Oxygen molecules (O_2), the second most abundant, make up 20.9% of air. Most of the remaining 0.5% consists of water molecules, with carbon dioxide (CO_2) contributing a mere 0.04%.

Atmospheric pressure, 760 mm Hg, represents the combined effects of collisions involving each type of molecule in air. At any moment, 78.6% of those collisions involve nitrogen molecules, 20.9% oxygen molecules, and so on. Thus, each of the gases contributes to the total pressure in proportion to its relative abundance. This relationship is known as **Dalton's law**.

The **partial pressure** of a gas is the pressure contributed by a single gas in a mixture of gases. The partial pressure is abbreviated by the symbol P or p. A subscript shows the gas in question. For example, the partial pressure of oxygen is abbreviated P_{O_2} .

All the partial pressures added together equal the total pressure exerted by a gas mixture. For the atmosphere, this relationship can be summarized as follows:

$$P_{N_2} + P_{O_2} + P_{H_2O} + P_{CO_2} = 760 \text{ mm Hg}$$

We can easily calculate the partial pressure of each gas because we know the individual percentages of each gas in air. For example, the partial pressure of oxygen, P_{O_2} , is 20.9% of 760 mm Hg, or 159 mm Hg. **Table 23-1** lists the partial pressures and percentages of atmospheric gases in inhaled, alveolar, and exhaled air.

Diffusion between Liquids and Gases (Henry's Law)

Differences in pressure, which move gas molecules from one place to another, also affect the movement of gas molecules into and out of solution. At a given temperature, the amount of a particular gas in solution is directly proportional to the partial pressure of that gas. This principle is known as **Henry's law**.

When a gas under pressure contacts a liquid, the pressure tends to force gas molecules into solution. At a given pressure, the number of dissolved gas molecules rises until an equilibrium is established. At equilibrium, gas molecules diffuse out of the liquid as quickly as they enter it, so the total number of gas molecules in solution remains constant. If the partial pressure increases, more gas molecules go into solution. If the partial pressure decreases, gas molecules come out of solution.

An example of Henry's law involves a can of carbonated soda. The soda was sealed into the can under high pressure of the gas carbon dioxide (CO_2) (**Figure 23-17a**). When the can is opened, the pressure decreases and the gas molecules (CO_2) begin coming out of solution (**Figure 23-17b**). Theoretically, the process will continue until equilibrium develops between the surrounding air and the gas in solution. In this case, equilibrium is reached quickly. This is because the volume of the can is so small, and the volume of the atmosphere so large, that within a half hour or so virtually all the additional carbon dioxide comes out of solution, and a can of "flat" soda remains.

Table 23-1 Partial Pressures (mm Hg) and Normal Gas Concentrations (%) in Air

Source of Sample	Nitrogen (N_2)	Oxygen (O_2)	Carbon Dioxide (CO_2)	Water Vapor (H_2O)
Inhaled air (dry)	597 (78.6%)	159 (20.9%)	0.3 (0.04%)	3.7 (0.5%)
Alveolar air (saturated)	573 (75.4%)	100 (13.2%)	40 (5.2%)	47 (6.2%)
Exhaled air (saturated)	569 (74.8%)	116 (15.3%)	28 (3.7%)	47 (6.2%)

Figure 23–17 Henry's Law and the Relationship between Solubility and Pressure.

Solubility of Gases

The actual *amount* of a gas in solution at a given partial pressure and temperature depends on the solubility of the gas in that particular liquid. In body fluids, carbon dioxide is highly soluble, and oxygen is somewhat less soluble. Nitrogen has very limited solubility. The dissolved gas content is usually reported in milliliters of gas per 100 mL (1 dL) of solution. To observe the differences in relative solubility of these three gases, we can compare the gas content of blood in the pulmonary veins with the partial pressure of each gas in the alveoli. In a pulmonary vein, plasma generally contains 2.62 mL/dL of dissolved CO_2 ($P_{\text{CO}_2} = 40$ mm Hg), 0.29 mL/dL of dissolved O_2 ($P_{\text{O}_2} = 100$ mm Hg), and 1.25 mL/dL of dissolved N_2 ($P_{\text{N}_2} = 573$ mm Hg). Thus, even though the partial pressure of carbon dioxide is less than one-tenth the partial pressure of nitrogen, the plasma contains more than twice as much carbon dioxide as nitrogen in solution.

Diffusion of Gases across the Blood-Air Barrier

Now, as part of our discussion of external respiration, let's consider how differing partial pressures and solubilities determine the direction and rate of gas diffusion in the lungs. This section covers the diffusion of oxygen and carbon dioxide across the blood-air barrier that separates the air within the alveoli from the blood in alveolar capillaries.

The Composition of Alveolar Air

As soon as air enters the respiratory tract, its characteristics begin to change, being warmed, filtered, and humidified. When incoming air reaches the alveoli, it mixes with air remaining in the alveoli from the previous respiratory cycle. For this reason, alveolar air contains more carbon dioxide and less oxygen than does atmospheric air.

The last 150 mL of inhaled air never gets farther than the conducting passageways. It remains in the anatomic dead space of the lungs. During the next exhalation, the departing alveolar air mixes with air in the dead space, producing yet another mixture that differs from both atmospheric and alveolar samples. As mentioned, the differences in composition between atmospheric (inhaled) and alveolar air are given in [Table 23–1](#).

Efficiency of Diffusion at the Blood-Air Barrier

Gas exchange at the blood-air barrier is efficient for the following reasons:

- *The differences in partial pressure across the blood-air barrier are substantial.* This fact is important, because the greater the difference in partial pressure, the faster the rate of gas diffusion. Conversely, if P_{O_2} in alveoli decreases, the rate of oxygen diffusion into blood decreases. For this reason, many people feel light-headed at altitudes of 3000 m or more. The partial pressure of oxygen in their alveoli

+ Clinical Note Decompression Sickness

Decompression sickness is a painful condition that develops when a person is exposed to a sudden drop in atmospheric pressure. This condition is caused by nitrogen's high partial pressure in air. When the pressure drops, nitrogen comes out of solution, forming bubbles like those in a shaken can of soda. The bubbles may form in joint cavities, in the bloodstream, and in cerebrospinal fluid. Individuals with decompression sickness typically curl up from the pain in affected joints. This reaction accounts for the condition's common name: *the bends*.

Decompression sickness most commonly affects scuba divers who return to the surface too quickly after breathing air under greater-than-normal pressure while submerged. It can also develop in airline passengers subjected to sudden loss of cabin pressure.

has dropped so low that the rate of oxygen absorption is significantly reduced.

- *The distances involved in gas exchange are short.* The fusion of capillary and alveolar basement membranes reduces the distance for gas exchange to as little as $0.1\ \mu\text{m}$, with an average of $0.5\ \mu\text{m}$. Inflammation of the lung tissue or a buildup of fluid in alveoli increases the diffusion distance and impairs alveolar gas exchange.
- *The gases are lipid soluble.* Both oxygen and carbon dioxide diffuse readily through the surfactant layer and the alveolar and endothelial plasma membranes.
- *The total surface area is large.* To meet the metabolic requirements of peripheral tissues, the surface area for gas exchange in the lungs must be very large. Estimates of the surface area involved in gas exchange range from $70\ \text{m}^2$ to $140\ \text{m}^2$ ($753\ \text{ft}^2$ to $1506\ \text{ft}^2$), about 35 times the surface area of the body, or slightly bigger than half a tennis court. Damage to alveolar surfaces, which occurs in emphysema, reduces the available surface area and the efficiency of gas transfer.
- *Blood flow and airflow are coordinated to continually deliver oxygen and remove carbon dioxide from alveoli.* This close coordination makes both pulmonary ventilation and pulmonary circulation more efficient. **Ventilation** is the flow of air into and out of the alveoli, while **perfusion** is blood flow to the alveolar capillaries. Ventilation and perfusion are variable depending on lung regions. Blood flow is greatest around alveoli with the highest P_{O_2} values, where oxygen uptake can proceed with maximum efficiency. This matching of alveolar ventilation with alveolar perfusion is called the *ventilation-to-perfusion ratio* (or *V/Q ratio*), the ratio of the amount of air reaching the alveoli to the amount of blood reaching the alveoli. If the normal blood flow is impaired (as it is in *pulmonary embolism*), or if the normal airflow is interrupted (as it is in

various forms of *pulmonary obstruction*), this coordination is lost and respiratory efficiency decreases.

Summary of Gas Exchange

We consider gas exchange as part of the processes of both external and internal respiration. **Figure 23–18** illustrates gas exchange due to the partial pressures of oxygen and carbon dioxide in the pulmonary and systemic circuits.

External Respiration

Blood arriving from the pulmonary arteries has a lower P_{O_2} and a higher P_{CO_2} than does alveolar air (**Figure 23–18a**). Diffusion between the alveolar gas mixture and the alveolar capillaries then increases the P_{O_2} of blood and decreases its P_{CO_2} . By the time the blood enters the pulmonary venules, it has reached equilibrium with the alveolar air. Blood departs the alveoli with a P_{O_2} of about 100 mm Hg and a P_{CO_2} of roughly 40 mm Hg.

+ Clinical Note Blood Gas Analysis

Blood samples can be analyzed to determine their concentrations of dissolved gases. The usual tests include the determination of pH, P_{CO_2} , and P_{O_2} in an arterial blood sample. Such samples provide information about the degree of oxygenation in peripheral tissues. For example, if the arterial P_{CO_2} is very high and the P_{O_2} is very low, tissues are not receiving adequate oxygen. This problem may be solved by giving the patient a gas mixture that has a high P_{O_2} (or even pure oxygen, with a P_{O_2} of 760 mm Hg).

Blood gas measurements also provide information on the efficiency of gas exchange at the lungs. If the arterial P_{O_2} remains low despite the administration of oxygen, or if the P_{CO_2} is very high, pulmonary exchange problems may exist. Such problems may include pulmonary edema, asthma, or pneumonia.

Figure 23–18 A Summary of Respiratory Processes and Partial Pressures in Respiration.

Partial pressure values are in mm Hg.

Be sure to view the
SmartArt
video for this figure.

Diffusion between alveolar air and blood in the alveolar capillaries occurs rapidly. When a person is at rest, a red blood cell moves through an alveolar capillary in about 0.75 second. When a person exercises, the passage takes less than 0.3 second. This amount of time is usually sufficient to reach an equilibrium between the alveolar air and the blood.

Internal Respiration

Oxygenated blood leaves the pulmonary (alveolar) capillaries to return to the heart, to be pumped into the systemic circuit. As this

blood enters the pulmonary veins, it mixes with blood that flowed through capillaries around conducting passageways. Because gas exchange in the lungs occurs only at alveoli, the blood leaving the conducting passageways carries relatively little oxygen. The partial pressure of oxygen in the pulmonary veins therefore drops to about 95 mm Hg. This is the P_{O_2} in the blood that enters the systemic circuit. No further changes in partial pressure occur until the blood reaches the systemic capillaries (**Figure 23–18b**).

Normal interstitial fluid has a P_{O_2} of 40 mm Hg. As a result, oxygen diffuses out of the systemic capillaries until the

capillary partial pressure is the same as that in the adjacent tissues. Inactive peripheral tissues normally have a P_{CO_2} of about 45 mm Hg, whereas blood entering peripheral capillaries normally has a P_{CO_2} of 40 mm Hg. As a result, carbon dioxide diffuses into the blood as oxygen diffuses out (**Figure 23–18b**).

23-9 In gas transport, most oxygen is transported bound to hemoglobin, whereas carbon dioxide is transported in three ways

Learning Outcome Describe the structure and function of hemoglobin and the transport of oxygen and carbon dioxide in the blood.

Oxygen and carbon dioxide have limited solubilities in blood plasma. For example, at the normal P_{O_2} of alveoli, 100 mL of plasma absorbs only about 0.3 mL of oxygen. The limited solubilities of these gases are a problem. The peripheral tissues need more oxygen and generate more carbon dioxide than the plasma alone can absorb and transport.

Red blood cells (RBCs) solve this problem. They remove dissolved O_2 and CO_2 molecules from plasma and bind them (in the case of oxygen) or mostly use them to manufacture soluble compounds (in the case of carbon dioxide). As the reactions in RBCs remove dissolved gases from blood plasma, these gases continue to diffuse into the blood, but never reach equilibrium. These reactions are both temporary and completely reversible. When the oxygen or carbon dioxide concentration in blood plasma is high, RBCs remove the excess molecules. When the plasma concentrations are falling, the RBCs release their stored reserves.

In this section we cover the transport of oxygen by RBCs, as well as the transport of carbon dioxide. CO_2 can be transported in three ways: as carbonic acid, bound to hemoglobin, or dissolved in plasma.

Oxygen Transport

Each 100 mL of blood leaving the alveolar capillaries carries away about 20 mL of oxygen. Only 1.5% (about 0.3 mL) of this amount is oxygen molecules in solution. The rest of the oxygen molecules are bound to *hemoglobin (Hb) molecules*. This section covers how hemoglobin carries oxygen in the blood and the factors that affect this process.

Transport of O_2 on Hemoglobin

The hemoglobin molecule consists of four globular protein subunits, each containing a heme unit. The oxygen molecules bind

to the iron ions in the center of heme units. Thus, each hemoglobin molecule can bind four molecules of oxygen, forming **oxyhemoglobin (HbO_2)**. We can summarize this process as

This reversible reaction allows hemoglobin to pick up oxygen in the lungs and then release it to body tissues elsewhere.

Each red blood cell has approximately 280 million molecules of hemoglobin. With four heme units per hemoglobin molecule, each RBC can potentially carry more than a billion molecules of oxygen!

The percentage of heme units containing bound oxygen at any given moment is called the **hemoglobin saturation**. If all the Hb molecules in the blood are fully loaded with oxygen, saturation is 100%. If, on average, each Hb molecule carries two O_2 molecules, saturation is 50%.

The shape and functional properties of a protein change in response to changes in its environment. Hemoglobin is no exception. Any changes in shape can affect oxygen binding.

Effect of P_{O_2} on Hemoglobin Saturation

Normally, the most important factor affecting hemoglobin saturation is the P_{O_2} of blood. Hemoglobin in RBCs carries most of the oxygen in the bloodstream and releases it in response to changes in the partial pressure of oxygen in the surrounding plasma. If the P_{O_2} increases, hemoglobin binds oxygen. If the P_{O_2} decreases, hemoglobin releases oxygen.

An **oxygen–hemoglobin saturation curve**, or *oxygen–hemoglobin dissociation curve*, is a graph that relates the hemoglobin saturation to the partial pressure of oxygen (**Figure 23–19**).

Figure 23–19 An Oxygen–Hemoglobin Saturation Curve. The saturation characteristics of hemoglobin at various partial pressures of oxygen under normal conditions (body temperature of 37°C and blood pH of 7.4).

The binding and dissociation, or release, of oxygen to hemoglobin is a typical reversible reaction. At equilibrium, oxygen molecules bind to heme at the same rate at which other oxygen molecules are being released. If the P_{O_2} increases, then more oxygen molecules bind to hemoglobin, and fewer are released. Referring to the equation given in the previous section, we say that the reaction shifts to the right. If the P_{O_2} decreases, more oxygen molecules are released from hemoglobin, while fewer oxygen molecules bind. In this case, we say that the reaction shifts to the left.

Notice that the graph of this relationship between P_{O_2} and hemoglobin saturation is a curve rather than a straight line. It is a curve because the shape of the hemoglobin molecule changes slightly each time it binds an oxygen molecule. This change in shape enhances the ability of hemoglobin to bind *another* oxygen molecule. In other words, the binding of the first oxygen molecule makes it easier to bind the second; binding the second promotes binding of the third; and binding the third enhances binding of the fourth.

Because each arriving oxygen molecule makes it easier for hemoglobin to bind the *next* oxygen molecule, the saturation curve takes the form shown in **Figure 23–19**. Once the first oxygen molecule binds to the hemoglobin, the slope rises rapidly until it levels off near 100% saturation. Where the slope is steep, a very small change in plasma P_{O_2} results in a large change in the amount of oxygen bound to Hb or released from HbO_2 . Notice that hemoglobin will be more than 90% saturated if exposed to an alveolar P_{O_2} above 60 mm Hg. Thus, near-normal oxygen transport can continue even when the oxygen content of alveolar air decreases below normal, or $P_{O_2} = 100$ mm Hg. Without this ability, humans could not survive at high altitudes. Conditions that significantly reduce pulmonary ventilation would be immediately fatal.

At normal alveolar pressures ($P_{O_2} = 100$ mm Hg), the hemoglobin saturation is very high (97.5%), but complete saturation does not occur until the P_{O_2} reaches an excessively high level (about 250 mm Hg). In functional terms, the maximum saturation is not as important as the ability of hemoglobin to provide oxygen over the normal P_{O_2} range in body tissues. Over that range—from 100 mm Hg at the alveoli to perhaps 15 mm Hg in active tissues—the saturation drops from 97.5% to less than 20%, and a small change in P_{O_2} makes a big difference in terms of the amount of oxygen bound to hemoglobin.

Note that the relationship between P_{O_2} and hemoglobin saturation remains valid whether the P_{O_2} is rising or falling. If the P_{O_2} increases, the saturation goes up and hemoglobin stores oxygen. If the P_{O_2} decreases, hemoglobin releases oxygen into its surroundings. When oxygenated blood arrives in the peripheral capillaries, the blood P_{O_2} decreases rapidly due to gas exchange with the interstitial fluid. As the P_{O_2} falls, hemoglobin gives up its oxygen.

The relationship between the P_{O_2} and hemoglobin saturation provides a mechanism for automatic regulation of oxygen

delivery. Inactive tissues have little demand for oxygen, and the local P_{O_2} is usually about 40 mm Hg. Under these conditions, hemoglobin does not release much oxygen. As it passes through the capillaries, it goes from 97% saturation ($P_{O_2} = 95$ mm Hg) to 75% saturation ($P_{O_2} = 40$ mm Hg). Because hemoglobin still retains three-quarters of its oxygen, venous blood has a relatively large oxygen reserve. This reserve is important, because it can be mobilized if the tissue oxygen demand increases.

Active tissues use oxygen at an accelerated rate, so the P_{O_2} of active tissues may decrease to 15–20 mm Hg. Hemoglobin passing through these capillaries goes from 97% saturation to about 20% saturation. In practical terms, this means that as blood circulates through peripheral capillaries, active tissues receive 3.5 times as much oxygen as do inactive tissues.

Effect of Other Factors on Hemoglobin Saturation

At least three other factors may affect the oxygen saturation rate of hemoglobin. These factors are (1) blood pH, (2) temperature, and (3) the products of ongoing metabolic activity within RBCs.

Hemoglobin and pH. Hemoglobin helps buffer acids by binding hydrogen ions (H^+). At a given P_{O_2} , hemoglobin releases additional oxygen if the blood pH decreases. The oxygen–hemoglobin saturation curve in **Figure 23–19** was determined in normal blood, with a pH of 7.4 and a temperature of 37°C. In addition to consuming oxygen, active tissues generate acids that lower the pH of the interstitial fluid. When the pH decreases, the shape of hemoglobin molecules changes. As a result of this change, the molecules release their oxygen reserves more readily, so the slope of the hemoglobin saturation curve changes (**Figure 23–20a**). In other words, as pH decreases, the saturation decreases. At a tissue P_{O_2} of 40 mm Hg, for example, **Figure 23–20a** shows that a decrease in pH from 7.4 to 7.2 changes hemoglobin saturation from 75% to 60%. This means that hemoglobin molecules release 20% more oxygen in peripheral tissues at a pH of 7.2 than they do at a pH of 7.4. This effect of pH on the hemoglobin saturation curve is called the **Bohr effect**.

Carbon dioxide is the primary compound responsible for the Bohr effect. When CO_2 diffuses into the blood, it rapidly diffuses into red blood cells. In red blood cells, an enzyme called **carbonic anhydrase** catalyzes the reaction of CO_2 with water molecules:

The product of this enzymatic reaction, H_2CO_3 , is called *carbonic acid* because it dissociates into a hydrogen ion (H^+) and a bicarbonate ion (HCO_3^-). The rate of carbonic acid formation depends on the amount of carbon dioxide in solution, which, as noted earlier, depends on the P_{CO_2} . When the P_{CO_2} rises, the rate of carbonic acid formation accelerates and the reaction proceeds from left to right. The hydrogen ions that are generated diffuse out of the RBCs, and the pH of the plasma decreases. When the P_{CO_2} decreases, hydrogen ions diffuse out

Figure 23–20 The Effects of Blood pH and Temperature on Hemoglobin Saturation.

a Effect of pH. When the blood pH decreases below the normal range, more oxygen is released; the oxygen–hemoglobin saturation curve shifts to the right. When the pH increases, less oxygen is released; the curve shifts to the left.

b Effect of temperature. When the temperature increases, more oxygen is released; the oxygen–hemoglobin saturation curve shifts to the right. When the temperature decreases, the curve shifts to the left.

According to these graphs, more oxygen is released when the pH is (higher or lower) than normal and when temperature is (higher or lower) than normal.

of the plasma and into the RBCs. As a result, the pH of the plasma increases as the reaction proceeds from right to left.

Hemoglobin and Temperature. At a given P_{CO_2} , hemoglobin releases additional oxygen if the temperature of the blood increases. Changes in temperature affect the slope of the hemoglobin saturation curve (Figure 23–20b). As the temperature increases, hemoglobin releases more oxygen. As the temperature decreases, hemoglobin holds oxygen more tightly. Temperature effects are significant only in active tissues that are generating large amounts of heat. For example, active skeletal muscles generate heat, and the heat warms blood that flows through these organs. As the blood warms, the Hb molecules release more oxygen than the active muscle fibers can use.

Hemoglobin and BPG. Red blood cells lack mitochondria. These cells produce ATP only by glycolysis. As a result, lactate is formed, as we saw in Chapter 10. The metabolic pathways involved in glycolysis in an RBC also generate the compound **2,3-bisphosphoglycerate** (biz-fos-fō-GLIS-er-āt), or **BPG**. This compound has a direct effect on oxygen binding and release. For any partial pressure of oxygen, the higher the concentration of BPG, the greater the release of oxygen by Hb molecules. Normal RBCs always contain BPG.

Both BPG synthesis and the Bohr effect improve oxygen delivery when the pH changes: The BPG level rises when the pH decreases, and the Bohr effect appears. The concentration of BPG can be increased by exercise, thyroid hormones, growth hormone, epinephrine, and androgens. When the plasma P_{O_2} level is low for an extended time, red blood cells generate more BPG. These factors improve oxygen delivery to the tissues, because when the BPG level is elevated, hemoglobin releases about 10% more oxygen at a given P_{O_2} than it would do otherwise.

The production of BPG decreases as RBCs age. For this reason, the level of BPG can determine how long a blood bank can store fresh whole blood. When the BPG level gets too low, hemoglobin becomes firmly bound to the available oxygen. The blood is then useless for transfusions because the RBCs will no longer release oxygen to peripheral tissues, even at a disastrously low P_{O_2} .

Transport of O_2 by Fetal Hemoglobin

The RBCs of a developing fetus contain **fetal hemoglobin**. The structure of fetal hemoglobin differs from that of adult hemoglobin, giving it a much higher affinity for oxygen. At the same P_{O_2} , fetal hemoglobin binds more oxygen than does adult hemoglobin (Figure 23–21). This trait is key to transferring oxygen across the placenta.

Figure 23–21 A Functional Comparison of Fetal and Adult Hemoglobin.

A fetus obtains oxygen from the maternal bloodstream. At the placenta, maternal blood has a relatively low P_{O_2} , ranging from 35 to 50 mm Hg. If maternal blood arrives at the placenta with a P_{O_2} of 40 mm Hg, hemoglobin saturation is roughly 75%. The fetal blood arriving at the placenta has a P_{O_2} close to 20 mm Hg. However, because fetal hemoglobin has a higher affinity for oxygen, it is still 58% saturated.

As diffusion takes place between fetal blood and maternal blood, oxygen enters the fetal bloodstream until the P_{O_2} reaches equilibrium at 30 mm Hg. At this P_{O_2} , the maternal hemoglobin is less than 60% saturated, but the fetal hemoglobin is over 80% saturated (Figure 23–21). The steeper slope of the fetal hemoglobin saturation curve means that when fetal RBCs reach

peripheral tissues of the fetus, the Hb molecules release a large amount of oxygen in response to a very small change in P_{O_2} .

Carbon Dioxide Transport

Carbon dioxide is generated by aerobic metabolism in peripheral tissues. Carbon dioxide travels in the bloodstream in three different ways. After entering the blood, a CO_2 molecule (1) is converted to a molecule of carbonic acid, (2) binds to hemoglobin within red blood cells, or (3) dissolves in plasma. All three reactions are completely reversible, allowing carbon dioxide to be picked up from body tissues and then delivered to the alveoli. Next, we consider the events that take place as blood enters peripheral tissues in which the P_{CO_2} is 45 mm Hg.

Transport of CO_2 as Bicarbonate Ions

Roughly 70% of the carbon dioxide absorbed by blood is transported as bicarbonate ions (HCO_3^-). Most of the carbon dioxide that enters the bloodstream diffuses into RBCs. Within the RBCs, carbon dioxide and water are combined and converted to carbonic acid through the activity of the enzyme *carbonic anhydrase* (Figure 23–22). The carbonic acid molecules immediately dissociate into hydrogen ions and bicarbonate ions, as

Figure 23–22 Carbon Dioxide Transport in Blood.

+ Clinical Note Carbon Monoxide Poisoning

The exhaust from automobiles and other petroleum-burning engines, oil lamps, and fuel-fired space heaters contains *carbon monoxide* (CO). Each winter people die from **carbon monoxide poisoning**. Carbon monoxide competes with oxygen molecules for the binding sites on heme units. Unfortunately, the carbon monoxide usually wins the competition. The reason is that at very low partial pressures it has a much stronger affinity for hemoglobin than does oxygen. The bond formed between CO and heme is extremely strong. As a result, the attachment of a CO molecule essentially makes that heme unit inactive for respiratory purposes.

If carbon monoxide molecules make up just 0.1% of inhaled air, enough hemoglobin is affected that human survival becomes impossible without medical assistance. Treatment includes (1) preventing further CO exposure; (2) administering pure oxygen, because at sufficiently high partial pressures, the oxygen molecules gradually replace CO at the hemoglobin molecules; and, if necessary, (3) transfusing compatible red blood cells.

previously described. We can ignore the intermediate steps in this sequence and summarize the reaction as follows:

This reaction is completely reversible. In peripheral capillaries, it proceeds vigorously, tying up large numbers of CO_2 molecules. The reaction continues as carbon dioxide diffuses out of the interstitial fluids.

The hydrogen ions and bicarbonate ions have different fates. Most of the hydrogen ions bind to hemoglobin molecules, forming HbH^+ . The Hb molecules function as pH buffers, tying up the released H^+ before the ions can leave the RBCs and lower the pH of the plasma. The bicarbonate ions move into the plasma with the aid of a countertransport mechanism that exchanges intracellular bicarbonate ions (HCO_3^-) for extracellular chloride ions (Cl^-). This exchange trades one anion for another and does not require ATP. The result is a mass movement of chloride ions into the RBCs, an event known as the **chloride shift**.

Transport of CO_2 on Hemoglobin

About 23% of the carbon dioxide carried by blood is bound to the protein portions of Hb molecules inside RBCs. These CO_2 molecules are attached to exposed amino groups ($-\text{NH}_2$) of the Hb molecules. The resulting compound is called **carbaminohemoglobin** (kar-BAM-ih-nō-hē-mō-glō-bin), HbCO_2 . The formation of this compound decreases oxygen affinity to hemoglobin. We can summarize the reversible reaction as follows:

We can abbreviate this reaction without the amino groups as

23

Transport of CO_2 in Plasma

Plasma becomes saturated with carbon dioxide quite rapidly. Only about 7% of the carbon dioxide absorbed at peripheral capillaries is transported as dissolved gas molecules. RBCs absorb the rest and convert it using carbonic anhydrase or store it as carbaminohemoglobin.

Figure 23-22 summarizes carbon dioxide transport.

Summary of Gas Transport

Figure 23-23 summarizes the transport of oxygen and carbon dioxide in the respiratory and cardiovascular systems. Note that the top part of the figure shows oxygen pickup by hemoglobin in the alveoli and delivery to peripheral tissues. The bottom part of the figure shows the carbon dioxide being picked up in peripheral tissues and delivered to the alveoli. The reactions we have just discussed then proceed in the reverse direction.

Gas transport is a dynamic process. Its responses can be varied to meet changing circumstances. Some of the responses

are automatic and result from the basic chemistry of the transport mechanisms. Other responses require coordinated adjustments in the activities of the cardiovascular and respiratory systems. We consider those levels of control next.

Checkpoint

23. Identify the three ways that carbon dioxide is transported in the bloodstream.
24. During exercise, hemoglobin releases more oxygen to active skeletal muscles than it does when those muscles are at rest. Why?
25. How would blockage of the trachea affect blood pH?

See the blue Answers tab at the back of the book.

23-10 Respiratory centers in the brainstem, along with respiratory reflexes, control respiration

Learning Outcome List the factors that influence respiration rate, and discuss reflex respiratory activity and the brain centers involved in the control of respiration.

Peripheral cells continuously absorb oxygen and generate carbon dioxide. Under normal conditions, the cellular rates of absorption and generation are matched by the capillary rates of delivery and removal. Both rates are identical to those of oxygen absorption and carbon dioxide excretion at the lungs.

If diffusion rates at the peripheral and alveolar capillaries become unbalanced, homeostatic mechanisms intervene to restore equilibrium. Such mechanisms involve (1) local changes in oxygen delivery to peripheral tissues and in the ventilation-to-perfusion ratio in the lungs, and (2) changes in the depth and rate of respiration under the control of the brain's *respiratory centers*. The activities of the respiratory centers are coordinated with changes in cardiovascular function, such as fluctuations in blood pressure and cardiac output.

Local Regulation of Oxygen Delivery and Ventilation-to-Perfusion Ratio

The rate of oxygen delivery in each tissue and the efficiency of oxygen pickup at the lungs are largely regulated at the local level. For example, when a peripheral tissue becomes more active, the interstitial P_{O_2} falls and the P_{CO_2} rises. These changes increase the difference between the partial pressures in the tissues and in the arriving blood. As a result, more oxygen is delivered and more carbon dioxide is carried away. In addition, the rising P_{CO_2} level causes the relaxation of smooth muscles in the walls of arterioles and capillaries in the area, increasing local blood flow.

At the lungs, local factors coordinate (1) *lung perfusion*, or blood flow to the alveoli, with (2) *alveolar ventilation*, or airflow. This local coordination, called the **ventilation-to-perfusion ratio**, or **V/Q ratio**, takes place over a wide range of conditions

Figure 23-23 A Summary of the Primary Gas Transport Mechanisms. Partial pressure values are in mm Hg.

and activity levels. As blood flows toward the alveolar capillaries, it is directed toward lobules with a relatively high P_{O_2} . This movement takes place because alveolar capillaries constrict when the local P_{O_2} is low. (This response is the opposite of what happens in peripheral tissues.)

Also in the lungs, smooth muscles in the walls of bronchioles are sensitive to the P_{CO_2} of the air they contain. When the P_{CO_2} goes up, the bronchioles increase in diameter (bronchodilation). When the P_{CO_2} decreases, the bronchioles constrict (bronchoconstriction). Airflow is therefore directed to lobules with a high P_{CO_2} . These lobules get their carbon dioxide from blood and are actively engaged in gas exchange. The response of the bronchioles to P_{CO_2} is especially important because improvements in airflow to functional alveoli can at least partially compensate for damage to pulmonary lobules.

Local adjustments improve the efficiency of gas transport by directing blood flow to alveoli with low CO_2 levels and increasing

airflow to alveoli with high CO_2 levels. These adjustments in alveolar blood flow and bronchiole diameter take place automatically.

Neural Control of Respiration

When activity levels increase and the demand for oxygen rises, respiratory rates increase under neural control. Neural control of respiration has both involuntary and voluntary components. The brain's involuntary *respiratory centers* set and adjust the respiratory rhythm by regulating the activities of the respiratory muscles.

The voluntary control of respiration reflects activity in the higher centers of the cerebral cortex. This activity affects the output of either the respiratory centers or motor neurons in the spinal cord that control respiratory muscles. These spinal motor neurons are generally controlled by *respiratory reflexes*, but they can also be controlled voluntarily through commands delivered by the corticospinal pathway.

Involuntary Control of the Basic Respiratory Rhythm

The respiratory centers are three pairs of nuclei in the reticular formation of the medulla oblongata and pons. These centers control the respiratory minute volume by adjusting the frequency and depth of pulmonary ventilation. They make these adjustments in response to sensory information arriving from the lungs and other parts of the respiratory tract, as well as from a variety of other sites.

Function of the Respiratory Rhythmicity Centers. The paired **respiratory rhythmicity centers** of the medulla oblongata were introduced in Chapter 14; these centers play a key role in establishing the respiratory rate and rhythm. Each respiratory rhythmicity center can be subdivided into a **dorsal respiratory group (DRG)** and a **ventral respiratory group (VRG)**. The DRG is chiefly concerned with inspiration, whereas the VRG is primarily associated with expiration.

The DRG functions in every respiratory cycle, whether quiet or forced. The DRG's *inspiratory center* contains neurons that control lower motor neurons innervating the external intercostal muscles and the diaphragm.

The VRG functions only during forced breathing. It has an *expiratory center* consisting of neurons that innervate lower motor neurons controlling accessory respiratory muscles involved in active exhalation. Its inspiratory center contains neurons involved in maximal inhalation, such as gasping.

Reciprocal inhibition takes place between the neurons involved with inhalation and exhalation. When the inspiratory neurons are active, the expiratory neurons are inhibited, and vice versa. The pattern of interaction between these groups differs between quiet breathing and forced breathing. During quiet breathing (**Figure 23–24a**):

- Activity in the DRG increases over a period of about 2 seconds, stimulating the inspiratory muscles. Over this period, inhalation takes place.
- After 2 seconds, the DRG neurons become inactive. They remain quiet for the next 3 seconds and allow the inspiratory muscles to relax. Over this period, passive exhalation takes place.

During forced breathing (**Figure 23–24b**):

- Increases in the level of activity in the DRG stimulate neurons of the VRG that activate the accessory muscles involved in inhalation.
- After each inhalation, active exhalation takes place as the neurons of the expiratory center stimulate the appropriate accessory muscles.

The basic pattern of respiration thus reflects a cyclic interaction between the DRG and the VRG. However, the timing of this interaction is highly variable, and current research suggests that respiratory rate and rhythm cannot be attributed to a single area. The nuclei involved in respiratory control form a complex

Figure 23–24 Basic Regulatory Patterns of Respiration.

network that includes (1) the rhythmicity centers, (2) centers in the pons that are modulated by peripheral and higher central inputs, and (3) an area in the ventrolateral medulla, known as the pre-Bötzinger complex (*central pattern generator*), that is essential to all forms of breathing. There are reciprocal pathways between all these nuclei, so deciphering their communication is extremely difficult, especially because the patterns change with different situations. Central nervous system stimulants, such as amphetamines or even caffeine, increase the respiratory rate by facilitating the respiratory centers. These actions are opposed by CNS depressants, such as barbiturates or opiates.

Respiratory control is an area of intense study and our understanding of the interactions and mechanisms remains incomplete. Due to the brainstem locations, it is nearly impossible to study this mechanism in humans, and much of the work has been done in cats and newborn rodents.

Function of the Apneustic and Pneumotaxic Centers. The *apneustic centers* and *pneumotaxic centers* (also called the *pontine respiratory group*) of the pons regulate the depth and rate of respiration in response to sensory stimuli or input from other brain centers. Each apneustic center provides continuous stimulation to the DRG on that side of the brainstem. During quiet breathing, stimulation from the apneustic center helps increase the intensity of inhalation over the next 2 seconds. Under normal conditions, after 2 seconds the apneustic center is inhibited by signals from the pneumotaxic center on that side. During forced breathing, the apneustic centers also respond to sensory input from the vagus nerves regarding the amount of lung inflation.

The pneumotaxic centers inhibit the apneustic centers and promote passive or active exhalation. Centers in the hypothalamus and cerebrum can alter the activity of the pneumotaxic centers, as well as the respiratory rate and depth. However, essentially normal respiratory cycles continue even if the brainstem superior to the pons has been severely damaged.

In some cases, the inhibitory output of the pneumotaxic centers is cut off by a stroke or other damage to the brainstem, or sensory innervation from the lungs is eliminated due to damage to the vagus nerves. In these cases, the person inhales to maximum capacity and maintains that state for 10–20 seconds at a time. Intervening exhalations are brief, and little pulmonary ventilation occurs.

The CNS regions involved with respiratory control are diagrammed in **Spotlight Figure 23–25**. Interactions between the DRG and the VRG establish the basic rate and depth of respiration. The pneumotaxic centers modify that rate: An increase in pneumotaxic output quickens the pace of respiration by shortening the duration of each inhalation. A decrease in pneumotaxic output slows the respiratory rate, but increases the depth of respiration, because the apneustic centers are more active.

Sudden infant death syndrome (SIDS), also known as *crib death*, is the leading cause of death for babies 1–12 months old and kills an estimated 2250 infants each year in the United

States alone. Most crib deaths occur between midnight and 9:00 a.m., in the late fall or winter, and involve infants 2 to 4 months old. Eyewitness accounts indicate that the sleeping infant suddenly stops breathing, turns blue, and relaxes. Genetic factors appear to be involved, but controversy remains as to the relative importance of other factors. The age at the time of death corresponds with a period when the pacemaker complex and respiratory centers are establishing connections with other portions of the brain. It has been suggested that SIDS results from a problem in the interconnection process that disrupts the reflexive respiratory pattern.

Modification of Respiratory Rhythm by Respiratory Reflexes

The activities of the respiratory centers are modified by sensory information from several sources:

- Chemoreceptors sensitive to the P_{CO_2} , pH, or P_{O_2} of the blood or cerebrospinal fluid;
- Baroreceptors in the aortic or carotid sinuses sensitive to changes in blood pressure;
- Stretch receptors that respond to changes in the volume of the lungs (the *Hering–Breuer reflexes*);
- Irritating physical or chemical stimuli in the nasal cavity, larynx, or bronchial tree; and
- Other sensations, including pain, changes in body temperature, and abnormal visceral sensations.

Information from these receptors alters the pattern of respiration. The induced changes have been called *respiratory reflexes*.

Chemoreceptor Reflexes. The respiratory centers are strongly influenced by chemoreceptor inputs from cranial nerves IX and X, and from receptors that monitor the composition of the cerebrospinal fluid (CSF):

- The glossopharyngeal nerves (IX) carry chemoreceptive information from the carotid bodies, adjacent to the carotid sinus. The carotid bodies are stimulated by a decrease in the pH or P_{O_2} of blood. Because changes in P_{CO_2} affect pH, an increase in the P_{CO_2} indirectly stimulates these receptors.
- The vagus nerves (X) monitor chemoreceptors in the aortic bodies, near the aortic arch. These receptors are sensitive to the same stimuli as the carotid bodies. Carotid and aortic body receptors are often called *peripheral chemoreceptors*.
- Chemoreceptors are located on the ventrolateral surface of the medulla oblongata in a region known as the *chemosensitive area*. The neurons in that area respond only to the P_{CO_2} and pH of the CSF. They are often called *central chemoreceptors*.

Respiratory control involves multiple levels of regulation. Most of the regulatory activities occur outside of our awareness.

LEVEL 3

Higher Centers

Higher centers in the cerebral cortex, limbic system, and hypothalamus can alter the activity of the pneumotaxic centers, but essentially normal respiratory cycles continue even if the brainstem superior to the pons has been severely damaged.

LEVEL 2

Apneustic and Pneumotaxic Centers in the Pons

The **apneustic** (ap-NŪ-stik) **centers** and the **pneumotaxic** (nū-mō-TAK-sik) **centers** of the pons are paired nuclei that adjust the output of the respiratory rhythmicity centers.

The pneumotaxic centers inhibit the apneustic centers and promote passive or active exhalation. An increase in pneumotaxic output quickens the pace of respiration by shortening the duration of each inhalation. A decrease in pneumotaxic output slows the respiratory pace but increases the depth of respiration, because the apneustic centers are more active.

The apneustic centers promote inhalation by stimulating the DRG. During forced breathing, the apneustic centers adjust the degree of stimulation in response to sensory information from the vagus nerve (X) concerning the amount of lung inflation.

LEVEL 1

Respiratory Rhythmicity Centers in the Medulla Oblongata

The most basic level of respiratory control involves pacemaker cells in the medulla oblongata. These neurons generate cycles of contraction and relaxation in the diaphragm. The **respiratory rhythmicity centers** set the pace of respiration by adjusting the activities of these pacemakers and coordinating the activities of additional respiratory muscles. Each rhythmicity center can be subdivided into a **dorsal respiratory group (DRG)** and a **ventral respiratory group (VRG)**. The DRG is mainly concerned with inspiration and the VRG is primarily associated with expiration. The DRG modifies its activities in response to input from chemoreceptors and baroreceptors that monitor O_2 , CO_2 , and pH in the blood and CSF, and from stretch receptors that monitor the degree of stretching in the walls of the lungs.

To diaphragm

To external
intercostal
muscles

To accessory
inspiratory
muscles

To accessory
expiratory
muscles

The inspiratory center of the DRG contains neurons that control lower motor neurons innervating the external intercostal muscles and the diaphragm. This center functions in every respiratory cycle.

The VRG has inspiratory and expiratory centers that function only when breathing demands increase and accessory muscles become involved.

Medulla oblongata

Pons

In addition to the centers in the pons, the DRG, and the VRG, the pre-Bötzinger complex in the medulla is essential to all forms of breathing. Its mechanisms are poorly understood.

Respiratory Centers and Reflex Controls

This illustration shows the locations and relationships among the major respiratory centers in the pons and medulla oblongata and other factors important to the reflex control of respiration. Pathways for conscious control over respiratory muscles are not shown.

Chemoreceptors and their effects on cardiovascular function were discussed in Chapters 15 and 21. Stimulation of these chemoreceptors leads to an increase in the rate and depth of respiration. Under normal conditions, a drop in arterial P_{O_2} has little effect on the respiratory centers until the arterial P_{O_2} drops by about 40%, to below 60 mm Hg. If the P_{O_2} of arterial blood drops to 40 mm Hg (the level in peripheral tissues), the respiratory rate increases by only 50–70%. In contrast, a rise of just 10% in the arterial P_{CO_2} causes the respiratory rate to double, even if the P_{O_2} remains completely normal. The carbon dioxide level is therefore responsible for regulating respiratory activity under normal conditions.

Although the receptors monitoring the CO_2 level are more sensitive, oxygen and carbon dioxide receptors work together in a crisis. Carbon dioxide is generated during oxygen consumption, so when the oxygen concentration is falling rapidly, the CO_2 level is usually increasing. This cooperation breaks down only under unusual circumstances. For example, a person can hold their breath longer than normal by taking deep, full breaths beforehand, but the practice is very dangerous. The danger lies in the fact that the increased ability is due not to extra oxygen, but to less carbon dioxide. If the P_{CO_2} is decreased far enough, a person's ability to hold their breath can increase to the point at which they would become unconscious from oxygen starvation in the brain without ever feeling the urge to breathe.

The chemoreceptors are subject to adaptation—a decrease in sensitivity after chronic stimulation—if the P_{O_2} or P_{CO_2} remains abnormal for an extended period. This adaptation can complicate the treatment of chronic respiratory disorders. For example, if the P_{O_2} remains low for an extended period while the P_{CO_2} remains chronically elevated, the chemoreceptors will reset to those values. They will then oppose any attempts to return the partial pressures to the proper range.

Any condition altering the pH of blood or CSF affects respiratory performance because the chemoreceptors monitoring the CO_2 level are also sensitive to pH. The increase in the lactate level after exercise, for example, is accompanied by a decrease in pH that helps stimulate respiratory activity.

Hypercapnia is an increase in the P_{CO_2} of arterial blood. **Figure 23–26a** diagrams the central response to hypercapnia. Stimulation of chemoreceptors in the carotid and aortic bodies triggers this response. It is reinforced by the stimulation of CNS chemoreceptors. Carbon dioxide crosses the blood-brain barrier quite rapidly. For this reason, a rise in arterial P_{CO_2} almost immediately increases the CO_2 level in the CSF, decreasing the pH of the CSF and stimulating the chemoreceptive neurons of the medulla oblongata.

These chemoreceptors stimulate the respiratory centers to increase the rate and depth of respiration. Breathing becomes more rapid, and more air moves into and out of the lungs with each breath. Because more air moves into and out of the

alveoli each minute, alveolar concentrations of carbon dioxide decrease, accelerating the diffusion of carbon dioxide out of alveolar capillaries. In this way, homeostasis is restored.

The most common cause of hypercapnia is hypoventilation. In **hypoventilation**, the respiratory rate remains abnormally low and cannot meet the demands for normal oxygen delivery and carbon dioxide removal. Carbon dioxide then accumulates in the blood.

If the rate and depth of respiration exceed the demands for oxygen delivery and carbon dioxide removal, the condition called **hyperventilation** exists. Hyperventilation gradually leads to **hypocapnia**, an abnormally low P_{CO_2} . If the arterial P_{CO_2} drops below the normal level, chemoreceptor activity decreases and the respiratory rate falls (**Figure 23–26b**). This situation continues until the P_{CO_2} returns to normal and homeostasis is restored.

Baroreceptor Reflexes. The effects of carotid and aortic baroreceptor stimulation on systemic blood pressure were described in Chapter 21. The output from these baroreceptors also affects the respiratory centers. When blood pressure falls, the respiratory rate increases. When blood pressure rises, the respiratory rate decreases. These adjustments result from the stimulation or inhibition of the respiratory centers by sensory fibers in the glossopharyngeal nerves (IX) and vagus nerves (X) nerves.

Hering–Breuer Reflexes. The **Hering–Breuer reflexes** are named after the physiologists who described them in 1865. The sensory information from these reflexes goes to the apneustic centers and the ventral respiratory group. The Hering–Breuer reflexes are *not* involved in normal quiet breathing or in tidal volumes under 1000 mL. There are two such reflexes:

- The **inflation reflex** prevents overexpansion of the lungs during forced breathing. Lung expansion stimulates stretch receptors in the smooth muscle tissue around bronchioles. Sensory fibers from the stretch receptors of each lung reach the respiratory rhythmicity center on the same side by the vagus nerve. As lung volume increases, the dorsal respiratory group is gradually inhibited, and the expiratory center of the VRG is stimulated. Inhalation stops as the lungs near maximum volume. Active exhalation then begins.
- The **deflation reflex** normally functions only during forced exhalation, when both the inspiratory and expiratory centers are active. This reflex inhibits the expiratory centers and stimulates the inspiratory centers when the lungs are deflating. These receptors are distinct from those of the inflation reflex. They are located in the alveolar wall near the alveolar capillary network. The smaller the volume of the lungs, the greater the degree of inhibition. Finally, exhalation stops and inhalation begins.

Figure 23–26 The Chemoreceptor Response to Changes in P_{CO_2} .

Inhibition of medulla oblongata chemoreceptors and respiratory muscles has what effect on respiratory rate, elimination of CO_2 at alveoli, and arterial P_{CO_2} ?

Protective Reflexes. Protective reflexes operate when exposed to toxic vapors, chemical irritants, or mechanical stimulation of the respiratory tract. The receptors involved are located in the epithelium of the respiratory tract. Examples of protective reflexes include sneezing, coughing, and laryngeal spasms.

Sneezing is triggered by an irritation of the nasal cavity wall. **Coughing** is triggered by an irritation of the larynx, trachea, or bronchi. Both reflexes involve **apnea** (AP-nē-uh), a period in which respiration is suspended. A forceful expulsion of air usually follows to remove the offending stimulus. The glottis is forcibly closed while the lungs are still relatively full. The abdominal and internal intercostal muscles then contract suddenly, creating pressures

that blast air out of the respiratory passageways when the glottis reopens. Air leaving the larynx can travel at 99 mph (160 kph), carrying mucus, foreign particles, and irritating gases out of the respiratory tract by the nose or mouth.

Laryngeal spasms result when chemical irritants, foreign objects, or fluids enter the area around the glottis. This reflex generally closes the airway temporarily. A very strong stimulus, such as a toxic gas, could close the glottis so powerfully that a person could lose consciousness and die without taking another breath. Fine chicken bones or fish bones that pierce the laryngeal walls can also stimulate laryngeal spasms, swelling, or both, restricting the airway.

Voluntary Control of Respiration by Higher Brain Centers

Activity of the cerebral cortex has an indirect effect on the respiratory centers, as the following examples show:

- Conscious thought processes tied to strong emotions, such as rage or fear, affect the respiratory rate by stimulating centers in the hypothalamus.
- Emotional states can affect respiration by activating the sympathetic or parasympathetic division of the autonomic nervous system. Sympathetic activation causes bronchodilation and increases the respiratory rate. Parasympathetic stimulation has the opposite effects.
- An anticipation of strenuous exercise can trigger an automatic increase in the respiratory rate, along with increased cardiac output, by sympathetic stimulation.

Conscious control over respiratory activities may bypass the respiratory centers completely, using cortical pyramidal fibers that innervate the same lower motor neurons that are controlled by the dorsal respiratory group and ventral respiratory group. This control mechanism is an essential part of speaking, singing, and swimming, when respiratory activities must be precisely timed. Higher centers can also have an inhibitory effect on the apneustic centers and on the dorsal respiratory group and ventral respiratory group. This effect is important when one holds their breath.

The ability to override the respiratory centers has limits, however. The chemoreceptor reflexes are extremely powerful in stimulating respiration, and one cannot consciously suppress them. For example, a person cannot kill themselves by holding their breath “till they turn blue.” Once the P_{CO_2} increases to a critical level, one is forced to take a breath.

23

✓ Checkpoint

26. What effect would exciting the pneumotaxic centers have on respiration?
27. Are peripheral chemoreceptors more sensitive or less sensitive to the level of carbon dioxide than they are to the level of oxygen? Why?
28. Little Omar is angry with his mother, so he says that he will hold his breath until he turns blue and dies. Is Omar likely to die if he holds his breath as long as he can? Why or why not?

23-11 Respiratory performance changes over the life span

Learning Outcome Describe age-related changes in the respiratory system.

From birth to death, our respiratory system undergoes age-related changes. In healthy people, many of the changes associated with age may not lead to symptoms. Some changes may decrease

one’s ability to engage in vigorous exercise, but heart function is more likely to affect pulmonary function. Here we discuss some factors associated with respiratory performance.

Changes in the Respiratory System in Newborns

The respiratory systems of fetuses and newborns differ in several important ways. Before delivery, pulmonary arterial resistance is high, because the pulmonary vessels are collapsed. The rib cage is compressed, and the lungs and conducting passageways contain only small amounts of fluid and no air. During delivery, the lungs are compressed further. As the placental connection is lost, the blood oxygen level falls and the carbon dioxide level climbs rapidly.

At birth, the newborn infant takes a truly heroic first breath through powerful contractions of the diaphragm and external intercostal muscles. The inhaled air must enter the respiratory passageways with enough force to overcome surface tension and inflate the bronchial tree and most of the alveoli. The same drop in pressure that pulls air into the lungs also pulls blood into the pulmonary circulation. The changes in blood flow and rise in oxygen level result in the closure of the *foramen ovale*, an interatrial connection, and the *ductus arteriosus*, the fetal connection between the pulmonary trunk and the aorta.

The exhalation that follows does not empty the lungs completely, because the rib cage does not return to its former, fully compressed state. Cartilages and connective tissues keep the conducting passageways open, and surfactant covering the alveolar surfaces prevents their collapse. The next breaths complete the inflation of the alveoli.

After a stillbirth, pathologists sometimes use these physical changes to determine whether the infant died before delivery or shortly thereafter. Before the first breath, the lungs are filled with amniotic fluid, and extracted lungs will sink if placed in water. After the infant’s first breath, even the collapsed lungs contain enough air to keep them afloat.

Changes in the Respiratory System Associated with Aging

Many factors interact to reduce respiratory system efficiency as humans age. Here are three examples:

- With age, elastic tissue deteriorates throughout the body. These changes decrease lung compliance, lowering the vital capacity.
- Chest movements are restricted by arthritic changes in the rib articulations and by decreased flexibility at the costal cartilages. Along with elastic tissue deterioration, the stiffening and reduction in chest movement effectively limit the respiratory minute volume. This restriction contributes to the reduction in exercise performance and capabilities with increasing age.

Figure 23–27 Decreased Respiratory Performance Associated with Age and Smoking. The relative respiratory performances of people who have never smoked, people who quit smoking at age 45, people who quit smoking at age 65, and lifelong smokers.

- Some degree of emphysema is normal in individuals over age 50. However, the extent varies widely with the lifetime exposure to cigarette smoke and other respiratory irritants. **Figure 23–27** compares the respiratory performance of individuals who have never smoked with individuals who have smoked for various periods of time. The message is quite clear: Some decrease in respiratory performance is inevitable, but serious respiratory deterioration can be prevented by stopping smoking or never starting.

✓ Checkpoint

- Name several age-related factors that affect the respiratory system.

See the blue Answers tab at the back of the book.

23-12 The respiratory system provides oxygen to, and eliminates carbon dioxide from, other organ systems

Learning Outcome Give examples of interactions between the respiratory system and other organ systems studied so far.

The goal of respiratory activity is to maintain homeostatic oxygen and carbon dioxide levels in peripheral tissues. Changes in respiratory activity alone are seldom enough to accomplish this. Coordinated changes in cardiovascular activity must also take place.

These examples highlight the integration between the respiratory and cardiovascular systems:

- At the local level, changes in lung perfusion in response to changes in alveolar P_{O_2} improve the efficiency of gas exchange within or among lobules.

+ Clinical Note Smoking and the Lungs

Emphysema and lung cancer are two common disorders associated with cigarette smoking. **Emphysema** (em-fih-ZĒ-muh) is a chronic, progressive condition. It is characterized by shortness of breath and an inability to tolerate physical exertion. The underlying problem is the destruction of alveolar surfaces and inadequate surface area for oxygen and carbon dioxide exchange. The alveoli gradually expand and merge to form larger air spaces supported by fibrous tissue without alveolar capillary networks. As connective tissues are eliminated, compliance increases, so air moves into and out of the lungs more easily than before. But the loss of respiratory surface area restricts oxygen absorption, so the individual becomes short of breath.

Emphysema has been linked to breathing air that contains fine particles or toxic vapors, such as those in cigarette smoke. Genetic factors also predispose individuals to the condition. Some degree of emphysema is a normal consequence of aging. An estimated 66% of adult males and 25% of adult females have detectable areas of emphysema in their lungs.

Lung cancer (bronchogenic carcinoma) is cancer that forms in the lungs. It typically affects the epithelial cells that line conducting passageways, mucous glands, or alveoli. Signs and symptoms generally do not appear until tumors restrict airflow or compress adjacent structures. Chest pain, shortness of breath, a cough or a wheeze, and weight loss are common. Treatment varies with the cellular organization of the tumor and whether *metastasis* (cancer cell migration) has occurred. Surgery, radiation, or chemotherapy may be involved. According to the Centers for Disease Control and Prevention (CDC), more people die from lung cancer than any other type of cancer.

- Chemoreceptor stimulation not only increases the respiratory rate, but also causes blood pressure to rise and cardiac output to increase.
- The stimulation of baroreceptors in the lungs has secondary effects on cardiovascular function. For example, the stimulation of airway stretch receptors not only triggers the inflation reflex, but also increases heart rate. Thus, as the lungs fill, cardiac output rises and more blood flows through the alveolar capillaries.

The adaptations that take place at high altitudes are an excellent example of the functional interplay between the respiratory and cardiovascular systems. Atmospheric pressure decreases with increasing altitude, as do the partial pressures of the component gases, including oxygen. People living in Denver or Mexico City function normally with alveolar oxygen pressures in the 80–90 mm Hg range. At higher elevations, alveolar P_{O_2} is even lower. At 3300 meters (10,826 ft),

Build Your Knowledge

Figure 23–28 Integration of the RESPIRATORY system with the other body systems presented so far.

an altitude many hikers and skiers have experienced, alveolar P_{O_2} is about 60 mm Hg.

Despite the low alveolar P_{O_2} , millions of people live and work at altitudes this high or higher. Important physiological adjustments include an increased respiratory rate, an increased heart rate, an increased BPG level, and an elevated hematocrit. Thus, even though the hemoglobin is not fully saturated, the bloodstream holds more of it, and the round trip between the lungs and the peripheral tissues takes less time. However, most of these adaptations take days to weeks to develop. As a result, athletes planning to compete in events at high altitude must begin training under such conditions well in advance.

The respiratory system is functionally linked to all other body systems as well. Build Your Knowledge **Figure 23-28** illustrates these interrelationships with the other body systems studied so far.

Checkpoint

30. Identify the functional relationship between the respiratory system and all other organ systems.
31. Describe the functional relationship between the respiratory system and the lymphatic system.

See the blue Answers tab at the back of the book.

23 Chapter Review

Study Outline

An Introduction to the Respiratory System

1. Body cells must obtain oxygen and eliminate carbon dioxide. Gas exchange takes place at respiratory surfaces inside the lungs.

23-1 The respiratory system, organized into an upper respiratory system and a lower respiratory system, functions primarily to aid gas exchange

2. The functions of the **respiratory system** include (1) providing an area for gas exchange between air and circulating blood; (2) moving air to and from exchange surfaces; (3) protecting respiratory surfaces from environmental variations and defending the respiratory system and other tissues from invasion by pathogens; (4) producing sounds; and (5) facilitating the detection of olfactory stimuli.
3. The respiratory system includes the **upper respiratory system**, composed of the nose, nasal cavity, paranasal sinuses, and pharynx, and the **lower respiratory system**, which includes the larynx, trachea, bronchi, bronchioles, and alveoli of the lungs. (Figure 23-1)
4. The **respiratory tract** consists of the conducting airways that carry air to and from the **alveoli**. The passageways of the upper respiratory tract filter and humidify incoming air. The lower respiratory tract includes delicate conduction passages and the exchange surfaces of the alveoli.
5. The **respiratory mucosa** (respiratory epithelium and underlying connective tissue) lines the conducting portion of the respiratory tract.
6. The respiratory epithelium changes in structure along the respiratory tract. It is supported by the **lamina propria**, a layer of areolar tissue. (Figure 23-2)

Media Resources:

- PhysioEx

7. Contamination of the respiratory system is prevented by the mucus and cilia of the **respiratory defense system**. (Figure 23-2)

23-2 The conducting portion of the upper respiratory system filters, warms, and humidifies air

8. The upper respiratory system consists of the nose, nasal cavity, paranasal sinuses, and pharynx. (Figures 23-1, 23-3)
9. Air normally enters the respiratory system through the **nostrils**, which open into the **nasal cavity**. The **nasal vestibule** (entryway) is guarded by hairs that screen out large particles. (Figure 23-3)
10. Incoming air flows through the **superior**, **middle**, and **inferior meatuses** (narrow grooves) and bounces off the conchal surfaces. (Figure 23-3)
11. The **hard palate** separates the oral and nasal cavities. The **soft palate** separates the superior nasopharynx from the rest of the pharynx. The **choanae** connect the nasal cavity and nasopharynx.
12. The nasal mucosa traps particles, warms and humidifies incoming air, and dehumidifies and absorbs heat of outgoing air.
13. The **pharynx**, or throat, is a chamber shared by the digestive and respiratory systems. The **nasopharynx** is the superior part of the pharynx. The **oropharynx** is continuous with the oral cavity. The **laryngopharynx** includes the narrow zone between the hyoid bone and the entrance to the esophagus. (Figure 23-3)

23-3 The conducting portion of the lower respiratory system conducts air to the respiratory portion and produces sound

14. Inhaled air passes through the glottis on the way to the lungs; the **larynx** surrounds and protects the glottis, or vocal apparatus. (Figure 23-4)
15. The cylindrical larynx is composed of three large cartilages (the **median thyroid cartilage**, median **cricoid cartilage**, and **epiglottis**) and three smaller pairs of cartilages (the **arytenoid**, **corniculate**, and **cuneiform cartilages**). The epiglottis projects into the pharynx. (Figures 23-4, 23-5)
16. A pair of inelastic **vestibular folds** surrounds the glottis. The **glottis** includes the elastic **vocal folds** and the gap, or space, between them, the *rima glottidis*. (Figure 23-5)
17. Air passing through the open glottis vibrates its vocal folds, producing sound. The pitch of the sound depends on the diameter, length, and tension of the vocal folds.
18. The muscles of the neck and pharynx position and stabilize the larynx. The smaller intrinsic muscles regulate tension in the vocal folds or open and close the glottis. During swallowing, both sets of muscles help prevent particles from entering the glottis.
19. The **trachea** extends from the sixth cervical vertebra to the fifth thoracic vertebra. The **submucosa** contains C-shaped **tracheal cartilages**, which stiffen the tracheal walls and protect the airway. The posterior tracheal wall can distort to permit large masses of food to pass through the esophagus. (Figure 23-6)
20. The trachea branches within the mediastinum to form the **right** and **left main bronchi**. Each bronchus enters a lung at the **hilum** (a groove). The **root of the lung** is a connective tissue mass that includes the bronchus, pulmonary vessels, and nerves. (Figures 23-6, 23-9)
21. The main bronchi and their branches form the **bronchial tree**. The **lobar** and **segmental bronchi** are branches within the lungs. As they branch, the amount of cartilage in their walls decreases and the amount of smooth muscle increases. (Figure 23-7)
22. Each tertiary bronchus supplies air to a single **bronchopulmonary segment**. (Figure 23-7)
23. **Bronchioles** within the bronchopulmonary segments ultimately branch into **terminal bronchioles**.

23-4 The respiratory portion of the lower respiratory system is where gas exchange occurs

24. Each terminal bronchiole delivers air to a single **pulmonary lobule** in which the terminal bronchiole branches into **respiratory bronchioles**. The connective tissues of the root of the lung extend into the parenchyma of the lung as a series of *trabeculae* (partitions) that branch to form **interlobular septa**, which divide the lung into lobules. (Figure 23-7)
25. The respiratory bronchioles open into **alveolar ducts**, where many alveoli are interconnected. The respiratory exchange surfaces are extensively connected to the circulatory system by the capillaries of the pulmonary circuit. (Figure 23-7)

26. The **blood-air barrier** consists of a simple squamous epithelium, the endothelial cell lining an adjacent capillary, and their fused basement membranes. **Pneumocytes type II** (type II alveolar cells) scattered in the blood-air barrier produce **surfactant** that reduces surface tension and keeps the alveoli from collapsing. **Alveolar macrophages** patrol the epithelium and engulf foreign particles. (Figure 23-8)

23-5 Enclosed by pleural cavities, the lungs are paired organs made up of multiple lobes

27. The **lobes** of the lungs are separated by fissures. The right lung has three lobes, the left lung two. (Figure 23-9)
28. The anterior and lateral surfaces of the lungs follow the inner contours of the rib cage. The concavity of the medial surface of the left lung is the **cardiac notch**, which conforms to the shape of the pericardium. (Figures 23-9, 23-10)
29. The respiratory exchange surfaces receive blood from arteries of the pulmonary circuit. The conducting portions of the respiratory tract receive blood from the bronchial arteries. Most of the returning venous blood flows into the pulmonary veins, bypassing the rest of the systemic circuit and diluting the oxygenated blood leaving the alveoli.
30. Each lung is surrounded by a single **pleural cavity** lined by a **pleura** (serous membrane). The two types of pleurae are the **parietal pleura**, covering the inner surface of the thoracic wall, and the **visceral pleura**, covering the lungs.

23-6 External respiration and internal respiration allow gas exchange within the body

31. Respiratory physiology focuses on a series of integrated processes. **External respiration** is the exchange of oxygen and carbon dioxide between interstitial fluid and the external environment and includes *pulmonary ventilation* (breathing). **Internal respiration** is the exchange of oxygen and carbon dioxide between interstitial fluid and cells. If the oxygen content decreases, **hypoxia** ensues in affected tissues; if the oxygen supply is completely shut off, **anoxia** and tissue death result. (Figure 23-11)

23-7 Pulmonary ventilation—air exchange between the atmosphere and the lungs—involves muscle actions and volume changes that cause pressure changes

32. **Pulmonary ventilation** is the physical movement of air into and out of the respiratory tract.
33. Decreasing the volume of a gas increases its pressure. Increasing the volume of a gas decreases its pressure. This inverse relationship is **Boyle's law**. (Figure 23-12)
34. Movement of the diaphragm and ribs changes lung volume. **Primary respiratory muscles** are the diaphragm and external intercostal muscles. (Spotlight Figure 23-13, Figure 23-14)
35. The relationship between **intrapulmonary pressure** (the pressure inside the respiratory tract) and **atmospheric pressure (atm)** determines the direction of airflow. **Intrapleural pressure** is the pressure in the potential space between the parietal and visceral pleurae. (Figure 23-15)

36. A **respiratory cycle** is a single cycle of inhalation and exhalation. The amount of air moved in one respiratory cycle is the **tidal volume**. A **spirometer** is an instrument used to measure the capacity of the lungs. (Figure 23–15)
37. **Alveolar ventilation** is the amount of air reaching the alveoli each minute. The **vital capacity** includes the **tidal volume** plus the **expiratory** and **inspiratory reserve volumes**. The air left in the lungs at the end of maximum exhalation is the **residual volume**. (Figure 23–16)

23-8 Gas exchange depends on the partial pressures of gases and the diffusion of gas molecules

38. In a mixture of gases, the individual gases exert a pressure proportional to their abundance in the mixture (**Dalton's law**). The pressure contributed by a single gas is its **partial pressure**. (Table 23–1)
39. The amount of a gas in solution is directly proportional to the partial pressure of that gas (**Henry's law**). (Figure 23–17)
40. Alveolar air and atmospheric air differ in composition. Gas exchange across the blood-air barrier is efficient due to differences in partial pressures, the short diffusion distance, lipid-soluble gases, the large surface area of all the alveoli combined, and the coordination of blood flow (perfusion) and airflow (ventilation). (Figure 23–18)

23-9 In gas transport, most oxygen is transported bound to hemoglobin, whereas carbon dioxide is transported in three ways

41. Blood entering peripheral capillaries delivers oxygen and absorbs carbon dioxide. The transport of oxygen and carbon dioxide in blood involves reactions that are completely reversible.
42. Oxygen is carried mainly by RBCs, reversibly bound to hemoglobin. At alveolar P_{O_2} , hemoglobin is almost fully saturated; at the P_{O_2} of peripheral tissues, it releases oxygen but still retains a substantial oxygen reserve. The effect of pH on the hemoglobin saturation curve is called the **Bohr effect**. When low plasma P_{O_2} continues for extended periods, red blood cells generate more **2,3-bisphosphoglycerate (BPG)**, which reduces hemoglobin's affinity for oxygen. (Figures 23–19, 23–20)
43. **Fetal hemoglobin** has a stronger affinity for oxygen than does adult hemoglobin, aiding the removal of oxygen from maternal blood. (Figure 23–21)
44. Aerobic metabolism in peripheral tissues generates CO_2 . Roughly 70% is transported as bicarbonate ions (HCO_3^-), 23% is bound as **carbaminohemoglobin**, and about 7% of the CO_2 in blood is dissolved in the plasma. (Figure 23–22)

45. Driven by differences in partial pressure, oxygen enters the blood at the lungs and leaves it in peripheral tissues; similar forces drive carbon dioxide into the blood at the tissues and into the alveoli at the lungs. (Figure 23–23)

23-10 Respiratory centers in the brainstem, along with respiratory reflexes, control respiration

46. Normally, the cellular rates of gas absorption and generation are matched by the capillary rates of delivery and removal and are identical to the rates of oxygen absorption and carbon dioxide removal at the lungs. When these rates are unbalanced, homeostatic mechanisms restore equilibrium.
47. Local factors regulate alveolar blood flow (*lung perfusion*) and airflow (*alveolar ventilation*). Alveolar capillaries constrict under conditions of low oxygen, and bronchioles dilate under conditions of high carbon dioxide.
48. The **respiratory centers** include three pairs of nuclei in the reticular formation of the pons and medulla oblongata. The *respiratory rhythmicity centers* set the pace for respiration; the **apneustic centers** cause strong, sustained inspiratory movements; and the **pneumotaxic centers** inhibit the apneustic centers and promote exhalation. (Figure 23–24, Spotlight Figure 23–25)
49. Stimulation of the chemoreceptor reflexes is based on the level of carbon dioxide in the blood and CSF. (Spotlight Figure 23–25, Figure 23–26)
50. The **inflation reflex** prevents overexpansion of the lungs during forced breathing. The **deflation reflex** stimulates inhalation when the lungs are collapsing.
51. Conscious and unconscious thought processes can affect respiration by affecting the respiratory centers.

23-11 Respiratory performance changes over the life span

52. Before delivery, the fetal lungs are filled with body fluids and are collapsed. At the first breath, the lungs inflate and do not collapse completely thereafter.
53. The respiratory system is generally less efficient with age because (1) elastic tissue deteriorates, lowering compliance and the vital capacity of the lungs; (2) movements of the chest are restricted by arthritic changes and decreased flexibility of costal cartilages; and (3) some degree of emphysema is generally present. (Figure 23–27)

23-12 The respiratory system provides oxygen to, and eliminates carbon dioxide from, other organ systems

54. The respiratory system has extensive anatomical and physiological connections with the cardiovascular system. (Figure 23–28)

Review Questions

See the blue Answers tab at the back of the book.

LEVEL 1 Reviewing Facts and Terms

- The blood-air barrier of the alveoli contains **(a)** the capillary endothelium, **(b)** red blood cells, **(c)** the capillary lumen, **(d)** alveolar macrophages, **(e)** pneumocytes type II.
- The pharyngeal tonsil is located in the **(a)** roof of the laryngopharynx, **(b)** posterior wall of the nasopharynx, **(c)** entrance to the oropharynx, **(d)** upper part of the nasal cavity, **(e)** root of the tongue.
- Air moves into the lungs because **(a)** the gas pressure in the lungs is less than atmospheric pressure, **(b)** the volume of the lungs decreases with inspiration, **(c)** the thorax is muscular, **(d)** contraction of the diaphragm decreases the volume of the thoracic cavity, **(e)** the respiratory control center initiates active expansion of the thorax.
- To keep the air passageways open, rings or plates of cartilage reinforce their walls. However, no cartilage is present in the walls of some passageways. Which passageway(s) is (are) this (these)? **(a)** the trachea, **(b)** the lobar bronchi, **(c)** the main bronchi, **(d)** the bronchioles, **(e)** the segmental bronchi.
- All of the following muscles are accessory respiratory muscles *except* **(a)** sternocleidomastoid, **(b)** scalenes, **(c)** pectoralis minor, **(d)** serratus anterior, **(e)** diaphragm.
- Identify the structures of the respiratory system in the figure below.

- During the winter, Sherwin sleeps in a dorm room that lacks any humidifier for the heated air. In the mornings he notices that his nose is "stuffy," similar to when he has a cold, but after showering and drinking some water, the stuffiness disappears until the next morning. What might be the cause of Sherwin's nasal condition?
- Distinguish the structures of the upper respiratory system from those of the lower respiratory system.
- Name the two mucosal regions in the nasal cavity. What is the difference between these two regions?
- List the cartilages of the larynx. What are the functions of each?
- What three integrated steps are involved in external respiration?
- What important physiological differences exist between fetal hemoglobin and maternal hemoglobin?
- Which chemoreceptor inputs influence the respiratory centers in the brain?

LEVEL 2 Reviewing Concepts

- Which of the following does *not* occur in internal respiration?
(a) Oxygen diffuses from the blood to the interstitial spaces. **(b)** Carbon dioxide diffuses from the interstitial spaces to the blood. **(c)** Hemoglobin binds more oxygen. **(d)** Bicarbonate ions are formed in red blood cells. **(e)** Chloride ions diffuse into red blood cells as bicarbonate ions diffuse out.
- To calculate the anatomic dead space, you should **(a)** multiply the tidal volume by the respiratory rate, **(b)** divide the respiratory minute volume by 0.3, **(c)** multiply the tidal volume by 0.3, **(d)** divide the alveolar ventilation rate by the respiratory rate.
- For any partial pressure of oxygen, if the concentration of 2,3-bisphosphoglycerate (BPG) increases, **(a)** the amount of oxygen released by hemoglobin will decrease, **(b)** the oxygen levels in hemoglobin will be unaffected, **(c)** the amount of oxygen released by hemoglobin will increase, **(d)** the amount of carbon dioxide carried by hemoglobin will increase.
- Neurons located in the chemosensitive area on the ventrolateral surface of the medulla oblongata respond only to **(a)** changes in blood pressure, **(b)** input from stretch receptors, **(c)** abnormal visceral sensations, **(d)** the P_{CO_2} and pH of the CSF.
- Why is breathing through the nasal cavity more desirable than breathing through the mouth?
- Correctly justify the statement "The bronchioles are to the respiratory system what the arterioles are to the cardiovascular system."
- How does the epiglottis prevent food from entering the respiratory tract?
- How does pulmonary ventilation differ from alveolar ventilation, and what is the function of each type of ventilation?
- What is the significance of **(a)** Boyle's law, **(b)** Dalton's law, and **(c)** Henry's law to the process of respiration?
- What happens when a fish bone or a fine chicken bone pierces the laryngeal wall?
- Contrast diaphragmatic breathing and costal breathing. Which of these two becomes dominant during pregnancy, and why?
- What is the functional difference between the pneumotaxic centers and the apneustic centers of the pons?

LEVEL 3 Critical Thinking and Clinical Applications

- Billy's normal alveolar ventilation rate (AVR) during mild exercise is 6.0 L/min. While at the beach on a warm summer day, he goes snorkeling. The snorkel has a volume of 50 mL. Assuming that the water is not too cold and that snorkeling is mild exercise for Billy, what would his respiratory rate have to be for him to maintain an AVR of 6.0 L/min while snorkeling? (Assume a constant tidal volume of 500 mL and an anatomic dead space of 150 mL.)
- Mr. M. has had chronic advanced emphysema for 15 years. While hospitalized with a respiratory infection, he goes into respiratory distress. Without thinking, his nurse immediately administers pure oxygen, which causes Mr. M. to stop breathing. Why?
- Eleven-year-old Susy notices that the voice of her brother, who is older than her by three years, has recently become lower pitched than it was before. Susy wonders why and whether this will happen to her too. What would you tell her?
- Why do individuals who are anemic generally not exhibit an increase in respiratory rate or tidal volume, even though their blood is not carrying enough oxygen?
- Margot has an obstruction of her right primary bronchus. As a result, how would the oxygen-hemoglobin saturation curve for her right lung contrast with that for her left?

CLINICAL CASE Wrap-Up No Rest for the Weary

Leonard has *obstructive sleep apnea*. During sleep his airway becomes blocked and he stops breathing. Several risk factors are promoting this condition. Leonard's throat is tight due to the structure of his palate. Excess fat in his neck compresses his throat from the outside. When he falls asleep on his back, his pharyngeal muscles and tongue relax and drop back into his throat, helped by the muscle-relaxing effects of alcohol. As he breathes, especially on inhalation, the tissues in his throat vibrate and make the noise of snoring. The narrower a person's airway, the louder their snoring. Every time his throat collapses completely, Leonard experiences apnea: He gets no oxygen for a period of multiple seconds to a minute or more. Apnea puts strain on his heart and raises his blood pressure. His nighttime rest is disturbed and so is his daytime function. This is a serious problem.

The doctor wants Leonard to reduce his risk factors by losing weight and avoiding alcohol at night. In the short term, the treatment of choice for sleep apnea is a CPAP (continuous positive airway pressure) machine. Leonard wears the mask device at night. It keeps his airway open by blowing air into the back of his throat.

1. Which parts of the upper respiratory tract can contribute to obstructed breathing?
2. Children can snore, too. A tonsillectomy might eliminate the snoring. Why?

See the blue Answers tab at the back of the book.

Related Clinical Terms

asbestosis: Pneumoconiosis, disease of the lungs, caused by the inhalation of asbestos particles over time.

asphyxia: Impaired oxygen–carbon dioxide exchange that results in suffocation.

aspirate: Drawing fluid from the body by suction; foreign material accidentally sucked into the lungs.

bronchography: A procedure in which radiopaque materials are introduced into the airways to improve x-ray imaging of the bronchial tree.

bronchoscope: A fiberoptic bundle small enough to be inserted into the trachea and finer airways; the procedure is called *bronchoscopy*.

cardiopulmonary resuscitation (CPR): The application of cycles of compression to the rib cage to restore cardiovascular and respiratory function.

Cheyne-Stokes breathing: Hyperpnea (deep, fast breathing) alternating with apnea (absence of breathing).

chronic obstructive pulmonary disease (COPD): A general term describing temporary or permanent lung disease of the bronchial tree.

coronavirus disease (COVID-19): An infectious, respiratory disease caused by the SARS-CoV-2 virus that emerged in December 2019. Symptoms are similar to flu, which is caused by influenza viruses. However, COVID-19 can cause more serious illnesses.

dyspnea: The condition of labored breathing.

endotracheal tube: Tube that is passed through the mouth or nose to the trachea.

Heimlich maneuver or abdominal thrust: Sudden compression applied to the abdomen just inferior to the diaphragm, to force air out of the lungs to clear a blocked trachea or larynx.

hemoptysis: Coughing up blood or bloody mucus.

hemothorax: The condition of having blood in the pleural cavity.

hyperbaric oxygenation: Therapy to force more oxygen into the blood by use of a pressure chamber.

nasal polyps: Benign growths on the mucous lining of the nasal cavity.

orthopnea: Condition in which one has breathing difficulty except when in an upright position.

otorhinolaryngology: Branch of medicine dealing with disease and treatment of the ear, nose, and throat.

rales: Abnormal hissing or other respiratory sounds.

rhinitis: Inflammation of the nasal cavity.

rhinoplasty: Plastic surgery of the nose.

severe acute respiratory syndrome (SARS): A harsh viral respiratory illness caused by a coronavirus that typically progresses to pneumonia.

sputum: A mixture of saliva and mucus coughed up from the respiratory tract, often as the result of an infection.

stridor: Harsh, vibrating breathing sound caused by an obstruction in the windpipe or larynx.

stuttering: To speak with a continued involuntary repetition of sounds.

tachypnea: Rapid rate of breathing.

tussis: A cough.

wheeze: An audible whistling sound when breathing.

24

The Digestive System

Learning Outcomes

These Learning Outcomes correspond by number to this chapter's sections and indicate what you should be able to do after completing the chapter.

- 24-1 ■ Identify the organs of the digestive system, list their major functions, describe the histology of the digestive tract, and outline the mechanisms that regulate digestion.
- 24-2 ■ Discuss the anatomy of the oral cavity and list the functions of its major structures and regions.
- 24-3 ■ Describe the structure and functions of the pharynx and the esophagus.
- 24-4 ■ Describe the anatomy of the stomach, including its histology, and discuss its roles in digestion and absorption.
- 24-5 ■ Describe the structure, functions, and regulation of the accessory digestive organs.
- 24-6 ■ Describe the anatomy and histology of the small intestine and explain the functions and regulation of intestinal secretions.
- 24-7 ■ Describe the gross and histological structures of the large intestine, including its regional specializations and role in nutrient absorption.
- 24-8 ■ List the nutrients required by the body, describe the chemical events responsible for the digestion of organic nutrients, and describe the mechanisms involved in the absorption of organic and inorganic nutrients.
- 24-9 ■ Summarize the effects of aging on the digestive system.
- 24-10 ■ Give examples of interactions between the digestive system and other body systems studied so far.

CLINICAL CASE An Unusual Transplant

Mirasol has been in the hospital and on antibiotics for a stubborn case of pneumonia for over a week. She desperately misses her grandchildren and is feeling worse than ever. Her cough has resolved, but she has had watery diarrhea 10 times today. The last few times, there was blood in her stool. She has lost her appetite and feels crampy abdominal pain. She is dehydrated and unable to drink enough liquids to keep up with her fluid loss from diarrhea. She also has a fever and has lost weight.

Her doctor enters the room with the results of recent tests performed on her stool. “I’m afraid the normal, helpful bacteria that live in your colon have been killed off by the antibiotics used to cure your pneumonia. Now, harmful bacteria have taken over and are causing

your bloody diarrhea,” reports the doctor. “Your colon is overgrown with *Clostridium difficile* bacteria. These bacteria are producing toxins that are causing your colitis (inflammation of the colon). The usual treatment for this condition is more antibiotics.”

“Doctor,” cries Mirasol, “I don’t think I can take any more antibiotics. I feel worse now than when I arrived.”

“Well, I have an idea that may work,” the doctor replies. “A transplant, from one of your healthy, adult

grandchildren. It’s a little unusual, however. You need to keep an open mind.” **What kind of transplant can possibly help Mirasol? To find out, turn to the Clinical Case Wrap-Up at the end of the chapter.**

An Introduction to the Digestive System

All living organisms must get nutrients from their environment to sustain life. These nutrients are used as raw materials for synthesizing essential compounds (anabolism). They are also broken down to provide the energy that cells need to continue functioning (catabolism). The *digestive system*, working with the cardiovascular and lymphatic systems, provides the needed nutrients in the form of organic molecules (such as carbohydrates, fats, or proteins). In effect, the digestive system supplies both the fuel that keeps all the body’s cells functioning and the building blocks needed for cell growth and repair.

In this chapter we discuss the structure and function of the major body passage known as the *digestive tract*, as well as several accessory organs. We examine the process of digestion and how it breaks down large and complex organic molecules into smaller fragments that can be absorbed by the digestive epithelium. And we then consider how some types of organic wastes are removed from the body.

24-1 The digestive system, consisting of the digestive tract and accessory organs, functions primarily to break down and absorb nutrients from food and to eliminate wastes

Learning Outcome Identify the organs of the digestive system, list their major functions, describe the histology of the digestive tract, and outline the mechanisms that regulate digestion.

The **digestive system** (*alimentary system*) consists of a muscular tube, the **digestive tract**, also called the *gastrointestinal (GI) tract*

or *alimentary canal*, and various **accessory organs**. **Figure 24-1** shows the major organs of the digestive system. The digestive tract begins at the *oral cavity* (mouth). It continues through the *pharynx* (throat), *esophagus*, *stomach*, *small intestine*, and *large intestine*, which opens to the exterior at the *anus*. Accessory digestive organs include the teeth, tongue, and various *glandular organs*, such as the *salivary glands*, *liver*, and *pancreas*, as well as the *gallbladder*, which only has a secretory function.

These structures have overlapping functions that all contribute to the main function of the digestive system, which is to break down food, absorb the nutrients that can be used by body cells, and eliminate the remaining waste. However, each of these structures also has certain areas of specialization and so shows distinctive histological characteristics. This section introduces the functions of the digestive system. We also look at several structural and functional characteristics of the system, including how its epithelial lining is specialized for absorption, how materials move through it, and how those movements are regulated.

Functions and Processes of the Digestive System

Food enters the digestive tract and passes along its length. Along the way, the digestive system performs six integrated processes. These processes include the following:

1. **Ingestion** takes place when food enters the oral cavity. Ingestion is an active process involving choices and decision making.
2. **Mechanical digestion and propulsion** involve the crushing and shearing of food and then propelling the food along the digestive tract. Mechanical digestion may not be required

Figure 24–1 Organs of the Digestive System.

before ingestion. Liquids can be swallowed immediately, but most solids must be chewed first. Tearing and mashing with the teeth, followed by squashing and compressing by the tongue, are examples of preliminary mechanical digestion. Swirling, mixing, and churning motions of the stomach and intestines provide mechanical digestion after ingestion. Mechanical digestion also increases the surface area of ingested materials, making them more accessible to enzymes.

3. **Chemical digestion** refers to the chemical breakdown of food into small organic and inorganic molecules suitable for absorption by the digestive epithelium. Simple molecules in food, such as glucose, can be absorbed intact. However, epithelial cells have no way to absorb molecules with the size and complexity of proteins, polysaccharides, or triglycerides. Digestive enzymes must first disassemble these molecules. For example, the starches in a potato are of no nutritional value until enzymes have broken them down to simple sugars.

4. **Secretion** is the release of water, acids, enzymes, buffers, and salts by the epithelium of the digestive tract, glandular organs, and the gallbladder. The glandular organs and gallbladder secrete their products into ducts that empty into the digestive tract.
5. **Absorption** is the movement of organic molecules, electrolytes (inorganic ions), vitamins, minerals, and water across the digestive epithelium. These materials are absorbed into the interstitial fluid of the digestive tract for distribution to body cells.
6. **Defecation** (def-eh-KĀ-shun) is the elimination of wastes from the body. The digestive tract and glandular and secretory organs discharge wastes in secretions that enter the lumen of the tract. Most of these wastes mix with the indigestible food of the digestive process. These wastes are dehydrated and compacted into matter called *feces* and ejected from the digestive tract through the anus.

This chapter explores these specific processes in more detail as we consider the structure and function of individual regions of the digestive system.

In addition to its main function, the digestive system also plays a protective role. The lining of the digestive tract safeguards surrounding tissues against (1) the corrosive effects of digestive acids and enzymes; (2) mechanical stresses, such as abrasion; and (3) bacteria that are swallowed with food or live in the digestive tract. The digestive epithelium and its secretions provide a nonspecific defense against these bacteria. When bacteria reach the underlying layer of areolar tissue, the *lamina propria*, macrophages and other cells of the immune system attack them.

Relationship between the Digestive Organs and the Peritoneum: The Mesenteries

The abdominopelvic cavity contains the *peritoneal cavity*, which is lined by a serous membrane called the **peritoneum**. This membrane consists of a superficial mesothelium covering a layer of areolar tissue. We divide the peritoneum into two parts. The serosa, or *visceral peritoneum*, covers organs that project into the peritoneal cavity. The *parietal peritoneum* lines the inner surfaces of the body wall.

The serous membrane lining the peritoneal cavity continuously produces peritoneal fluid, which lubricates the surfaces. Because a thin layer of peritoneal fluid separates them, the parietal and visceral surfaces can slide without friction and resulting irritation. The parietal peritoneum secretes and reabsorbs about 7 liters (7.4 quarts) of fluid each day, but the volume within the peritoneal cavity at any one time is very small. Liver disease, kidney disease, and heart failure can increase the rate at which fluids move into the peritoneal cavity. The buildup of fluid creates a characteristic abdominal swelling called **ascites** (a-SĪ-tēz). This fluid can distort internal organs and cause symptoms such as heartburn, indigestion, and lower back pain.

Portions of the digestive tract are suspended within the peritoneal cavity by sheets of serous membrane that connect the parietal peritoneum with the visceral peritoneum. These **mesenteries** (MEZ-en-ter-ēz) are double sheets of peritoneal membrane. The areolar tissue between the mesothelial surfaces provides a route to and from the digestive tract for blood vessels, nerves, and lymphatic vessels. Mesenteries stabilize the positions of the attached organs. The mesenteries also prevent the intestines from becoming entangled during digestive movements or sudden changes in body position.

During embryonic development, the digestive tract and accessory organs are suspended within the peritoneal cavity by *dorsal* and *ventral mesenteries* (Figure 24-2a). The ventral mesentery later disappears along most of the digestive tract.

It persists in adults in only two places: on the ventral surface of the stomach, between the stomach and the liver (the *lesser omentum*) (Figure 24-2b,d), and between the liver and the anterior abdominal wall (the *falciform ligament*) (Figure 24-2c,d). The **lesser omentum** (ō-MEN-tum; *omentum*, apron) stabilizes the position of the stomach and provides an access route for blood vessels and other structures entering or leaving the liver. The **falciform** (FAL-si-form; *falx*, sickle + *forma*, form) **ligament** helps stabilize the position of the liver relative to the diaphragm and abdominal wall.

As the digestive tract elongates, it twists and turns within the crowded peritoneal cavity. The dorsal mesentery of the stomach becomes greatly enlarged and forms an enormous pouch that extends inferiorly between the body wall and the anterior surface of the small intestine. This pouch is the **greater omentum** (Figure 24-2b,d). It hangs like an apron from the lateral and inferior borders of the stomach. Adipose tissue in the greater omentum conforms to the shapes of the surrounding organs, providing padding and protection across the anterior and lateral surfaces of the abdomen. When a person gains weight, this adipose tissue contributes to the characteristic “beer belly.” The lipids in the adipose tissue are an important energy reserve. The greater omentum also insulates the body, reducing heat loss across the anterior abdominal wall.

All but the first 25 cm (10 in.) of the small intestine is suspended by the **mesentery proper**, a thick mesenterial sheet. It provides stability but does permit some independent movement. The mesentery associated with the initial portion of the small intestine (the *duodenum*) and the pancreas fuses with the posterior abdominal wall and locks those structures in place. Only their anterior surfaces remain covered by peritoneum. These organs are **retroperitoneal** (*retro*, behind) because their mass lies posterior to the peritoneal cavity.

Clinical Note Peritonitis

An inflammation of the peritoneum, the serous membrane of the abdominopelvic cavity, is called **peritonitis** (pehr-ih-tō-NĪ-tis). This painful condition interferes with the normal functions of the affected organs. Physical damage, chemical irritation, and bacterial invasion of the peritoneum can lead to severe cases of peritonitis. Such cases can even be fatal. In untreated appendicitis, the appendix may rupture and release bacteria into the peritoneal cavity. This event may cause peritonitis. Peritonitis can also be a complication of any surgery that opens the peritoneal cavity. There is a danger of peritonitis in any disease or injury that perforates the stomach or intestines.

Figure 24-2 The Mesenteries.

a During embryonic development, the digestive tube is initially suspended by dorsal and ventral mesenteries. In adults, the ventral mesentery is lost except at the lesser omentum between the stomach and liver and the falciform ligament between the liver and diaphragm (see part d).

b A diagrammatic view of the organization of mesenteries in an adult. As the digestive tract enlarges, mesenteries associated with the proximal portion of the small intestine, the pancreas, and the ascending and descending portions of the colon fuse to the body wall.

c An anterior view of the empty peritoneal cavity, showing the attachment of mesenteries to the posterior body wall. Some visceral organs that were originally suspended within the peritoneal cavity are now retroperitoneal due to fusion of the serosa with the parietal peritoneum.

d A sagittal section showing the mesenteries of an adult. Notice that the pancreas, duodenum, and rectum are retroperitoneal.

A **mesocolon** is a mesentery associated with a portion of the large intestine. During normal development, the mesocolon of the *ascending colon*, the *descending colon*, and the *rectum* of the large intestine fuses to the posterior body wall. These regions become locked in place. Thereafter, these organs are retroperitoneal. The visceral peritoneum covers only their anterior surfaces and portions of their lateral surfaces (**Figure 24–2b,c,d**).

Histology of the Digestive Tract

The four major layers of the digestive tract are (1) the *mucosa*, (2) the *submucosa*, (3) the *muscular layer*, and (4) the *serosa*. The structure of these layers varies by region. **Figure 24–3** is a composite view. It most closely resembles the small intestine, the longest segment of the digestive tract.

The lining of the digestive tract varies by region. For example, the stomach lining has longitudinal folds, which disappear as the tract fills. The lining of the small intestine has permanent transverse folds called *circular folds*, or *plicae* (PLĭ-sē; folds) *circulares* (**Figure 24–3**). This folding, along with small mucosal projections called *villi*, increases the surface area available for absorption. The secretions of gland cells in the mucosa and submucosa—or in accessory glandular organs and the gallbladder—are carried to the epithelial surfaces by ducts.

The Mucosa

The inner lining, or **mucosa**, of the digestive tract is a *mucous membrane*. It consists of an epithelium, moistened by glandular secretions, a *lamina propria* of areolar tissue, and a muscular *muscularis mucosae*.

The Digestive Epithelium. The mucosal epithelium is either simple or stratified, depending on its location and the stresses placed on it. Mechanical stresses are most severe in the oral cavity, pharynx, esophagus, and anal canal. These structures are lined by a stratified squamous epithelium. In contrast, the stomach, the small intestine, and almost the entire length of the large intestine are lined by a simple columnar epithelium. In the stomach, this epithelium contains mucous cells, and in the intestines the epithelium contains goblet cells. Scattered among the columnar cells are **enteroendocrine cells**. They secrete hormones that coordinate the activities of the digestive tract and the accessory glands.

The Lamina Propria. The lamina propria is a layer of areolar tissue that also contains blood vessels, sensory nerve endings, lymphatic vessels, smooth muscle cells, and scattered lymphatic tissue. In the oral cavity, pharynx, esophagus, stomach, and the proximal portion of the small intestine, the lamina propria also contains the secretory cells of intestinal glands.

Figure 24–3 Histological Organization of the Digestive Tract. A diagrammatic view of a representative portion of the digestive tract. The features illustrated are typical of those of the small intestine.

Clinical Note Epithelial Renewal and Repair

The life span of a typical epithelial cell varies from 2 to 3 days in the esophagus to 6 days in the large intestine. Epithelial stem cells continuously divide to renew the lining of the entire digestive tract. These divisions normally keep pace with the rates of cell destruction and loss at epithelial surfaces. This high rate of cell division explains why radiation and anticancer drugs that inhibit mitosis have drastic effects on the digestive tract. Lost epithelial cells are no longer replaced. The cumulative damage to the epithelial lining quickly leads to problems in absorbing nutrients. In addition, the exposure of the lamina propria to digestive enzymes can cause internal bleeding and other serious problems.

The Muscularis Mucosae. In most areas of the digestive tract, deep to the lamina propria is a narrow sheet of smooth muscle and elastic fibers. This sheet is called the **muscularis** (musk-yū-LAIR-is) **mucosae** (myū-KŌ-sē) (**Figure 24-3**). The smooth muscle cells in the muscularis mucosae are arranged in two concentric layers. The inner layer encircles the lumen (the *circular muscle*), and the outer layer contains muscle cells arranged parallel to the long axis of the tract (the *longitudinal layer*). Contractions in these layers alter the shape of the lumen.

The Submucosa

The **submucosa** is a layer of dense irregular connective tissue that binds the mucosa to the muscular layer (**Figure 24-3**). The submucosa has numerous blood vessels and lymphatic vessels. In some regions it also contains exocrine glands that secrete buffers and enzymes into the lumen of the digestive tract.

Along its outer margin, the submucosa contains a network of intrinsic nerve fibers and scattered neurons. This network is the **submucosal neural plexus**. It contains sensory neurons, parasympathetic ganglionic neurons, and sympathetic postganglionic fibers that innervate the mucosa and submucosa.

The Muscular Layer

The submucosal plexus lies along the inner border of the **muscular layer**. Smooth muscle cells dominate this region. Like the smooth muscle cells in the muscularis mucosae, those in the muscular layer are arranged in an inner circular layer and an outer longitudinal layer. These layers play an essential

role in mechanical digestion and in moving materials along the digestive tract.

The movements of the digestive tract are coordinated primarily by the sensory neurons, interneurons, and motor neurons of the enteric nervous system (ENS). The ENS is primarily innervated by the parasympathetic division of the ANS. Sympathetic postganglionic fibers also synapse here. Many of these fibers continue onward to innervate the mucosa and the **myenteric** (mī-en-TER-ik) **plexus** (mys, muscle + *enteron*, intestine). This plexus is a network of parasympathetic ganglia, sensory neurons, interneurons, and sympathetic postganglionic fibers. It lies sandwiched between the circular and longitudinal muscle layers. In general, parasympathetic stimulation *increases* muscle tone and activity. Sympathetic stimulation decreases muscle tone and activity.

Tips

Because the parasympathetic nervous system plays a dominant role in the digestive process, it is often referred to as the “rest and digest” division of the ANS.

The Serosa

A serous membrane known as the **serosa** covers the muscular layer along most portions of the digestive tract enclosed by the peritoneal cavity (**Figure 24-3**).

In areas where there is no serosa covering the muscular layer, a dense network of collagen fibers firmly attaches the digestive tract to adjacent structures. This fibrous sheath is called an *adventitia* (ad-ven-TISH-uh).

Motility of the Digestive Tract

The muscular layers of the digestive tract consist of *visceral smooth muscle tissue*, which we introduced in Chapter 10. This visceral smooth muscle includes cells called *pacemaker cells* that are in the muscularis mucosae and muscular layer, which surround the lumen of the digestive tract. Pacemaker cells undergo spontaneous depolarization, triggering a wave of contraction that spreads throughout the entire muscular sheet. The coordinated contractions of the muscular layer cause the digestive tract to rhythmically squeeze and move materials along the tract, a propulsion process called *peristalsis*. A related type of movement, or *motility*, called *segmentation*, also mechanically digests materials.

Propulsion: Peristalsis

The muscular layer propels materials from one portion of the digestive tract to another by contractions known as **peristalsis** (pehr-ih-STAL-sis). Peristalsis consists of waves of muscular contractions that move a *bolus* (BŌ-lus), or soft rounded ball of digestive contents, along the length of the digestive

Figure 24-4 Peristalsis. Peristalsis propels materials along the length of the digestive tract.

Why do muscles behind the bolus contract while muscles ahead of the bolus relax?

tract (**Figure 24-4**). During peristalsis, circular and longitudinal muscles behind the bolus contract, while muscles ahead of the bolus relax. The wave of muscular contractions forces the bolus forward, pushing it along adjacent segments. This cycle repeats, propelling the bolus along the digestive tract.

Tips

Squeezing toothpaste out of a tube is like peristalsis: Hand squeezing (contracting circular muscles) forces toothpaste (the bolus) along and out of the tube (the digestive tract).

Mechanical Digestion: Segmentation

Most areas of the small intestine and some portions of the large intestine undergo cycles of contraction that churn and fragment the bolus, mixing the contents with intestinal secretions. This activity, called **segmentation**, does not follow a set pattern. For this reason, segmentation does not push materials along the tract in any one direction.

Regulation of Digestive Functions

Local factors interact with neural and hormonal mechanisms to regulate the activities of the digestive system (**Figure 24-5**).

Local Factors

The initial regulation of digestive function occurs at the local level (**Figure 24-5 1**). Local environmental factors such as the pH, volume, or chemical composition of the intestinal contents can have a direct effect on digestive activity in that segment of the digestive tract. Some of these local factors have a direct effect on local digestive activities; for example, stretching of the intestinal wall can stimulate localized contractions of smooth muscles. In other cases, the local factors stimulate the release of chemicals. Prostaglandins, histamine, and other chemicals released into interstitial fluid may affect adjacent cells within a small segment of the tract. For example, the release of histamine in the lamina propria of the stomach stimulates the secretion of acid by cells in the adjacent epithelium.

Neural Mechanisms

Neural mechanisms control digestive tract movement (**Figure 24-5 2**). For example, sensory receptors in the walls of the digestive tract trigger peristaltic movements that are limited to a few centimeters. The visceral motor neurons that control smooth muscle contraction and glandular secretion are in the myenteric plexus. These neurons are usually considered parasympathetic because some of them synapse with parasympathetic preganglionic fibers. However, the plexus also contains sensory neurons, motor neurons, and interneurons responsible for local reflexes that operate entirely outside the control of the central nervous system. As we noted in Chapter 16, local reflexes are called *short reflexes*.

In general, short reflexes control localized activities that involve small segments of the digestive tract. For example, they may coordinate local peristalsis and trigger secretion by

Media resource available for this topic: Practice Anatomy Lab: Digestive System: Human Cadaver and Anatomical Models

Figure 24-5 The Regulation of Digestive Activities.

digestive glands in response to the arrival of a bolus. Many neurons are involved. The enteric nervous system (ENS) has about 100 million neurons (more than the spinal cord or the PNS) and as many neurotransmitters as the brain. The specific functions and interactions of these neurotransmitters in the enteric nervous system are unknown.

Sensory information from receptors in the digestive tract also reaches the CNS. There it can trigger *long reflexes*, which involve interneurons and motor neurons in the CNS.

Hormonal Mechanisms

Digestive hormones can enhance or diminish the sensitivity of the smooth muscle cells to neural commands (Figure 24-5 3). These hormones, produced by enteroendocrine cells in the digestive tract, travel through the bloodstream to reach their target organs.

✓ Checkpoint

1. Identify the organs of the digestive system.
2. What is the main function of the digestive system?
3. List and define the six primary processes of the digestive system.
4. What is the importance of the mesenteries?
5. Name the layers of the gastrointestinal tract beginning at the surface of the lumen.
6. Which is more efficient in propelling intestinal contents from one place to another: peristalsis or segmentation?
7. What effect would a drug that blocks parasympathetic stimulation of the digestive tract have on peristalsis?

See the blue Answers tab at the back of the book.

24-2 The oral cavity, which contains the tongue, teeth, and salivary glands, functions in the ingestion and mechanical digestion of food

Learning Outcome Discuss the anatomy of the oral cavity and list the functions of its major structures and regions.

Let's start our exploration of the digestive tract with how ingested food is processed in the oral cavity. The process of chewing, or *mastication*, involves not only the tongue and teeth but also *saliva* produced by the salivary glands.

The Oral Cavity

We begin at the **oral cavity** (mouth) (Figure 24-6). The functions of the oral cavity include (1) *sensory analysis* of food before swallowing; (2) *mechanical digestion* through the actions of the teeth, tongue, and palatal surfaces; (3) *lubrication* by mixing with mucus and saliva; and (4) limited *chemical digestion* of carbohydrates and lipids.

The oral cavity is lined by the **oral mucosa**, which has a stratified squamous epithelium. A layer of keratinized cells covers regions exposed to severe abrasion, such as the superior surface of the tongue and the opposing surface of the hard palate (part of the roof of the mouth). The epithelial lining of the cheeks, lips, and inferior surface of the tongue is relatively thin and nonkeratinized. Nutrients are not absorbed in the oral cavity, but the mucosa inferior to the tongue is thin enough and vascular enough

to permit the rapid absorption of lipid-soluble drugs. *Nitroglycerin* may be administered by this route to treat acute angina pectoris (severe chest pain due to inadequate blood supply to the heart).

The mucosae of the **cheeks**, or lateral walls of the oral cavity, are supported by buccal fat pads and the buccinator muscles. Anteriorly, the mucosa of each cheek is continuous with that of the **lips**. The **oral vestibule** is the space between the cheeks (or lips) and the teeth. The **gingivae** (JIN-ji-vē), or *gums*, are ridges of oral mucosa that surround the base of each tooth on the alveolar processes of the maxillae and the alveolar part of the mandible. In most regions, the gingivae are firmly bound to the periosteum of the underlying bones. The *frenulum of lower lip* and the *frenulum of upper lip* are folds of mucosa that extend from the gingiva to the lower lip and upper lip respectively, attaching the lips to the gum.

The hard and soft palates form the roof of the oral cavity, while the tongue dominates its floor. The floor of the mouth inferior to the tongue gains extra support from the geniohyoid and mylohyoid muscles. The palatine processes of the maxillae and the horizontal plates of the palatine bones form the **hard palate**. A prominent central ridge, or *palatine raphe* (RĀ-fee), extends along the midline of the hard palate. The mucosa lateral and anterior to the raphe is thick, with complex ridges. When the tongue compresses food against the hard palate, these ridges provide traction. The **soft palate** lies posterior to the hard palate. A thinner and more delicate mucosa covers the posterior margin of the hard palate and extends onto the soft palate.

Figure 24-6 Anatomy of the Oral Cavity.

The posterior margin of the soft palate supports the **uvula** (YŪ-vyū-luh), a dangling process that helps prevent food from entering the pharynx too soon (**Figure 24-6a**). On either side of the uvula are two pairs of muscular *palatal arches* (**Figure 24-6b**). The more anterior **palatoglossal** (pal-a-tō-GLOS-al) **arch** extends between the soft palate and the base of the tongue. The space between the oral cavity and the pharynx, bounded by the soft palate and the base of the tongue, is called the **fauces** (FAW-sēz). The more posterior **palatopharyngeal** (pal-ah-tō-fah-RIN-jē-al) **arch** extends from the soft palate to the pharyngeal wall. A palatine tonsil lies between the palatoglossal and palatopharyngeal arches on each side.

The Tongue

The **tongue** has four primary functions (**Figure 24-6**): (1) mechanical digestion by compression, abrasion, and distortion; (2) manipulation to assist in chewing and to prepare food for swallowing; (3) sensory analysis by touch, temperature, and taste receptors; and (4) secretion of mucins and the enzyme *lingual lipase*.

We can divide the tongue into an anterior **body**, or *oral portion*, and a posterior **root**, or *pharyngeal portion*. The superior surface, or *dorsum*, of the body contains a forest of fine projections, the *lingual papillae*. The thickened epithelium covering each papilla assists the tongue in moving materials. A V-shaped line of vallate papillae roughly marks the boundary between the body and the root of the tongue, which is in the oropharynx (**Figure 24-6a**).

The epithelium covering the inferior surface of the tongue is thinner and more delicate than that of the dorsum. Along the inferior midline is the **frenulum** (FREN-yū-lum; *frenum*, bridle) **of tongue**, or *lingual frenulum*, a thin fold of mucous membrane that connects the body of the tongue to the mucosa covering the floor of the oral cavity (**Figure 24-6b**). Ducts from two pairs of salivary glands open on each side of the frenulum, which prevents extreme movements of the tongue. However, an overly restrictive frenulum hinders normal eating or speech. A shortened lingual frenulum causes a partial or complete fusion of the tongue to the floor of the mouth. This condition, called *ankyloglossia* (ang-kih-lō-GLOS-ē-uh), can be corrected surgically.

Secretions of small glands that extend into the underlying lamina propria flush the tongue's epithelium. These secretions contain water, mucins, and the enzyme **lingual lipase**. Lingual lipase works over a broad pH range (3.0–6.0) so lipid digestion begins immediately. Because the enzyme tolerates an acid environment, it can continue to break down lipids—specifically, triglycerides—for a considerable time after the food reaches the stomach.

The tongue contains two groups of skeletal muscles. The large **extrinsic tongue muscles** perform all gross movements of the tongue.

The smaller **intrinsic tongue muscles** change the shape of the tongue and assist the extrinsic muscles during precise movements, as in speech. Both intrinsic and extrinsic tongue muscles are under the control of the hypoglossal cranial nerves (XII).

The Teeth

Tongue movements are important in passing food across the **teeth** during chewing. Let's look at the different types and sets of teeth.

Anatomy of a Tooth

Figure 24-7a is a sectional view through a permanent tooth. The bulk of each tooth consists of a mineralized matrix similar to bone matrix. This material, called **dentin**, differs from bone in that it does not contain cells. Instead, cytoplasmic processes extend into the dentin from cells in the central **pulp cavity**, an interior chamber. The pulp cavity receives blood vessels and nerves through the **root canal**, a narrow tunnel located at the **root**, or base, of the tooth. Blood vessels and nerves enter the root canal through an opening called the **apical foramen** to supply the pulp cavity.

The root of each tooth sits in a bony cavity or socket called the *tooth socket* or a *tooth alveolus*. Collagen fibers of the **periodontal ligament** extend from the dentin of the root to the alveolar bone, creating a strong articulation known as a *gomphosis*. A layer of **cement** (sē-MENT) covers the dentin of the root. Cement protects and firmly anchors the periodontal ligament. Cement is histologically similar to bone and is less resistant to erosion than is dentin.

The **neck** of the tooth marks the boundary between the root and the **crown**, the exposed portion of the tooth that projects beyond the soft tissue of the gingiva. A shallow groove called the **gingival sulcus** surrounds the neck of each tooth. The mucosa of the gingival sulcus is very thin and is not tightly bound to the periosteum. The epithelium is bound to the tooth at the base of the sulcus. This epithelial attachment prevents bacterial access to the lamina propria of the gingiva and the relatively soft cement of the root. When one brushes and massages their gums, the epithelial cells are stimulated and strengthen the epithelial attachment. A condition called *gingivitis*, an inflammation of the gingivae caused by bacterial infection, can occur if the attachment breaks down.

A layer of **enamel** covers the dentin of the crown. Enamel forms the **occlusal surface** of each tooth, which is the biting surface that grinds food against the opposing tooth surface. Elevations or projections of the occlusal surface are called **cusps**. Enamel, which contains calcium phosphate in a crystalline form, is the hardest biologically manufactured substance. Adequate amounts of calcium, phosphates, and vitamin D₃ during childhood are essential if the enamel coating is to be complete and resistant to decay.

Figure 24-7 The Teeth.

Tooth decay generally results from the action of bacteria that live in the mouth. Bacteria adhering to the surfaces of the teeth produce a sticky matrix that traps food particles and creates deposits known as *dental plaque*. Over time, this organic material can become calcified, forming a hard layer of *tartar*, or *dental calculus*, which can be difficult to remove. Tartar deposits most commonly develop at or near the gingival sulcus, where brushing cannot remove the soft plaque deposits.

Types of Teeth

The alveolar processes of the maxillae and the alveolar part of the mandible form the *maxillary dental arcade* and *mandibular dental arcade*, or upper and lower dental arcades, respectively. These arcades contain four types of teeth, each with specific functions (**Figure 24-7b**):

- 1. Incisor** (in-SĪ-zer) **teeth** are blade-shaped teeth located at the front of the mouth. Incisors are useful for clipping or cutting, as when biting off the tip of a carrot stick. These teeth have a single root.
- 2. Canine** (KĀ-nĭn) **teeth**, or *cuspids* (KUS-pidz), are conical with a single, pointed cusp. Also known as the “eyeteeth,” because they lie directly under the eye, the canines are used for tearing or slashing. Tough celery is weakened by using the biting action of the incisors and the shearing action of the canines. Canines have a single root.

- 3. Premolar teeth**, or *bicuspid* (bĪ-KUS-pidz), have flattened crowns with two prominent rounded cusps. They crush, mash, and grind. Bicuspid have one or two roots.
- 4. Molar teeth** have very large, flattened crowns with four to five prominent rounded cusps adapted for crushing and grinding. Tough food can usually be shifted to the premolars and molars for successful crunching. Molars in the upper jaw typically have three roots, while those in the lower jaw usually have two roots.

Sets of Teeth

The teeth are collectively called the *dentition*. Two such dentitions form during development: deciduous and permanent. The first to appear are the **deciduous teeth** (de-SID-yū-us; *deciduus*, falling off). Deciduous teeth are also called *primary teeth*, *milk teeth*, or *baby teeth*. Most children have 20 deciduous teeth (**Figure 24-8a**). On each side of the upper or lower jaw, the deciduous teeth consist of two incisors, one canine, and a pair of deciduous molars for a total of 20 teeth.

These teeth are later replaced by the **permanent teeth** of the larger adult jaws. As replacement proceeds, the periodontal ligaments and roots of the deciduous teeth erode. The deciduous teeth either fall out or are pushed aside by the **eruption**, or emergence, of the permanent teeth (**Figure 24-8b**). The permanent premolars take the place of the deciduous molars, while the permanent molars extend the tooth rows as the jaw

Figure 24-8 Deciduous and Permanent Dentitions.

enlarges (**Figure 24-8c**). Three additional molars appear on each side of the upper and lower jaws as the person ages. These molars extend the rows of teeth posteriorly and bring the permanent tooth count to 32.

The third molars, or *wisdom teeth*, may not erupt before age 21. Wisdom teeth may not erupt because they develop in inappropriate positions or because there is not enough space. Any teeth that develop in locations that do not allow them to erupt are called *impacted teeth*. Impacted wisdom teeth can be surgically removed to prevent the formation of abscesses.

The Salivary Glands

Three major pairs of salivary glands secrete into the oral cavity (**Figure 24-9a**). Each pair has a distinctive cellular organization

and produces *saliva*, a mixture of glandular secretions, with slightly different properties:

- The large **parotid** (pah-ROT-id) **glands** lie inferior to the zygomatic arch deep to the skin covering the lateral and posterior surface of the mandible. Each gland has an irregular shape. It extends from the mastoid process of the temporal bone across the outer surface of the masseter. The parotid glands produce a serous secretion containing large amounts of *salivary amylase*. This enzyme breaks down starches (complex carbohydrates). The secretions of each parotid gland are drained by a **parotid duct**, which empties into the vestibule at the second upper molar.
- The **sublingual** (sub-LING-gwal) **glands** are covered by the mucous membrane of the floor of the mouth. These

Figure 24–9 Anatomy of the Salivary Glands.

Which type of salivary glands produces glycoproteins called mucins?

glands produce mucus that acts as a buffer and lubricant. Numerous **sublingual ducts** open along either side of the lingual frenulum.

- The **submandibular glands** lie along the inner surfaces of the mandible within a depression called the *mandibular groove*. Cells of the submandibular glands (**Figure 24–9b**) secrete a mixture of buffers, glycoproteins called *mucins*, and salivary amylase. The **submandibular ducts** open into the mouth on each side of the frenulum of tongue immediately posterior to the teeth (**Figure 24–6b**).

Minor salivary glands include some 800–1000 submucosal glands in the oral cavity. These small (1–2 mm in diameter) glands may share an excretory duct and mainly secrete mucus.

Composition and Functions of Saliva

The salivary glands produce 1.0–1.5 liters of **saliva** each day. About 70% of saliva comes from the submandibular glands. Another 25% comes from the parotid glands, and 5% from the sublingual glands.

Saliva is 99.4% water. The remaining 0.6% includes electrolytes (mainly Na^+ , Cl^- , and HCO_3^-), buffers, glycoproteins, antibodies, enzymes, and wastes. Mucins give saliva its lubricating action.

Saliva continuously flushes the oral surfaces, helping to keep them clean. Buffers in the saliva keep the mouth pH near 7.0. They prevent the buildup of acids produced by bacteria. In addition, saliva contains antibodies (IgA) and *lysozyme*. Both help control populations of oral bacteria. A reduction in or elimination of salivary secretions—caused by radiation, emotional distress, certain drugs, sleep, or other factors—triggers a bacterial population explosion. Such a proliferation

Clinical Note Mumps

The *mumps virus* most often targets the major salivary glands, especially the parotid glands, but other organs can also be infected. Infection typically occurs at 5–9 years of age. The first exposure stimulates the production of antibodies and, in most cases, confers permanent immunity. In postpubertal males, mumps may infect the testes and cause subfertility (conception takes longer than expected) or infertility. Infection of the pancreas by the mumps virus can produce temporary or permanent diabetes. Other organ systems, including the central nervous system, are affected in severe cases. A mumps vaccine effectively confers active immunity. Widespread administration of that vaccine has almost eliminated mumps in the United States.

can rapidly result in recurring infections and progressive erosion of the teeth and gums.

The saliva produced when eating has a variety of functions, including the following:

- Lubricating the mouth
- Moistening and lubricating food in the mouth
- Dissolving chemicals that can stimulate the taste buds and provide sensory information about the food
- Beginning the digestion of complex carbohydrates before the food is swallowed. The enzyme involved is **salivary amylase**. Saliva also contains a small amount of lingual lipase secreted by the glands of the tongue.

Regulation of Salivary Secretions

The autonomic nervous system normally controls salivary secretions. Each salivary gland has parasympathetic and sympathetic innervation. The parasympathetic efferents originate in the **superior salivatory nucleus** and the **inferior salivatory nucleus** of the medulla oblongata and synapses in the submandibular and otic ganglia. Any object in the mouth can trigger a salivary reflex. It does so by stimulating receptors monitored by the trigeminal nerve (V) or taste buds innervated by cranial nerve VII, IX, or X. Parasympathetic stimulation speeds up secretion by all the salivary glands. As a result, large amounts of saliva are produced. The role of sympathetic innervation is unclear. Evidence suggests that it provokes the secretion of small amounts of very thick saliva.

The salivatory nuclei are also influenced by other brainstem nuclei, as well as by the activities of higher centers. For example, chewing with an empty mouth, smelling food, or even thinking about food increases salivation. That is why chewing gum keeps the mouth moist. Irritating stimuli in the esophagus, stomach, or intestines also speed up production of saliva, as does nausea. Increased saliva production in response to unpleasant stimuli helps reduce the stimulus by dilution, rinsing, or buffering strong acids or bases.

Mechanical Digestion: Mastication (Chewing)

During **mastication**, food is forced from the oral cavity to the vestibule and back, crossing and recrossing the occlusal surfaces of the teeth. This movement results in part from the action of the *muscles of mastication*, which close the jaws and slide or rock the lower jaw from side to side. The complicated process of mastication can involve any combination of mandibular elevation/depression, protrusion/retraction, and medial/lateral movement. Control would be impossible, however, without help from the muscles of the cheeks, lips, and tongue.

Mastication breaks down tough connective tissues in meat and the plant fibers in vegetables. It also helps saturate the food with salivary secretions and enzymes. Once the food is a satisfactory consistency, the tongue compacts it into a moist, cohesive **bolus** that is easy to swallow.

We have now discussed how mechanical and chemical digestion occur in the oral cavity. However, chemical digestion is not completed in the oral cavity because no absorption of nutrients takes place across the oral epithelium. Let's move on to more structures of the digestive tract.

✓ Checkpoint

8. Name the structures associated with the oral cavity.
9. Which type of epithelium lines the oral cavity?
10. The digestion of which nutrient would be affected by damage to the parotid salivary glands?
11. Which type of tooth is most useful for chopping off bits of rigid food?
12. Where are the fauces located?

See the blue Answers tab at the back of the book.

24-3 The pharynx and esophagus are passageways that transport the food bolus from the oral cavity to the stomach

Learning Outcome Describe the structure and functions of the pharynx and the esophagus.

The **pharynx** (FAR-ingks), or throat, is an anatomical space that serves as a common passageway for solid food, liquid, and air. Food normally passes through parts of the pharynx on its way to the esophagus. The **esophagus** is a hollow muscular tube that then conveys these ingested materials to the stomach.

The Pharynx

We described the regions of the pharynx—the nasopharynx, oropharynx, and laryngopharynx—in Chapter 23. These regions have a lining of stratified squamous epithelium similar to that of the oral cavity. The lamina propria contains scattered mucous glands and the lymphatic tissue of the pharyngeal, palatal, and lingual tonsils. Deep to the lamina propria lies a dense layer of elastic fibers, bound to the underlying skeletal muscles. Specific pharyngeal muscles work with muscles of the oral cavity to start swallowing, which pushes the bolus into the esophagus on its way to the stomach.

The Esophagus

Unlike the pharynx, the esophagus actively moves ingested materials down toward the stomach. Let's look at how its structure allows this function, and how this transport occurs.

Gross Anatomy of the Esophagus

The esophagus is approximately 25 cm (10 in.) in length and has a diameter of about 2 cm (0.80 in.) at its widest point. The esophagus begins posterior to the cricoid cartilage, at the level of vertebra C₆. It is narrowest at this point. The esophagus descends toward the thoracic cavity posterior to the trachea, continuing inferiorly along the posterior wall of the mediastinum. It then enters the abdominopelvic cavity through the **esophageal hiatus** (hī-ā-tus), an opening in the diaphragm. The esophagus empties into the stomach anterior to vertebra T₇.

Histology of the Esophagus

The wall of the esophagus contains a mucosa, submucosa, and muscular layer comparable to those shown in **Figure 24–3**. Distinctive features of the esophageal wall include the following (**Figure 24–10**):

- The mucosa of the esophagus contains a nonkeratinized, stratified squamous epithelium similar to that of the pharynx and oral cavity.
- The mucosa and submucosa are packed into large folds that extend the length of the esophagus. These longitudinal folds allow for expansion during the passage of a large bolus. Muscle tone in the walls keeps the lumen closed, except when swallowing.
- The muscularis mucosae consists of an irregular layer of smooth muscle.

- The submucosa contains scattered *esophageal glands*. They produce mucus that reduces friction between the bolus and the esophageal lining.
- The muscular layer has the usual inner circular and outer longitudinal layers. However, in the superior third of the esophagus, these layers contain skeletal muscle fibers. The middle third contains a mixture of skeletal and smooth muscle tissue. Along the inferior third, only smooth muscle occurs.
- An adventitia of connective tissue outside the muscular layer anchors the esophagus to the posterior body wall. Over the 1–2 cm (0.4–0.8 in.) distance between the diaphragm and stomach, the esophagus is retroperitoneal. Peritoneum covers the anterior and left lateral surfaces.

Physiology of the Esophagus

The esophagus is innervated by parasympathetic and sympathetic fibers from the esophageal plexus. Resting muscle tone in the circular muscle layer in the superior 3 cm (1.2 in.) of the esophagus normally prevents air from entering the esophagus. A comparable zone at the inferior end of the esophagus normally remains in a state of active contraction. This state prevents the backflow (reflux) of materials from the stomach into the esophagus. Neither region has a well-defined sphincter muscle. Nevertheless, we often use the terms *upper esophageal sphincter* and *lower esophageal sphincter* (*cardiac sphincter*) to describe these regions, which are similar in function to other sphincters.

Figure 24–10 Anatomy of the Esophagus.

Ingestion: Deglutition (Swallowing)

Deglutition (dē-glū-TISH-un), or swallowing, is a complex process. We divide swallowing into buccal, pharyngeal, and esophageal phases, detailed in **Figure 24–11**. When swallowing, different pharyngeal muscles work together to prevent food or drink from entering the glottis. Food is crushed and chewed into a bolus before being swallowed. When food is ready to be swallowed, the *palatal muscles* elevate the soft palate and adjacent portions of the pharyngeal wall. Muscles of the neck and pharynx, the *palatopharyngeus* and *stylopharyngeus*, then elevate the larynx. This bends the epiglottis over the glottis, so that the bolus can glide across the epiglottis rather than falling into the larynx. The *pharyngeal constrictor muscles* push the bolus toward and into the esophagus. While this movement is under way, the glottis is closed.

It takes less than a second for the pharyngeal muscles to propel the bolus into the esophagus. During this period, the respiratory centers are inhibited and breathing stops. Swallowing takes place at regular intervals as saliva collects at the back of the mouth. Each day, a person swallows approximately 2400 times.

Deglutition can be initiated voluntarily when one eats or drinks, but it proceeds automatically once it begins. The **swallowing reflex** begins when tactile receptors on the palatal arches and uvula are stimulated by the passage of the bolus. The information is relayed to the **swallowing center** of the medulla oblongata over the trigeminal nerves (V) and glossopharyngeal nerves (IX). Motor commands from this center then signal the pharyngeal musculature, producing a coordinated and stereotyped pattern of muscle contraction.

Primary peristaltic waves are peristaltic movements coordinated by afferent and efferent fibers in the glossopharyngeal nerves (IX) and vagus nerves (X). For a typical bolus, the entire trip along the esophagus takes about 9 seconds. Liquids may make the journey in a few seconds, flowing ahead of the peristaltic contractions with the assistance of gravity.

A dry or poorly lubricated bolus moves much more slowly. A series of *secondary peristaltic waves* may be required to push it all the way to the stomach. Secondary peristaltic waves are local reflexes triggered by the stimulation of sensory receptors in the esophageal walls.

✓ Checkpoint

13. Describe the structure and function of the pharynx.
14. Name the structure connecting the pharynx to the stomach.
15. Compared to other segments of the digestive tract, what is unusual about the muscular layer of the esophagus?
16. Identify the muscles associated with the pharynx and deglutition.
17. What process is occurring when the soft palate and larynx elevate and the glottis closes?

See the blue Answers tab at the back of the book.

Figure 24–11 The Process of Deglutition (Swallowing).

This sequence, based on a series of x-rays, shows the phases of swallowing and the movement of a bolus from the mouth to the stomach.

Tips

Just as security gates control the passage of people by opening and closing, sphincters control the passage of material through them by dilating and constricting.

24-4 The stomach is a J-shaped organ that receives the bolus and aids in its chemical and mechanical digestion

Learning Outcome Describe the anatomy of the stomach, including its histology, and discuss its roles in digestion and absorption.

The **stomach** is an expandable tubelike organ found in the upper left quadrant of the peritoneal cavity. The major functions of the stomach are to (1) temporarily store ingested food received from the esophagus, (2) mechanically digest food through muscular contractions, and (3) chemically digest food through the action of acid and enzymes. Ingested substances combine with the secretions of the stomach glands, producing a viscous, acidic, soupy mixture of partially digested food called **chyme** (KĪM). This section examines the anatomy of the stomach and then details these important functions.

Gross Anatomy of the Stomach

The stomach has the shape of an expanded J (**Figure 24-12**). A short **lesser curvature** forms the medial surface of the organ, and a long **greater curvature** forms the lateral surface. The anterior and posterior surfaces are rounded. The shape and size of the stomach can vary greatly from person to person and even from one meal to the next. In an “average” stomach, the lesser curvature is approximately 10 cm (4 in.) long, and the greater curvature measures about 40 cm (16 in.). The stomach typically extends between the levels of vertebrae T₇ and L₃.

We divide the stomach into the following four regions (**Figure 24-12**):

- **The Cardia.** The **cardia** (KAR-dē-uh) is the smallest region of the stomach. It consists of the superior, medial portion of the stomach within 3 cm (1.2 in.) of the junction between the stomach and the esophagus. The cardia contains abundant mucous glands. Their secretions coat the connection with the esophagus and help protect that tube from the acid and enzymes of the stomach.
- **The Fundus.** The **fundus** is the region of the stomach that is superior to the junction between the stomach and the esophagus. The fundus contacts the inferior, posterior surface of the diaphragm (**Figure 24-12a**).

- **The Body.** The area of the stomach between the fundus and the curve of the J is the **body**, the largest region of the stomach. The body acts as a mixing tank for ingested food and secretions produced in the stomach.
- **The Pyloric Part.** The **pyloric part** (pĪ-LOR-ick; *pyloros*, gatekeeper) forms the portion of the stomach between the body and the duodenum (first segment of the small intestine). It is divided into a **pyloric antrum**, which is connected to the body, a **pyloric canal**, which empties into the duodenum, and the **pylorus** (pĪ-LOR-us), which is the muscular tissue surrounding the **pyloric orifice** (stomach outlet).

During digestion, the shape of the pyloric part changes often. A thickening of the circular layer of muscle within the pylorus, called the **pyloric sphincter**, regulates the release of chyme into the duodenum.

The stomach’s volume increases while eating and then decreases as chyme enters the small intestine. When the stomach is relaxed (empty), the mucosa has prominent longitudinal folds called **rugae** (RŪ-gē; wrinkles). These temporary features let the gastric lumen expand (**Figure 24-12b**). The stomach can stretch up to 50 times its empty size. As the stomach fills, the rugae gradually flatten out until, at maximum distension, they almost disappear. (The world record, set in 2021, for eating hot dogs with buns was 76 in 10 minutes!) When empty, the stomach resembles a muscular tube with a narrow, constricted lumen. When full, it can contain 1–1.5 liters of material.

Tips

Both circular folds and rugae allow a large surface area to fit within a small volume, just as crumpling a sheet of paper rearranges its surface area so that it occupies a smaller space.

The muscularis mucosae and muscular layer of the stomach contain extra layers of smooth muscle cells in addition to the usual circular and longitudinal layers. The muscularis mucosae generally contain an outer, circular layer of muscle cells. The muscular layer has an inner, **oblique layer** of smooth muscle (**Figure 24-12b**). The extra layers of smooth muscle strengthen the stomach wall and assist in the mixing and churning essential to the formation of chyme.

Histology of the Stomach

Simple columnar epithelium lines all portions of the stomach (**Figure 24-13a**). The epithelium is a *secretory sheet*, which produces a carpet of mucus that covers the interior surface of the stomach. The alkaline mucous layer protects epithelial cells against the acid and enzymes in the gastric lumen.

Figure 24-12 Gross Anatomy of the Stomach.**a** The position and external appearance of the stomach, showing superficial landmarks**b** The structure of the stomach wall

Name the region of the stomach that connects to the esophagus.

Figure 24–13 Histology of the Stomach Lining.

Shallow depressions called **gastric pits** open onto the gastric surface (**Figure 24–13b**). The mucous cells at the base, or *neck*, of each gastric pit actively divide, replacing superficial cells that are shed into the chyme. A typical gastric epithelial cell has a life span of 3 to 7 days. Exposure to alcohol or other chemicals that damage or kill epithelial cells increases cell turnover.

Secretory Glands and Gastric Secretions

The gastric epithelium contains several types of glands that produce secretions needed for the function of the stomach. *Gastric* (*gaster*, stomach) *glands* in the fundus and body secrete most of the acid and enzymes involved in gastric digestion. Glands in the pyloric part secrete mucus and important digestive hormones, including *gastrin*, a hormone that stimulates gastric glands.

Clinical Note Gastritis and Peptic Ulcers

A superficial inflammation of the gastric mucosa is called *gastritis* (gas-TRĭ-tis). The condition can develop after a person has swallowed drugs, including alcohol and aspirin. Gastritis is also associated with smoking, severe emotional or physical stress, bacterial infection of the gastric wall, or ingestion of strongly acidic or alkaline chemicals. Over time, gastritis can lead to the erosion of the stomach or duodenal lining, and a *peptic ulcer* may form.

Gastric Glands and Gastric Juice

In the fundus and body of the stomach, each gastric pit communicates with several **gastric glands**, which extend deep into the underlying lamina propria (**Figure 24–13b**). Gastric glands are dominated by two types of secretory cells: *parietal cells* and *chief cells*. Together, they secrete about 1500 mL (1.6 qt) of **gastric juice** each day.

Parietal cells are especially common along the proximal portions of each gastric gland (**Figure 24–13b**). These cells secrete **intrinsic factor**, a glycoprotein that helps absorb vitamin B₁₂ across the intestinal lining.

Parietal cells also indirectly secrete *hydrochloric acid* (HCl). They do not produce HCl in the cytoplasm. This acid is so strong that it would erode a secretory vesicle and destroy the cell. Instead, these cells create the conditions for increasing the concentrations of both H⁺ and Cl[−], the two dissociation products of HCl. Each ion exits parietal cells independently and by different mechanisms (**Figure 24–14**).

In the process of H⁺ production, carbonic acid is formed within parietal cells. The dissociation of carbonic acid releases bicarbonate and hydrogen ions (1). The bicarbonate ions are exchanged for Cl[−] from the interstitial fluid (2). When gastric glands are actively secreting, enough bicarbonate ions diffuse into the bloodstream from the interstitial fluid to increase the pH of the blood significantly. This sudden influx of bicarbonate ions has been called the *alkaline tide*. The chloride ions diffuse across the parietal cell and into the lumen of the gastric gland (3), and H⁺ are actively transported there as well (4).

The hydrochloric acid produced by these processes can keep the stomach contents at pH 1.5–2.0. Although this highly acidic environment does not by itself digest chyme, it has the following important functions:

- It kills most of the microorganisms ingested with food.
- It denatures proteins and inactivates most of the enzymes in food.
- It helps break down plant cell walls and the connective tissues in meat.

An acidic environment is also necessary for the function of gastric cells called chief cells. **Chief cells** are most abundant near the base of a gastric gland (**Figure 24–13b**). These cells secrete **pepsinogen** (pep-SIN-ō-jen), an inactive proenzyme. Acid in the gastric lumen converts pepsinogen to **pepsin**, an active *proteolytic*, or protein-digesting, enzyme. Pepsin functions most effectively at a strongly acidic pH of 1.5–2.0.

In addition, the stomachs of newborn infants (but not of adults) produce **rennin**, also called *chymosin*, and **gastric lipase**. These enzymes are important for the digestion of milk. Rennin coagulates milk proteins. Gastric lipase initiates the digestion of milk fats.

Pyloric Glands, Enteroendocrine Cells, and Gastric Hormones

Glands in the pyloric part produce primarily mucous secretions, rather than enzymes or acid. In addition, several types of enteroendocrine cells are scattered among the mucus-secreting cells. These enteroendocrine cells produce at least seven hormones,

Figure 24–14 The Secretion of Hydrochloric Acid Ions.

most notably **gastrin**. Gastrin is produced by *G cells*, which are most abundant in the gastric pits of the pyloric antrum. Gastrin stimulates secretion by both parietal and chief cells, as well as contractions of the gastric wall that mix and stir the gastric contents.

The pyloric glands also contain *D cells*, which release **somatostatin**, a hormone that inhibits the release of gastrin. D cells continuously release their secretions into the interstitial fluid adjacent to the G cells. Neural and hormonal stimuli can override this inhibition of gastrin production when the stomach is preparing for digestion or is already engaged in digestion.

Several other hormones play a role in hunger and *satiety* (a feeling of not being hungry). The level of *ghrelin* (GREL-in), a hormone produced by *P/D1 cells* lining the fundic region of the stomach, increases before meals to initiate hunger. The ghrelin level decreases shortly after eating to curb appetite. Ghrelin is also antagonistic to *leptin*, a hormone derived from fat tissue that induces satiety. Another hormone from the stomach and small intestine, *obestatin*, is thought to decrease appetite and inhibit thirst. The same gene encodes both ghrelin and obestatin.

Tips

The stomach squeezes chyme into the small intestine just like squeezing cake frosting out of a pastry bag.

Physiology of the Stomach: Chemical Digestion

The stomach is a holding tank in which food is saturated with gastric juices and exposed to stomach acid and the digestive effects of pepsin. When ingested food reaches the stomach, salivary amylase and lingual lipase continue the digestion of carbohydrates and lipids. These enzymes continue to work until the pH throughout the contents of the stomach falls below 4.5. They generally remain active 1 to 2 hours after a meal.

As the stomach contents become more fluid and the pH approaches 2.0, the preliminary digestion of proteins by pepsin increases. Protein digestion is not completed in the stomach, because time is limited and pepsin acts on only specific types of peptide bonds, not all of them. However, pepsin generally has enough time to break down complex proteins into smaller peptide and polypeptide chains before the chyme enters the duodenum.

Although partial or limited chemical digestion takes place in the stomach, nutrients are not absorbed there. This is because (1) the mucus covering the epithelial cells means that they are not directly exposed to chyme, (2) the epithelial cells lack the specialized transport mechanisms of cells that line the small intestine, (3) the gastric lining is somewhat impermeable to water, and (4) digestion has not been completed by the time chyme leaves the stomach. At this stage, most carbohydrates, lipids, and proteins are only partially broken down.

Some drugs can be absorbed in the stomach. For example, ethyl alcohol can diffuse through the mucous barrier and penetrate the lipid membranes of the epithelial cells. As a result, alcohol is absorbed in the stomach before any nutrients in a meal reach the bloodstream. Meals containing large amounts of fat slow the rate of alcohol absorption. Why? The reason is that alcohol is lipid soluble, and some of it is dissolved in fat droplets in the chyme. Aspirin is another lipid-soluble drug that can enter the bloodstream across the gastric mucosa. Such drugs alter the properties of the mucous layer and can promote epithelial damage by stomach acid and enzymes. Prolonged use of aspirin can cause gastric bleeding, so individuals with stomach ulcers are usually advised to avoid aspirin.

Regulation of Gastric Activity in Phases of Digestion

The production of acid and enzymes by the gastric mucosa can be controlled by the CNS; regulated by short reflexes of the enteric nervous system, coordinated in the wall of the stomach; and regulated by hormones of the digestive tract. Gastric control proceeds in three overlapping phases. They are named according to the location of the control center: the *cephalic phase*, the *gastric phase*, and the *intestinal phase*. Study **Spotlight Figure 24–15** carefully before moving on.

Checkpoint

18. Name the four major regions of the stomach.
19. Discuss the significance of the low pH in the stomach.
20. How does a large meal affect the pH of blood leaving the stomach?
21. When a person has chronic gastric ulcers, the branches of the vagus nerves that supply the stomach are sometimes cut to provide relief. Why might this be an effective treatment?

See the blue Answers tab at the back of the book.

24-5 Accessory digestive organs, such as the pancreas and liver, produce secretions that aid in chemical digestion

Learning Outcome Describe the structure, functions, and regulation of the accessory digestive organs.

The pancreas provides digestive enzymes, as well as buffers that help neutralize chyme. The liver secretes *bile*, a solution stored in the gallbladder for discharge into the small intestine. Bile contains buffers and *bile salts*, compounds that facilitate the digestion and absorption of lipids. Let's study these accessory organs and their functions in more detail.

The duodenum plays a key role in controlling digestive function because it monitors the contents of the chyme and adjusts the activities of the stomach and accessory glands to protect the absorptive surfaces of the jejunum. This pivotal role of the duodenum is apparent when you consider the three phases of gastric secretion. The phases are named according to the location of the control center involved.

1

CEPHALIC PHASE

The **cephalic phase** of gastric secretion begins with the sight, smell, taste, or thought of food. This phase, which is directed by the CNS, prepares the stomach to receive food. The neural output proceeds by way of the parasympathetic division of the autonomic nervous system. The vagus nerves (X) innervate the submucosal plexus of the stomach. Next, postganglionic parasympathetic fibers innervate mucous cells, chief cells, parietal cells, and G cells of the stomach. In response to stimulation, gastric juice production speeds up, reaching rates of about 500 mL/h, or about 2 cups per hour. This phase generally lasts only minutes.

Emotional states can exaggerate or inhibit the cephalic phase. For example, anger or stress increases gastric secretion, while anxiety or fear decreases gastric secretion and gastric contractions, or *motility*.

2

GASTRIC PHASE

The **gastric phase** begins with the arrival of food in the stomach and builds on the stimulation provided during the cephalic phase. This phase may continue for three to four hours while the acid and enzymes process the ingested materials. The stimuli that initiate the gastric phase are (1) distension of the stomach, (2) an increase in the pH of the gastric contents, and (3) the presence of undigested materials in the stomach, especially proteins and peptides. The gastric phase consists of the following mechanisms:

Local Response

Distension of the gastric wall stimulates the release of histamine in the lamina propria, which binds to receptors on the parietal cells and stimulates acid secretion.

Neural Response

The stimulation of stretch receptors and chemoreceptors triggers short reflexes coordinated in the submucosal and myenteric plexuses. This in turn activates the stomach's secretory cells. The stimulation of the myenteric plexus produces powerful contractions called **mixing waves** in the muscularis externa.

Hormonal Response

Neural stimulation and the presence of peptides and amino acids in chyme stimulate the secretion of the hormone gastrin, primarily by G cells. Gastrin travels in the bloodstream to parietal and chief cells, whose increased secretions reduce the pH of the gastric juice. In addition, gastrin also stimulates gastric motility.

3

INTESTINAL PHASE

The **intestinal phase** of gastric secretion begins when chyme first enters the small intestine. The function of the intestinal phase is to control the rate of gastric emptying to ensure that the secretory, digestive, and absorptive functions of the small intestine can proceed with reasonable efficiency. Although here we consider the intestinal phase as it affects stomach activity, the arrival of chyme in the small intestine also triggers other neural and hormonal events that coordinate the activities of the intestinal tract, pancreas, liver, and gallbladder.

Neural Responses

Chyme leaving the stomach decreases the distension in the stomach, thereby reducing the stimulation of stretch receptors. Distension of the duodenum by chyme stimulates stretch receptors and chemoreceptors that trigger the **enterogastric reflex**. This reflex inhibits both gastrin production and gastric contractions and stimulates the contraction of the pyloric sphincter, which prevents further discharge of chyme. At the same time, local reflexes at the duodenum stimulate mucus production, which helps protect the duodenal lining from the arriving acid and enzymes.

Hormonal Responses

The arrival of chyme in the duodenum triggers hormonal responses:

- Arrival of lipids and carbohydrates stimulates the secretion of cholecystokinin (CCK) and gastric inhibitory peptide (GIP).
- A decrease in pH below 4.5 stimulates the secretion of secretin.
- Partially digested proteins in the duodenum stimulate G cells that secrete gastrin, which circulates to the stomach and accelerates gastric processing.

CENTRAL REFLEXES

Two central reflexes, the gastroenteric reflex and gastroileal reflex, are also triggered by the stimulation of stretch receptors in the stomach wall as it fills. These reflexes accelerate movement along the small intestine while the enterogastric reflex controls the rate of chyme entry into the duodenum.

In general, the rate of movement of chyme into the small intestine is highest when the stomach is greatly distended and the meal contains little protein. A large meal containing small amounts of protein, large amounts of carbohydrates (such as rice or pasta), wine (alcohol), or after-dinner coffee (caffeine) will exit the stomach quickly. One reason is that both alcohol and caffeine stimulate gastric secretion and motility.

The **vomiting reflex** occurs in response to irritation of the fauces, pharynx, esophagus, stomach, or proximal segment of the small intestine. These sensations are relayed to the vomiting center of the medulla oblongata, which coordinates motor responses. In preparation for vomiting, the pyloric sphincter relaxes and the contents of the duodenum are discharged back into the stomach by strong peristaltic waves that travel toward the stomach. Vomiting, or **emesis** (EM-e-sis), then occurs as the gastroesophageal sphincter relaxes and the stomach regurgitates its contents through the esophagus and pharynx and out through the mouth.

The Pancreas

The **pancreas** lies posterior to the stomach. It extends laterally from the duodenum toward the spleen. The pancreas is primarily an exocrine organ that produces digestive enzymes and buffers.

Gross Anatomy of the Pancreas

The pancreas is an elongate, pinkish-gray organ about 15 cm (6 in.) long and weighing about 80 g (3 oz.) (**Figure 24–16a**). The broad **head** of the pancreas lies within the loop formed by the duodenum as it leaves the pyloric part. The slender **body** of the pancreas extends toward the spleen, and the **tail** is short and bluntly rounded. The pancreas is retroperitoneal and is firmly bound to the posterior wall of the abdominal cavity. The surface of the pancreas has a lumpy, lobular texture. A thin, transparent capsule of connective tissue wraps the entire organ. The pancreatic lobules, associated blood vessels, and excretory ducts are visible through the anterior capsule and the overlying layer of peritoneum. Arterial blood reaches the pancreas by way of branches of the splenic, superior mesenteric, and

common hepatic arteries. The pancreatic arteries and pancreaticoduodenal arteries are the major branches from these vessels. The splenic vein and its branches drain the pancreas.

The large **pancreatic duct** delivers the secretions of the pancreas to the duodenum. (In 3–10% of the population, a small *accessory pancreatic duct* branches from the pancreatic duct.) The pancreatic duct extends within the attached mesentery to reach the duodenum, where it meets the *bile duct* from the liver and gallbladder (look ahead to **Figure 24–19b**). The two ducts then empty into the *duodenal ampulla*, a chamber located roughly halfway along the length of the duodenum. When present, the accessory pancreatic duct usually empties into the duodenum independently, outside the duodenal ampulla.

Histology of the Pancreas

Partitions of connective tissue divide the interior of the pancreas into distinct lobules. The blood vessels and tributaries of the pancreatic ducts are located within these connective tissue

Figure 24–16 Anatomy of the Pancreas.

septa (**Figure 24-16b**). The pancreas is an example of a *compound tubulo-alveolar gland*, a structure described in Chapter 4. In each lobule, the ducts branch repeatedly before ending in pockets called **pancreatic acini** (AS-ih-nī). Each pancreatic acinus is lined with simple cuboidal epithelium. *Pancreatic islets*, the endocrine tissues of the pancreas, are scattered among the acini (**Figure 24-16c**). The islets account for only about 1% of the cell population of the pancreas.

Pancreatic Secretions

The pancreas has two distinct functions, one endocrine and the other exocrine. The endocrine cells of the pancreatic islets secrete insulin and glucagon into the bloodstream to control blood sugar. The exocrine cells include the acinar cells and the epithelial cells that line the duct system. Together, these exocrine cells secrete **pancreatic juice**—an alkaline mixture of digestive enzymes, water, and ions—into the small intestine. Acinar cells secrete pancreatic enzymes, which do most of the digestive work in the small intestine. Pancreatic enzymes break down ingested materials into small molecules suitable for absorption. The water and ions, secreted primarily by the cells lining the pancreatic ducts, help dilute and neutralize acid in the chyme.

Physiology of the Pancreas

Each day, the pancreas secretes about 1000 mL (about 1 quart) of pancreatic juice. Hormones from the duodenum control these secretory activities. When chyme arrives in the duodenum, it releases the hormone *secretin*. This hormone triggers the pancreatic secretion of a watery buffer solution with a pH of 7.5–8.8. Among its other components, the secretion contains bicarbonate and phosphate buffers that help raise the pH of the chyme.

Another duodenal hormone, *cholecystokinin* (CCK), stimulates the production and secretion of pancreatic enzymes. Stimulation by the vagus nerves (X) also increases the secretion of pancreatic

enzymes. Recall that this stimulation takes place during the cephalic phase of gastric regulation, so the pancreas starts to synthesize enzymes before food even reaches the stomach. This head start is important because enzyme synthesis takes much longer than the production of buffers. By starting early, the pancreatic cells are ready to meet the demand when chyme arrives in the duodenum.

The pancreatic enzymes include the following:

- **Pancreatic alpha-amylase**, a **carbohydrase** (kar-bō-Hī-drās)—an enzyme that breaks down certain starches. Pancreatic alpha-amylase is almost identical to salivary amylase.
- **Pancreatic lipase**, which breaks down certain complex lipids, releasing products (such as fatty acids) that can be easily absorbed.
- **Nucleases**, which break down RNA or DNA.
- **Proteolytic enzymes**, which break apart proteins. These enzymes include **proteases**, which break apart large protein complexes, and **peptidases**, which break small peptide chains into individual amino acids.

Proteolytic enzymes account for about 70% of total pancreatic enzyme production. These enzymes are secreted as inactive proenzymes. They are activated only after they reach the small intestine. (Proenzymes discussed in previous chapters include pepsinogen, angiotensinogen, plasminogen, fibrinogen, and many of the clotting factors and enzymes of the complement system.) As in the stomach, the release of a proenzyme rather than an active enzyme protects the secretory cells from the destructive effects of their own products. Among the proenzymes secreted by the pancreas are **trypsinogen** (trip-SIN-ō-jen), **chymotrypsinogen** (kī-mo-trip-SIN-ō-jen) **procarboxypeptidase** (prō-kar-bok-sē-PEP-ti-dās), and **proelastase** (pro-ē-LAS-tās).

Inside the duodenum, trypsinogen is converted to **trypsin**, an active protease. Trypsin then activates the other proenzymes, producing **chymotrypsin**, **carboxypeptidase**, and **elastase**. Each enzyme breaks peptide bonds linking specific amino acids and ignores others. Together, these enzymes break down proteins into a mixture of dipeptides, tripeptides, and amino acids.

Clinical Note Pancreatitis

Pancreatitis (pan-krē-a-Tī-tis) is an inflammation of the pancreas. The condition is extremely painful. The factors that may produce it include a blockage of the excretory ducts, bacterial or viral infections, ischemia, and drug reactions—especially those involving alcohol. These stimuli provoke a crisis by injuring exocrine cells in at least a portion of the organ. Then lysosomes in the damaged cells release enzymes causing autolysis (self-digestion of cells), which spreads to surrounding normal cells. In most cases, only a portion of the pancreas is affected. The condition usually subsides in a few days. But in 10–15% of cases, the process continues and may ultimately destroy the pancreas. If the islet cells are damaged, diabetes mellitus may result.

The Liver

The **liver** is the largest visceral organ, a firm, reddish-brown organ weighing about 1.5 kg (3.3 lb). Most of its mass lies in the right hypochondriac and epigastric regions, but it may extend into the left hypochondriac and umbilical regions as well. The versatile liver performs essential metabolic and synthetic functions.

Gross Anatomy of the Liver

Most of surface of the liver is wrapped in a tough fibrous capsule and is covered by a layer of visceral peritoneum. On the anterior surface, the **falciform ligament** marks the division between the organ's left and right lobes (**Figure 24-17a,b**). A thickening in the posterior margin of the falciform ligament

Figure 24–17 Gross Anatomy of the Liver.

is the **round ligament**, or *ligamentum teres*. This fibrous band marks the path of the fetal umbilical vein.

On the posterior surface of the liver, the impression left by the inferior vena cava marks the division between the right lobe and the small **caudate** (KAU-dāt) **lobe** (Figure 24–17c). Inferior to the caudate lobe lies the **quadrate lobe**, sandwiched between the left lobe and the gallbladder. Afferent blood vessels and other structures reach the liver by traveling within the connective tissue of the lesser omentum. They converge at a region called the **porta hepatis** (“doorway to the liver”).

We discussed the circulation to the liver in Chapter 21 and summarized it in Figures 21–24 and 21–31. Nearly one-third of the blood supply to the liver is arterial blood from the hepatic artery proper. The rest is venous blood from the hepatic portal vein. Liver cells, called **hepatocytes** (HEP-ah-tō-sīts), adjust circulating levels of nutrients through selective absorption and secretion. The blood leaving the liver returns to the systemic

+ Clinical Note Liver Disease

Any condition that severely damages the liver is a serious threat to life. The liver has a high capacity to regenerate itself after injury. Even so, liver function does not fully recover unless the normal vascular pattern is restored. Examples of important types of liver disease include **cirrhosis** (sih-RŌ-sis), which is characterized by fibrous tissue replacing lobules, and various forms of **hepatitis** caused by viral infections. In some cases, liver transplants are used to treat liver failure. However, the supply of suitable donor tissue is limited. The success rate is highest in young, otherwise healthy individuals. A form of “liver dialysis” known as extra-corporeal liver assist device (ELAD) is beneficial for individuals with liver failure or chronic liver disease.

circuit through the hepatic veins. These veins open into the inferior vena cava.

Histology of the Liver

Connective tissue divides each lobe of the liver into approximately 100,000 liver **lobules**, the basic functional units of the liver. The histological organization and structure of a typical liver lobule are shown in **Figure 24–18**.

Each lobule is roughly 1 mm in diameter. Adjacent lobules are separated by an *interlobular septum*. The hepatocytes in

a liver lobule form a series of irregular plates arranged like the spokes of a wheel (**Figure 24–18a,b**). The plates are only one cell thick. Exposed hepatocyte surfaces are covered with short microvilli. Within a lobule, sinusoids between adjacent plates empty into the **central vein**. (We introduced sinusoids in Chapter 21.) The liver sinusoids lack a basement membrane, so large openings between the endothelial cells allow solutes—even those as large as plasma proteins—to pass out of the bloodstream and into the spaces surrounding the hepatocytes.

Figure 24–18 Histology of the Liver.

The lining of the sinusoids contains typical endothelial cells and many **stellate macrophages** (*Kupffer cells*). These phagocytic cells are part of the monocyte–macrophage system. They engulf pathogens, cell debris, and damaged blood cells. Stellate macrophages also store iron, some lipids, and heavy metals (such as tin or mercury) that are absorbed by the digestive tract.

The Hepatic Portal System. Blood enters the liver sinusoids from small branches of the hepatic portal vein and hepatic artery proper. A typical liver lobule has a hexagonal shape in cross section (**Figure 24–18a**). There are six **portal triads**, one at each corner of the lobule. A portal triad contains three structures: (1) an interlobular vein, (2) an interlobular artery, and (3) an interlobular bile duct (**Figure 24–18a,b,c**).

Branches from the arteries and veins deliver blood to the sinusoids of adjacent liver lobules (**Figure 24–18a,b**). As blood flows through the sinusoids, hepatocytes absorb solutes from the plasma and secrete materials such as plasma proteins. Blood then leaves the sinusoids and enters the central vein of the lobule. The central veins ultimately merge to form the hepatic veins, which then empty into the inferior vena cava. Liver diseases, such as the various forms of *hepatitis*, and conditions such as alcoholism, can lead to degenerative changes in the liver tissue and constriction of the circulatory supply.

Pressures in the hepatic portal system are usually low, averaging 10 mm Hg or less. This pressure can increase markedly, however, if blood flow through the liver is restricted by a blood clot or damage to the organ. Such a rise in portal pressure is called *portal hypertension*. As pressures rise, small peripheral veins and capillaries in the portal system become distended. If they rupture, extensive bleeding can take place. Portal hypertension can also force fluid into the peritoneal cavity across the serosal surfaces of the liver and viscera, producing ascites.

The Bile Duct System. The liver secretes a fluid called **bile** into a network of narrow channels between the opposing membranes of adjacent liver cells. These passageways, called **bile canaliculi**, extend outward, away from the central vein (**Figure 24–18b**). Eventually, they connect with fine bile ductules (DUK-tūlz), which carry bile to the bile ducts in the nearest portal triad area (**Figure 24–18a**). The **right** and **left hepatic ducts** (**Figure 24–19a**) collect bile from all the bile ducts of the liver lobes. These ducts unite to form the **common hepatic duct**, which leaves the liver. The bile in the common hepatic duct either flows into the *bile duct*, which empties into the duodenal ampulla, or enters the *cystic duct*, which leads to the gallbladder (**Figure 24–19a,b,c**).

The **bile duct** is formed by the union of the **cystic duct** and the common hepatic duct. The bile duct passes within the lesser omentum toward the stomach, turns, and penetrates the wall of the duodenum to meet the pancreatic duct at the duodenal ampulla (**Figure 24–19b**).

Physiology of the Liver

The liver carries out more than 200 functions. They fall into three general categories: (1) *metabolic regulation*, (2) *hematological regulation*, and (3) *bile production*. In this discussion we provide a general overview.

Metabolic Regulation. The liver is the primary organ involved in regulating the composition of circulating blood. All blood leaving the absorptive surfaces of the digestive tract enters the hepatic portal system and flows into the liver. Liver cells extract nutrients or toxins from the blood before it reaches the systemic circulation through the hepatic veins. The liver removes and stores excess nutrients. It corrects nutrient deficiencies by mobilizing stored reserves or performing synthetic activities. The liver's regulatory activities affect the following:

- **Carbohydrate Metabolism.** The liver stabilizes the blood glucose level at about 90 mg/dL. If the blood glucose level decreases, hepatocytes break down glycogen reserves and release glucose into the bloodstream. They also synthesize glucose from other carbohydrates or from available amino acids. The synthesis of glucose from other compounds is called *gluconeogenesis*. If the blood glucose level climbs, hepatocytes remove glucose from the bloodstream. They either store it as glycogen or use it to synthesize lipids that can be stored in the liver or other tissues. Circulating hormones, such as insulin and glucagon, regulate these metabolic activities.
- **Lipid Metabolism.** The liver regulates circulating levels of triglycerides, fatty acids, and cholesterol. When those levels decrease, the liver breaks down its lipid reserves and releases the breakdown products into the bloodstream. When the levels are high, the lipids are removed for storage. However, this regulation takes place only after lipid levels have risen within the general circulation, because most lipids absorbed by the digestive tract bypass the hepatic portal circulation.
- **Amino Acid Metabolism.** The liver removes excess amino acids from the bloodstream. These amino acids can be used to synthesize proteins or can be converted to lipids or glucose for energy storage.
- **Waste Removal.** When converting amino acids to lipids or carbohydrates, or when breaking down amino acids to get energy, the liver strips off the amino groups. This process is called *deamination*. Ammonia, a toxic waste product, is formed. The liver neutralizes ammonia by converting it to *urea* (yū-RE-ah), a harmless compound excreted by the kidneys. The liver also removes other waste products, circulating toxins, and drugs from the blood for inactivation, storage, or excretion.
- **Vitamin Storage.** Fat-soluble vitamins (A, D, E, and K) and vitamin B₁₂ are absorbed from the blood and stored in the

Figure 24–19 Anatomy and Physiology of the Gallbladder and Bile Ducts.

d Physiology of the gallbladder.

liver. These reserves are used when the diet has inadequate amounts of those vitamins.

- **Mineral Storage.** The liver converts iron reserves to ferritin and stores this protein–iron complex.
- **Drug Inactivation.** The liver removes and breaks down circulating drugs, limiting the duration of their effects.

When physicians prescribe a particular drug, they must consider the rate at which the liver removes that drug from the bloodstream. For example, a drug that is absorbed relatively quickly must be administered every few hours to keep the blood concentration at a therapeutic level.

Hematological Regulation. The liver receives about 25% of cardiac output. It is also the largest blood reservoir in the body. As blood passes through it, the liver performs the following functions:

- **Phagocytosis and Antigen Presentation.** Stellate macrophages in the liver sinusoids engulf old or damaged red blood cells, cellular debris, and pathogens, removing them from the bloodstream. Stellate macrophages are antigen-presenting cells (APCs) that can stimulate an immune response.
- **Synthesis of Plasma Proteins.** Hepatocytes synthesize and release most of the plasma proteins. These proteins include the albumins (which contribute to the osmotic concentration of the blood), the various types of transport proteins, clotting proteins, and complement proteins.
- **Removal of Circulating Hormones.** The liver is the primary site for the absorption and recycling of epinephrine, norepinephrine, insulin, thyroid hormones, and steroid hormones, such as the sex hormones (estrogens and androgens) and corticosteroids. The liver also absorbs *cholecalciferol* (vitamin D₃) from the blood. Liver cells then convert the cholecalciferol, which may be synthesized in the skin or absorbed in the diet, into an intermediary product, 25-hydroxy-D₃, that is released back into the bloodstream. The kidneys absorb this intermediary and use it to generate *calcitriol*, a hormone important to Ca²⁺ metabolism.
- **Removal of Antibodies.** The liver absorbs and breaks down antibodies, releasing amino acids for recycling.
- **Removal or Storage of Toxins.** The liver absorbs lipid-soluble toxins in the diet, such as the insecticide DDT (banned in the United States since 1972, but still found in the environment), and stores them in lipid deposits, where they do not disrupt cellular functions. The liver removes other toxins from the bloodstream and either breaks them down or excretes them in the bile.

Production and Functions of Bile. The liver synthesizes bile and secretes it into the lumen of the duodenum. Hormonal and neural mechanisms regulate bile secretion. Bile consists mostly of water, with minor amounts of ions, *bilirubin* (a pigment derived from hemoglobin), cholesterol, and an assortment of lipids collectively known as **bile salts**. The water and ions help dilute and buffer acids in chyme as they enter the small intestine. Bile salts are synthesized from cholesterol in the liver. Several related compounds are involved. The most abundant are derivatives of the steroids, *cholate* and *chenodeoxycholate*.

Bile salts play a role in the digestion of lipids. Most dietary lipids are not water soluble, so mechanical digestion in the stomach forms large drops containing a variety of lipids. Pancreatic lipase is not lipid soluble, so the enzymes can

interact with lipids only at the surface of a lipid droplet. The larger the droplet, the more lipids lie within it, isolated and protected from these enzymes. Bile salts break the droplets apart in a process called **emulsification** (ē-mul-sih-fih-KĀ-shun).

Emulsification creates tiny *emulsion droplets* with a superficial coating of bile salts. The formation of tiny droplets increases the total surface area available for enzymatic action. In addition, the layer of bile salts facilitates interaction between the lipids and lipid-digesting enzymes from the pancreas.

After lipid digestion has been completed, bile salts promote the absorption of lipids by the intestinal epithelium. More than 90% of the bile salts are themselves reabsorbed, primarily in the ileum of the small intestine, as lipid digestion is completed. The reabsorbed bile salts enter the hepatic portal circulation. The liver then collects and recycles them. The cycling of bile salts from the liver to the small intestine and back is called the **enterohepatic circulation** of bile.

The Gallbladder

The **gallbladder** is a hollow, pear-shaped organ that stores and concentrates bile prior to its release into the small intestine. This muscular sac is in a fossa, or recess, in the posterior surface of the liver's right lobe (**Figure 24-19a**).

Anatomy of the Gallbladder

The gallbladder is divided into three regions: (1) the **fundus**, (2) the **body**, and (3) the **neck**. The cystic duct extends from the gallbladder to the point where it unites with the common hepatic duct to form the bile duct. At the duodenum, the bile duct meets the pancreatic duct before emptying into a chamber called the **duodenal ampulla** (am-PUL-uh) (**Figure 24-19b**), which receives buffers and enzymes from the pancreas and bile from the liver and gallbladder. The duodenal ampulla opens into the duodenum at the **duodenal papilla**, a small mound. The muscular **hepatopancreatic sphincter** encircles the lumen of the bile duct and, generally, the pancreatic duct and duodenal ampulla as well.

Physiology of the Gallbladder

A major function of the gallbladder is bile storage. Bile is released into the duodenum only under the stimulation of the intestinal hormone cholecystokinin (CCK) (**Figure 24-19d**). Without CCK, the hepatopancreatic sphincter remains closed, so bile exiting the liver in the common hepatic duct cannot flow through the bile duct and into the duodenum. Instead, it enters the cystic duct and is stored within the expandable gallbladder. Whenever chyme enters the duodenum, CCK is released, relaxing the hepatopancreatic sphincter and stimulating contractions of the gallbladder that push bile into the small intestine. The amount of CCK secreted increases markedly when the chyme contains large amounts of lipids.

The gallbladder also functions in bile modification. When full, the gallbladder contains 40–70 mL of bile. The composition of bile gradually changes as it remains in the gallbladder: Much of the water is absorbed, and the bile salts and other components of bile become increasingly concentrated.

If bile becomes too concentrated, crystals of insoluble minerals and salts begin to form. These deposits are called *gallstones*. Small gallstones are not a problem if they can be flushed down the bile duct and excreted. In *cholecystitis* (kō-lē-sis-Tĭ-tis; *chole*, bile + *kystis*, bladder + *-itis*, inflammation), the gallstones are so large that they can damage the wall of the gallbladder or block the cystic duct or bile duct. In that case, the gallbladder may need to be surgically removed. This does not seriously impair digestion, because bile production continues at the normal level. However, the bile is more dilute, and its entry into the small intestine is not as closely tied to the arrival of food in the duodenum.

24-6 The small intestine primarily functions in the chemical digestion and absorption of nutrients

Learning Outcome Describe the anatomy and histology of the small intestine and explain the functions and regulation of intestinal secretions.

The **small intestine** is a long muscular tube where chemical digestion is completed and the products of digestion are absorbed. Ninety percent of nutrient absorption takes place in the small intestine (most of the rest occurs in the large intestine). This section examines the anatomy and physiology of this critical organ.

Gross Anatomy of the Small Intestine

The small intestine, also known as the *small bowel*, averages 6 m (19.7 ft) in length (range: 4.5–7.5 m; 14.8–24.6 ft). Its diameter ranges from 4 cm (1.6 in.) at the stomach to about 2.5 cm (1 in.) at the junction with the large intestine.

The small intestine fills much of the peritoneal cavity. It occupies all abdominal regions except the right and left hypochondriac and epigastric regions. Its position is stabilized by the mesentery proper, a broad mesentery attached to the posterior body wall (Figure 24-2c,d). The stomach, large intestine, abdominal wall, and pelvic girdle restrict movement of the

small intestine during digestion. Blood vessels, lymphatic vessels, and nerves reach the small intestine within the connective tissue of the mesentery. The primary blood vessels involved are branches of the superior mesenteric artery and the superior mesenteric vein.

The small intestine has three segments: the duodenum, the jejunum, and the ileum (Figure 24-20a). The **duodenum** (dū-ō-DE-num), 25 cm (10 in.) in length, is the segment closest to the stomach. This portion of the small intestine is a “mixing bowl.” It receives chyme from the stomach and digestive secretions from the pancreas and liver. From its connection with the stomach, the duodenum curves in a C that encloses the pancreas. Except for the proximal 2.5 cm (1 in.), the duodenum is in a retroperitoneal position between vertebrae L₁ and L₄ (Figure 24-2d).

A rather abrupt bend marks the boundary between the duodenum and the **jejunum** (jeh-JŪ-num). At this junction, the small intestine reenters the peritoneal cavity, supported by a sheet of mesentery. The jejunum is about 2.5 m (8.2 ft) long. The bulk of chemical digestion and nutrient absorption occurs there.

The (IL-ē-um), the final segment of the small intestine, is also the longest. It averages 3.5 m (11.5 ft) in length. The ileum ends at the **ileocecal** (il-ē-ō-SE-kal) **valve**. This sphincter controls the flow of material from the ileum into the *cecum* (SE-kum) of the large intestine.

Tips

To remember the order of the small intestine segments, beginning at the stomach, use this mnemonic: **Don't jump in—duodenum, jejunum, and ileum**. Also, make sure not to confuse *ileum*, the last segment of the small intestine, with *ilium*, which is a bone.

Histology of the Small Intestine

The intestinal lining has a series of transverse folds called **circular folds** (Figure 24-20b). Unlike the rugae in the stomach, the circular folds are permanent features—they do not disappear when the small intestine fills. The small intestine contains about 800 circular folds (roughly 2 per centimeter), which greatly increase the surface area available for absorption.

The Intestinal Villi

If the small intestine were a simple tube with smooth walls, it would have a total absorptive area of about 3300 cm² (3.6 ft²). Instead, the mucosa contains circular folds. Each circular fold in turn has a series of fingerlike projections, the **intestinal villi** (Figure 24-21). The villi are covered by simple columnar epithelium that is carpeted with microvilli. The cells have a

Figure 24–20 Gross Anatomy and Segments of the Intestine.

brush border, a term that describes the microvilli projecting from the epithelium like the bristles on a brush (**Figure 24–21e**). This arrangement increases the total area for absorption by a factor of more than 600, to approximately 2 million cm² (more than 2200 ft²).

24

The lamina propria of each villus contains an extensive network of capillaries that originate in a vascular network within the submucosa (**Figure 24–21d**). These capillaries carry absorbed nutrients to the hepatic portal circulation for delivery to the liver.

In addition to capillaries and nerve endings, each villus contains a central lymphatic vessel called a **lacteal** (LAK-tē-ul; *lacteus*, milky) (**Figure 24–21b,d**). Lacteals transport materials that cannot enter blood capillaries. For example, absorbed fatty acids are assembled into protein–lipid packages that are too large to diffuse into the bloodstream. These packets, called *chylomicrons*, reach the venous circulation through the thoracic duct, which delivers lymph into the left subclavian vein. The name *lacteal* refers to the pale, milky appearance of lymph that contains large quantities of lipids.

Intestinal Glands and Their Secretions

The duodenum has numerous goblet cells, both in the epithelium and deep to it. Goblet cells between the columnar epithelial cells secrete mucins onto the intestinal surfaces

(**Figure 24–21d,e**). At the bases of the villi are the entrances to the **intestinal glands**, also called *intestinal crypts*. These glandular pockets extend deep into the underlying lamina propria. Near the base of each intestinal gland, *stem cells* divide and produce new generations of epithelial cells, which are continuously displaced toward the intestinal surface. In a few days the new cells reach the tip of a villus and are shed into the intestinal lumen. This ongoing process renews the epithelial surface. The disintegration of the shed cells adds enzymes to the lumen. **Paneth cells** at the base of the intestinal glands have a role in innate (nonspecific) immunity and release defensins and lysozyme (**Figure 24–21b,c**). These secretions kill some bacteria and allow others to live, thereby establishing the flora of the intestinal lumen. Intestinal glands also contain enteroendocrine cells that produce several intestinal hormones, including gastrin, cholecystokinin, and secretin.

In addition to intestinal glands, the intestinal submucosa contains **duodenal submucosal glands**. Duodenal submucosal glands produce copious quantities of mucus when chyme arrives from the stomach. The mucus protects the epithelium from the acidity of chyme and contains bicarbonate ions that help raise the pH of the chyme. The duodenal submucosal glands also secrete the hormone *urogastrone*, which inhibits gastric acid production and stimulates the division of epithelial stem cells along the digestive tract.

Figure 24–21 Histology of the Intestinal Wall.

Specializations of the Segments

The segments of the small intestine—the duodenum, jejunum, and ileum—are distinguished by both histological specialization and primary function. The duodenum has few circular folds, and their villi are small. The primary function of the duodenum is to receive chyme from the stomach and neutralize

its acids before they can damage the absorptive surfaces of the small intestine.

Over the proximal half of the jejunum, however, circular folds and villi are very prominent. Thereafter, the circular folds and villi gradually decrease in size. This reduction parallels a reduction in absorptive activity: Most nutrient absorption takes place before

ingested materials reach the ileum. One rather drastic surgical method of promoting weight loss is the removal of a significant portion of the jejunum. The resulting reduction in absorptive area causes a marked weight loss and may not interfere with adequate nutrition, but the side effects can be very serious.

The distal portions of the ileum lack circular folds. The lamina propria in this region contains 20–30 masses of lymphoid tissue called aggregated lymphoid nodules, or *Peyer's patches*. These lymphoid tissues are most abundant in the terminal portion of the ileum, near the entrance to the large intestine. The lymphocytes in the aggregated lymphoid nodules protect the small intestine from bacteria that normally inhabit the large intestine.

Physiology of the Small Intestine

The primary functions of the small intestine are the chemical digestion of chyme from the stomach and the absorption of nutrients across the mucosal surface. Fats are absorbed into the lymphatic system, and other nutrients enter the bloodstream.

Chemical Digestion: Intestinal Secretions and Enzymes

Roughly 1.8 liters of watery **intestinal juice** enters the intestinal lumen each day. Intestinal juice moistens chyme, helps buffer acids, and keeps both the digestive enzymes and the products of digestion in solution. Much of this fluid arrives by osmosis, as water diffuses out of the mucosa and into the concentrated chyme. The rest is secreted by intestinal glands, stimulated by the activation of touch receptors and stretch receptors in the intestinal walls.

24 The mucosa of the small intestine produces only a few of the enzymes involved in chemical digestion. The most important of the enzymes introduced into the lumen comes from the apical portions of the intestinal cells. *Brush border enzymes* are integral membrane proteins on the surfaces of intestinal microvilli. These enzymes break down materials that contact the brush border. The epithelial cells then absorb the breakdown products. Once the epithelial cells are shed, they disintegrate within the lumen, releasing both intracellular and brush border enzymes. *Enteropeptidase* (previously called *enterokinase*) is one brush border enzyme that enters the lumen in this way. It does not directly participate in digestion. Instead, it activates the key pancreatic proenzyme, trypsinogen.

The duodenal submucosal glands help protect the duodenal epithelium from gastric acids and enzymes. As chyme travels the length of the duodenum, its pH increases from 1–2 to 7–8. These glands increase their secretion in response to (1) local reflexes, (2) the release of the hormone *enterocrinin* by enteroendocrine cells of the duodenum, and (3) parasympathetic stimulation through the vagus nerves. The first two

mechanisms operate only after chyme arrives in the duodenum. However, the duodenal glands begin secreting during the cephalic phase of gastric secretion, long before chyme reaches the pyloric sphincter. They do so because vagus nerve activity triggers their secretion. Thus, the duodenal lining has protection in advance.

Sympathetic stimulation inhibits the duodenal glands, leaving the duodenal lining unprepared for the arrival of chyme. This effect probably explains why chronic stress or other factors that promote sympathetic activation can cause duodenal ulcers.

Mechanical Digestion: Intestinal Motility

After chyme has arrived in the duodenum, weak peristaltic contractions move it slowly toward the jejunum. The contractions are myenteric reflexes that are not under CNS control. Their effects are limited to within a few centimeters of the site of the original stimulus. Motor neurons in the submucosal and myenteric plexuses control these short reflexes. In addition, some of the smooth muscle cells contract periodically, even without stimulation, establishing a basic contractile rhythm that then spreads from cell to cell.

The stimulation of the parasympathetic system increases the sensitivity of the weak myenteric reflexes and speeds up both local peristalsis and segmentation. More elaborate reflexes coordinate activities along the entire length of the small intestine. The gastroenteric and gastroileal reflexes speed up movement along the small intestine (**Spotlight Figure 24–15**). This effect is the opposite from that of the **enterogastric reflex**, of which one result is constriction of the pyloric sphincter and the discharge of chyme.

Hormones released by the digestive tract can enhance or suppress reflexes. For example, the gastroileal reflex is triggered by stretch receptor stimulation. However, the degree of ileocecal valve relaxation is enhanced by gastrin, which is secreted in large quantities when food enters the stomach.

Regulation: Coordination of Secretion and Absorption in the Digestive Tract

A combination of neural and hormonal mechanisms coordinates the activities of the digestive glands. These regulatory mechanisms are centered on the duodenum, where acids must be neutralized and appropriate enzymes added.

Neural mechanisms involving the CNS prepare the digestive tract for activity (through parasympathetic innervation) or inhibit its activity (through sympathetic innervation). Neural mechanisms also coordinate the movement of materials along the length of the digestive tract (through the enterogastric, gastroenteric, and gastroileal reflexes).

In addition, motor neurons synapsing in the digestive tract release a variety of neurotransmitters. Many of these chemicals are also released in the CNS. In general, their functions are

Figure 24–22 The Secretion and Effects of Major Duodenal Hormones.

poorly understood. Examples of neurotransmitters that may be important include substance P, enkephalins, and endorphins.

We now summarize the information presented thus far on the regulation of intestinal and glandular function. We also consider some additional details about the regulatory mechanisms involved.

Secretion and Effects of Intestinal Hormones

The intestinal tract secretes a variety of peptide hormones with similar chemical structures. Many of these hormones have

multiple effects in several regions of the digestive tract, and in the accessory glandular organs as well. The origins and primary effects of these important digestive hormones are shown in **Figure 24–22**.

Other intestinal hormones are produced in relatively small quantities. Examples include *motilin*, which stimulates intestinal contractions; *villikinin*, which promotes the movement of villi and the associated lymph flow; and *somatostatin*, which inhibits gastric secretion. Functional interactions among gastrin, GIP, secretin, CCK, and VIP are diagrammed in **Figure 24–23**.

Figure 24-23 The Secretion and Effects of Major Digestive Tract Hormones. The primary effects of gastrin, GIP, secretin, CCK, and VIP are shown.

Chyme in the duodenum stimulates the secretion of what hormones in the digestive tract?

Absorption in the Small Intestine

On average, it takes about 5 hours for materials to pass from the duodenum to the end of the ileum. The first materials to enter the duodenum after eating breakfast may leave the small intestine at lunchtime.

Along the way, the organ's absorptive effectiveness is enhanced by the fact that so much of the mucosa is movable. The microvilli can be moved by their supporting

microfilaments. The intestinal villi move back and forth, exposing the epithelial surfaces to the liquefied intestinal contents. Groups of villi are moved by the muscularis mucosae, and the muscularis mucosae and the muscular layer move the circular folds. These movements stir and mix the intestinal contents, making absorption more efficient by quickly eliminating local differences in nutrient concentration.

25. Name the three regions of the small intestine from proximal to distal.
26. How is the small intestine adapted for nutrient absorption?
27. Does a high-fat meal raise or lower the level of cholecystokinin in the blood?
28. How would the pH of the intestinal contents be affected if the small intestine did not produce secretin?

See the blue Answers tab at the back of the book.

24-7 The large intestine, which is divided into three parts, absorbs water from digestive materials and eliminates the remaining waste as feces

Learning Outcome Describe the gross and histological structures of the large intestine, including its regional specializations and role in nutrient absorption.

The horseshoe-shaped **large intestine** begins at the end of the ileum and ends at the anus. The large intestine lies inferior to the stomach and liver and almost completely frames the small intestine (**Figure 24-1**). The large intestine stores digestive wastes and reabsorbs water.

Gross Anatomy and Segments of the Large Intestine

The large intestine, also known as the *large bowel*, has an average length of about 1.5 meters (4.9 ft) and a width of 7.5 cm (3 in.). We can divide it into three segments: (1) the pouchlike *cecum*, the first portion of the large intestine; (2) the *colon*, the largest portion; and (3) the *rectum*, the last 15 cm (6 in.) of the large intestine and the end of the digestive tract (**Figure 24-24a**).

The Cecum and Appendix

Material arriving from the ileum first enters an expanded pouch called the **cecum**. The ileum attaches to the medial surface of the cecum and opens into the cecum at the *ileocecal valve* (**Figure 24-24a,b**). The cecum collects and stores materials from the ileum and begins the process of compaction.

The slender, hollow **appendix**, or *vermiform appendix* (*vermis*, worm), is attached to the posteromedial surface of the cecum (**Figure 24-24a,b**). The appendix is normally about 9 cm (3.6 in.) long, but its size and shape are quite variable. A small mesentery called the **meso-appendix** connects the appendix to the ileum and cecum. The primary function of the appendix is as an organ of the lymphatic system. Lymphoid nodules dominate the mucosa and submucosa of the appendix. Inflammation of the appendix is known as *appendicitis*.

The Colon

The **colon** has a larger diameter and a thinner wall than the small intestine. Distinctive features of the colon include the following (**Figure 24-24a**):

- The wall of the colon forms a series of pouches, or **haustra** (HAWS-truh; singular, *haustrum*). The creases between the haustra affect the mucosal lining as well, producing a series of internal folds. Haustra permit the colon to expand and elongate.
- Three separate longitudinal bands of smooth muscle—called the **teniae coli** (TĒ-nĒ-Ē KŌ-lĒ)—extend along the outer surfaces of the colon just deep to the serosa. These bands correspond to the outer layer of the muscular layer in other portions of the digestive tract. Muscle tone within the teniae coli is what creates the haustra.
- The serosa of the colon contains numerous teardrop-shaped sacs of fat called **omental appendices**, or the *fatty appendices of colon*.

We can subdivide the colon into four segments: the ascending colon, transverse colon, descending colon, and sigmoid colon (**Figure 24-24a**).

1. The **ascending colon** begins at the superior border of the cecum and ascends along the right lateral and posterior wall of the peritoneal cavity to the inferior surface of the liver. There, the colon bends sharply to the left at the **right colic flexure**, or *hepatic flexure*. This bend marks the end of the ascending colon and the beginning of the transverse colon.
2. The **transverse colon** curves anteriorly from the right colic flexure and crosses the abdomen from right to left. The transverse colon is supported by the transverse mesocolon. It is separated from the anterior abdominal wall by the layers of the greater omentum. At the left side of the body, the transverse colon passes inferior to the greater curvature of the stomach. Near the spleen, the colon makes a 90° turn at the **left colic flexure**, or *splenic flexure*, and becomes the descending colon.
3. The **descending colon** proceeds inferiorly along the left side until reaching the iliac fossa formed by the inner surface of the left ilium. The descending colon is retroperitoneal and firmly attached to the abdominal wall. At the iliac fossa, the descending colon curves and becomes the sigmoid colon.
4. The **sigmoid** (SIG-moyd; *sigmeidos*, the Greek letter S) **colon** is an S-shaped segment that is only about 15 cm (6 in.) long. The sigmoid colon lies posterior to the urinary bladder, suspended from the sigmoid mesocolon. The sigmoid colon empties into the rectum.

The colon, and indeed the entire large intestine, receives blood from branches of the superior mesenteric and inferior mesenteric arteries. The superior mesenteric and inferior mesenteric veins collect venous blood from the large intestine.

Figure 24–24 Anatomy of the Large Intestine.

Clinical Note Colorectal Cancer

Colorectal cancer (colon and rectal cancer combined) is the third most common cancer in the United States. The best defense appears to be early detection (screening) and prompt treatment. Standard screening involves checking the feces for blood. This simple procedure can be performed easily on a stool (fecal) sample as part of a routine physical. For individuals at increased risk because of family history, associated disease, or older age, visual inspection of the intestinal lumen by fiberoptic colonoscopy is prudent. Such examination can find polyps before they develop into cancers. The 5-year survival rate for people whose cancer is found at an early stage and treated immediately is greater than 90%.

The Rectum

The **rectum** (REK-tum) forms the last 15 cm (6 in.) of the digestive tract (**Figure 24–24a,c**). It is an expandable organ for the temporary storage of **feces**.

The last portion of the rectum, the **anal canal**, contains small longitudinal folds called **anal columns**. The distal margins of these columns are joined by transverse folds that mark the boundary between the columnar epithelium of the proximal rectum and a stratified squamous epithelium like that in the oral cavity. The **anus** is the exit of the anal canal. There, the epidermis becomes keratinized and identical to the surface of the skin.

The circular layer of muscle in this region forms the **internal anal sphincter** (**Figure 24–24c**). The smooth muscle cells of this sphincter are not under voluntary control. The **external anal sphincter**, which guards the anus, consists of a ring of skeletal muscle fibers that encircles the distal portion of the anal canal. This sphincter is under voluntary control.

The lamina propria and submucosa of the anal canal contain a network of veins. If venous pressures there rise too high due to straining during defecation or pregnancy, the veins can become distended, producing *hemorrhoids*.

Histology of the Large Intestine

The luminal diameter of the large intestine is about three times that of the small intestine, but its wall is much thinner. Large lymphoid nodules are scattered throughout the lamina propria and submucosa. The muscular layer of the large intestine is unusual, because the longitudinal layer has been reduced to the muscular bands of the teniae coli.

The major characteristics of the colon are the lack of villi, the abundance of goblet cells, and the presence of distinctive intestinal glands (**Figure 24–25**). The glands in the large intestine are deeper than those of the small intestine and are dominated by goblet cells. The mucus provides lubrication as the fecal material becomes drier and more compact. Mucus is secreted as local stimuli, such as friction or exposure to harsh chemicals, trigger short reflexes involving local nerve plexuses.

Physiology of the Large Intestine

Any digestion that occurs in the large intestine results from enzymes introduced in the small intestine or from bacterial action. Although less than 10% of the nutrient absorption in the digestive tract occurs in the large intestine, the absorptive operations that do occur in this segment of the digestive tract are nevertheless important. The mixing and propulsive contractions of the colon resemble those of the small intestine. The large intestine also prepares fecal material for defecation.

Absorption and the Microbiome in the Large Intestine

The reabsorption of water is an important function of the large intestine. Roughly 1500 mL of material enters the colon each day, but only about 200 mL of feces is ejected. To appreciate how efficient our digestion is, consider the average composition of feces: 75% water, 5% bacteria, and the rest a mixture of indigestible materials, small quantities of inorganic matter, and the remains of epithelial cells.

In addition, the large intestine absorbs a few other substances that remain in the feces or were secreted into the digestive tract along its length. Examples include useful compounds such as bile salts and vitamins, organic wastes, and various toxins generated by bacterial action. Most of the bile salts entering the large intestine are promptly reabsorbed in the cecum and transported in blood to the liver for secretion into bile.

Bacteria that inhabit the large intestine contribute to our *microbiome*. The human **microbiome** is made up of the microbes (bacteria, fungi, and viruses) that live in and on the human body. Most of the gut bacteria live in the large intestine, where they break down nutrients not absorbed in the small intestine and produce vitamins.

Vitamins. *Vitamins* are organic molecules required in very small quantities. The normal bacterial residents of the colon generate three vitamins that are absorbed in the large intestine:

- *Vitamin K*, a fat-soluble vitamin the liver requires for synthesizing four clotting factors, including prothrombin
- *Biotin*, a water-soluble vitamin important in various reactions, notably those of glucose metabolism

Figure 24–25 Histology of the Colon.

- **Vitamin B₅** (pantothenic acid), a water-soluble vitamin required in the manufacture of steroid hormones and some neurotransmitters.

Intestinal bacteria produce about half the daily vitamin K requirements. Vitamin K deficiencies lead to impaired blood clotting. They result from either (1) not enough lipids in the diet, which impairs the absorption of all fat-soluble vitamins, or (2) problems affecting lipid processing and absorption, such as inadequate bile production or chronic diarrhea (frequent, watery bowel movements). Because the intestinal bacteria generally produce enough biotin and vitamin B₅ to supplement any dietary shortage, disorders due to deficiencies of these vitamins are extremely rare after infancy.

Organic Wastes. We discussed the fate of bilirubin, a breakdown product of heme, in Chapter 19. In the large intestine, bacteria convert bilirubin to *urobilinogens* and *stercobilinogens*. Some urobilinogens are absorbed into the bloodstream and then excreted in urine. The urobilinogens and stercobilinogens remaining within the colon are converted to **urobilins** and **stercobilins** by exposure to oxygen. These pigments in various proportions give feces a yellow-brown or brown color.

Bacterial action breaks down peptides that remain in the feces. This action generates (1) ammonia, in the form of soluble ammonium ions (NH₄⁺); (2) *indole* and *skatole*, two nitrogen-containing compounds that are primarily responsible

for the odor of feces; and (3) hydrogen sulfide (H₂S), a gas with a “rotten egg” odor. Significant amounts of ammonia and smaller amounts of other toxins cross the colonic epithelium and enter the hepatic portal circulation. The liver removes these toxins and converts them to relatively nontoxic compounds that can be released into the blood and excreted at the kidneys.

Intestinal enzymes do not alter indigestible carbohydrates, and the mucosa of the large intestine does not produce enzymes. These materials arrive in the colon virtually intact. These complex polysaccharides provide a reliable nutrient source for bacteria in the colon. The metabolic activities of these bacteria create small amounts of **flatus**, or intestinal gas. Foods with large amounts of indigestible carbohydrates (such as beans) stimulate bacterial gas production. Distension of the colon, cramps, and the frequent discharge of intestinal gases can result.

Motility of the Large Intestine and the Defecation Reflex

During eating, the gastroileal and gastroenteric reflexes move materials into the cecum. Movement from the cecum to the transverse colon is very slow, allowing hours for water absorption to convert the already thick material into a sludgy paste. Peristaltic waves move material along the length of the colon. Segmentation movements, called *haustral churning*, mix the contents of adjacent haustra. When the stomach and duodenum are distended, signals are relayed over the intestinal nerve plexuses. These signals

Figure 24–26 The Defecation Reflex.

What stimulates stretch receptors in the rectum?

cause powerful peristaltic contractions called **mass movements** that move material from the transverse colon through the rest of the large intestine. The contractions force feces into the rectum. When feces move into the rectum, the distension on the rectal wall stimulates stretch receptors, initiating the *defecation reflex*.

The rectal chamber is usually empty, except when a mass movement forces feces out of the sigmoid colon into the rectum. The defecation reflex is an involuntary response to stimuli in the lower bowel that results in a bowel movement. This reflex involves two positive feedback loops, a short *intrinsic myenteric defecation reflex* and a long *parasympathetic defecation reflex* (Figure 24–26).

- *Intrinsic Myenteric Defecation Reflex.* In this short feedback loop, afferent fibers from the stretch receptors in the rectal walls stimulate the myenteric plexus to initiate a series of increased local peristaltic contractions in the sigmoid colon and rectum. The waves of contraction move feces toward the anus and further increase distension of the rectum. When the peristaltic contractions reach the anus, the internal anal sphincter relaxes.
- *Parasympathetic Defecation Reflex.* In this long feedback loop of the enteric nervous system, the stretch receptors in the rectal walls also stimulate parasympathetic motor

Clinical Note Colonoscopy

Colonoscopy is the visual examination of the entire colon. This vital screening test can identify early colorectal cancer. A thorough preparation of the colon is required to properly evaluate the mucosal lining. One day before the procedure, the patient consumes a clear liquid diet, then takes laxatives and enemas to clear feces from the colon. After the patient is sedated in outpatient surgery, the gastroenterologist introduces a fiberoptic colonoscope (a flexible viewing tube) into the rectum and slides it back through the colon to the cecum, examining the interior and taking photos. Any lesions, such as polyps (abnormal fleshy growths), can be biopsied at the time and sent to pathology.

An initial colonoscopy is recommended after the age of 50. If the results are normal, and there are no significant risk factors, such as family history of colon cancer, the test can be repeated at 10-year intervals.

neurons in the sacral spinal cord. These neurons stimulate increased peristalsis (mass movements) in the descending colon and sigmoid colon that pushes feces toward the rectum, which further increases rectal pressure and distension. The stimulated motor neurons send efferent impulses within the pelvic nerves that cause the internal anal sphincter to relax.

Both the internal and external anal sphincters must relax for feces to be eliminated. The actual release of feces requires activation of the somatic nervous system to consciously open the external sphincter. The pudendal nerves carry the somatic motor commands. However, because the parasympathetic defecation reflex magnifies the intrinsic myenteric defecation reflex, the force generated may be great enough to cause defecation, despite consciously controlling the voluntary external anal sphincter.

If the external anal sphincter remains constricted, the peristaltic contractions cease. As more feces enter the rectum, the expansion triggers further defecation reflexes. The urge to defecate usually develops when rectal pressure reaches about 15 mm Hg. If this pressure is more than 55 mm Hg, the external anal sphincter involuntarily relaxes and defecation takes place. This mechanism causes defecation in infants and in adults with spinal cord injuries.

In addition, other consciously directed activities can increase intra-abdominal pressure and help force fecal material out of the rectum. These activities include the *Valsalva maneuver*, a tensing of the abdominal muscles and an increase in intra-abdominal pressure by exhaling forcibly with a closed glottis.

Checkpoint

29. Identify the four regions of the colon.
30. Name some major histological differences between the large intestine and the small intestine.
31. Differentiate between haustral churning and mass movements.

See the blue Answers tab at the back of the book.

24-8 Chemical digestion is the enzyme-mediated hydrolysis of food into nutrients that can be absorbed and used by the body

Learning Outcome List the nutrients required by the body, describe the chemical events responsible for the digestion of organic nutrients, and describe the mechanisms involved in the absorption of organic and inorganic nutrients.

A balanced diet contains all the ingredients needed to maintain homeostasis. These ingredients include six nutrients: carbohydrates, lipids, proteins, vitamins, minerals, and water. This section describes the chemical events involved in the processing and absorption of these nutrients.

Hydrolysis of Nutrients by Enzymes

Food contains large organic molecules, many of them insoluble. The digestive system first breaks down the physical structure of the ingested material and then disassembles the component molecules into smaller fragments. This disassembly eliminates any antigenic properties, so that the fragments do not trigger an immune response after absorption. Cells absorb the molecules released into the bloodstream and either (1) break them down to provide energy for the synthesis of ATP or (2) use these molecules to synthesize carbohydrates, proteins, and lipids. In this section we focus on the mechanics of chemical digestion and absorption. The fates of the compounds inside cells are the focus in Chapter 25.

Most ingested organic materials are complex chains, or polymers, of simpler molecules called monomers. In a typical dietary carbohydrate, the basic molecules are simple sugars. In a protein, the building blocks are amino acids. In lipids, they are generally fatty acids. And in nucleic acids, they are nucleotides. In a process called *hydrolysis*, digestive enzymes break the bonds between the component molecules of carbohydrates, proteins, lipids, and nucleic acids.

The classes of digestive enzymes differ with respect to their specific substrates. *Carbohydrases* break the bonds between simple sugars, *proteases* split the linkages between amino acids, and *lipases* separate fatty acids from glycerides. Some enzymes in each class are even more selective, breaking bonds between specific molecules. For example, a particular carbohydrase

might break the bond between two glucose molecules, but not those between glucose and another simple sugar.

Digestive enzymes secreted by the salivary glands, tongue, stomach, and pancreas are mixed into the ingested material as it passes along the digestive tract. These enzymes break down large carbohydrates, proteins, lipids, and nucleic acids into smaller fragments. These fragments in turn must be broken down even further before absorption can occur. The final enzymatic steps involve brush border enzymes, which are embedded in the exposed surfaces of intestinal microvilli.

The major digestive enzymes and their functions are summarized in **Table 24-1**. The digestive fates of carbohydrates, lipids, and proteins, the major dietary components, are shown in **Spotlight Figure 24-27**. The next section focuses on the digestion and absorption of carbohydrates, lipids, proteins, and nucleic acids.

Carbohydrate Digestion and Absorption

Carbohydrates are a large group of organic compounds, such as sugars, starch, and cellulose, found in food. Our bodies break down carbohydrates for use in cellular metabolism. This section discusses how these processes occur.

Chemical Digestion of Carbohydrates

The digestion of complex carbohydrates (simple polysaccharides and starches) proceeds in two steps. The first step involves carbohydrases produced by the salivary glands and pancreas. The second step uses brush border enzymes.

Actions of Salivary and Pancreatic Enzymes. The digestion of complex carbohydrates involves two enzymes—salivary amylase and pancreatic alpha-amylase (**Spotlight Figure 24-27**). Both enzymes function best over a pH range of 6.7–7.5. Carbohydrate

Table 24-1 Digestive Enzymes and Their Functions

Enzyme (proenzyme)	Source	Optimal pH	Substrate	Products	Remarks
CARBOHYDRASES					
Maltase, sucrase, lactase	Brush border of small intestine	7–8	Maltose, sucrose, lactose	Monosaccharides	Found in membrane surface of microvilli
Pancreatic alpha-amylase	Pancreas	6.7–7.5	Complex carbohydrates	Disaccharides and trisaccharides	Breaks bonds between sugars
Salivary amylase	Salivary glands	6.7–7.5	Complex carbohydrates	Disaccharides and trisaccharides	Breaks bonds between sugars
PROTEASES					
Carboxypeptidase (procarboxypeptidase)	Pancreas	7–8	Proteins, polypeptides, amino acids	Short-chain peptides	Activated by trypsin
Chymotrypsin (chymotrypsinogen)	Pancreas	7–8	Proteins, polypeptides	Short-chain peptides	Activated by trypsin
Dipeptidases, peptidases	Brush border of small intestine	7–8	Dipeptides, tripeptides	Amino acids	Found in membrane surface of brush border
Elastase (proelastase)	Pancreas	7–8	Elastin	Short-chain peptides	Activated by trypsin
Enteropeptidase	Brush border and lumen of small intestine	7–8	Trypsinogen	Trypsin	Reaches lumen through disintegration of shed epithelial cells
Pepsin (pepsinogen)	Chief cells of stomach	1.5–2.0	Proteins, polypeptides	Short-chain polypeptides	Secreted as proenzyme pepsinogen; activated by H ⁺ in stomach acid
Rennin	Stomach	3.5–4.0	Milk proteins		Secreted only in infants; causes protein coagulation
Trypsin (trypsinogen)	Pancreas	7–8	Proteins, polypeptides	Short-chain peptides	Proenzyme activated by enteropeptidase; activates other pancreatic proteases
LIPASES					
Lingual lipase	Glands of tongue	3.0–6.0	Triglycerides	Fatty acids and monoglycerides	Begins lipid digestion
Pancreatic lipase	Pancreas	7–8	Triglycerides	Fatty acids and monoglycerides	Bile salts must be present for efficient action
NUCLEASES					
	Pancreas	7–8	Nucleic acids	Nitrogenous bases and simple sugars	Includes ribonuclease for RNA and deoxyribonuclease for DNA

A typical meal contains carbohydrates, proteins, lipids, water, minerals, electrolytes, and vitamins. The digestive system handles each component differently. Large organic molecules must be chemically broken down before they can be absorbed. Water, minerals, and vitamins can be absorbed without processing, but they may require special transport mechanisms.

digestion begins in the mouth during mastication, through the action of salivary amylase from the parotid and submandibular salivary glands. Salivary amylase breaks down starches (complex carbohydrates) into a mixture composed mostly of *disaccharides* (two simple sugars, or *monosaccharides*, joined together) and *trisaccharides* (three monosaccharides). Salivary amylase continues to digest the starches and glycogen in food for 1 to 2 hours before stomach acids render the enzyme inactive. Only a small amount of digestion takes place over this period because the enzymatic content of saliva is not high.

In the duodenum, pancreatic alpha-amylase breaks down the remaining complex carbohydrates. Any disaccharides or trisaccharides that result, and any present in the food, are not broken down further until they contact the intestinal mucosa.

Actions of Brush Border Enzymes. Brush border enzymes of the intestinal microvilli break disaccharides and trisaccharides into monosaccharides prior to absorption. The enzyme **maltase** splits bonds between the two glucose molecules of the disaccharide **maltose**. **Sucrase** breaks the disaccharide **sucrose** into glucose and *fructose*, another six-carbon sugar. **Lactase** breaks the disaccharide **lactose** into a molecule of glucose and one of *galactose*.

Lactose is the main carbohydrate in milk, so lactase provides an essential function in infancy and early childhood by breaking down lactose. If the intestinal mucosa stops producing lactase, the person becomes **lactose intolerant**. After ingesting milk and other dairy products, people with lactose intolerance can experience a variety of unpleasant digestive problems, including lower abdominal pain, gas, diarrhea, and vomiting.

Absorption of Monosaccharides

The intestinal epithelium then absorbs the monosaccharides by facilitated diffusion and cotransport mechanisms (look back at **Figure 3-18**). Both methods involve a carrier protein. Facilitated diffusion and cotransport differ in the following major ways:

- **Number of Transported Substances.** Facilitated diffusion moves only one molecule or ion through the plasma membrane at a time. Cotransport moves more than one molecule or ion through the membrane at the same time. In cotransport, the transported substances move in the same direction.
- **Concentration Gradients.** Facilitated diffusion does not take place if there is an opposing concentration gradient for the molecule or ion. By contrast, cotransport can take place despite an opposing concentration gradient for one of the transported substances. For example, cells lining the small intestine continue to absorb glucose when glucose concentrations inside the cells are much higher than they are in the intestinal contents.
- **ATP Requirement.** Facilitated diffusion is a passive process and does not require ATP. Cotransport by itself does not consume ATP. However, the cell must often expend ATP to preserve homeostasis in a process called *secondary active transport*. For

example, in the cotransport of glucose and sodium ions, the sodium ions must later be pumped out of the cell.

Glucose cotransport is an example of sodium-linked cotransport. Comparable cotransport mechanisms exist for other simple sugars and for some amino acids. These mechanisms deliver valuable nutrients to the cytoplasm, but they also bring in sodium ions that must be ejected by the sodium-potassium exchange pump.

The simple sugars that are transported into the intestinal epithelial cell at its apical surface diffuse through the cytoplasm. They then reach the interstitial fluid by facilitated diffusion across the basolateral surfaces. These monosaccharides diffuse into the capillaries of the villus for eventual transport to the liver in the hepatic portal vein.

Lipid Digestion and Absorption

Lipid digestion involves lingual lipase from glands of the tongue and pancreatic lipase from the pancreas (**Spotlight Figure 24-27**). The most important and abundant dietary lipids are *triglycerides*. They consist of three fatty acids attached to a single molecule of glycerol (**Figure 2-17**). The lingual and pancreatic lipases break off two of the fatty acids, leaving *monoglycerides*.

Lipases are water-soluble enzymes, and lipids tend to form large drops that exclude water molecules. As a result, lipases can only interact with the exposed surfaces of the lipid drops. Lingual lipase begins breaking down triglycerides in the mouth and continues for a variable time within the stomach. The lipid drops are so large, however, and the available time so short, that only about 20% of the lipids have been digested by the time the chyme enters the duodenum.

Bile salts improve chemical digestion by emulsifying the lipid drops into tiny emulsion droplets, thereby providing better access for pancreatic lipase. The emulsification takes place only after the chyme has been mixed with bile in the duodenum. Pancreatic lipase then breaks apart the triglycerides to form a mixture of monoglycerides and fatty acids. As these molecules are released, they interact with bile salts in the surrounding chyme to form small lipid-bile salt complexes called **micelles** ($m\bar{i}-SELZ$). A micelle is only about 2.5 nm (0.0025 μm) in diameter.

When a micelle contacts the intestinal epithelium, the lipids diffuse across the plasma membrane and enter the cytoplasm. The intestinal cells synthesize new triglycerides from the monoglycerides and fatty acids. These triglycerides, together with absorbed steroids, phospholipids, and fat-soluble vitamins, are then coated with proteins. The resulting complexes are known as **chylomicrons** ($k\bar{i}-l\bar{o}-M\bar{i}-kronz$; *chylos*, juice + *mikros*, small).

The intestinal cells then secrete the chylomicrons into interstitial fluid by exocytosis. The protein coating keeps the chylomicrons suspended in the interstitial fluid, but they are generally too large to diffuse into capillaries. Most of the chylomicrons diffuse into the intestinal lacteals, which lack basement membranes and have large gaps between adjacent endothelial cells. From the lacteals, the chylomicrons proceed

along the lymphatic vessels and through the thoracic duct. They finally enter the bloodstream at the left subclavian vein.

Most of the bile salts within micelles are reabsorbed by sodium-linked cotransport. Only about 5% of the bile salts secreted by the liver enters the colon. Only about one percent is lost in feces.

Protein Digestion and Absorption

Proteins have very complex structures, so protein digestion is both complex and time consuming. Proteases must access individual proteins, so the three-dimensional organization of food must first be disrupted. This step involves mechanical digestion in the oral cavity, through mastication, and chemical digestion in the stomach, through the action of hydrochloric acid. The strong acid in the stomach disrupts tertiary and secondary protein structure, exposing peptide bonds to enzymatic action.

The acidic content of the stomach also provides the proper environment for the activity of pepsin, the proteolytic enzyme secreted in an inactive form by chief cells of the stomach (**Spotlight Figure 24–27**). Pepsin works effectively at a pH of 1.5–2.0. It breaks the peptide bonds within a polypeptide chain.

When chyme enters the duodenum, enteropeptidase from the small intestine triggers the conversion of trypsinogen to trypsin. Buffers increase the pH to 7–8. Pancreatic proteases can now begin working. Trypsin, chymotrypsin, and elastase are like pepsin in that they break specific peptide bonds within a polypeptide. For example, trypsin breaks peptide bonds involving the amino acids *arginine* or *lysine*. Chymotrypsin targets peptide bonds involving *tyrosine* or *phenylalanine*.

Carboxypeptidase also acts in the small intestine. This enzyme chops off the last amino acid of a polypeptide chain, no matter which amino acids are involved. Thus, while the other peptidases generate a variety of short peptides, carboxypeptidase produces free amino acids. The epithelial surfaces of the small intestine contain several peptidases, notably **dipeptidases**. These enzymes break short peptide chains into individual amino acids. (Dipeptidases break apart *dipeptides*.)

These amino acids, as well as those produced by the pancreatic enzymes, are absorbed through both facilitated diffusion and cotransport mechanisms. The amino acids diffuse through the cell to its basolateral surface. There they are released into interstitial fluid by facilitated diffusion and cotransport. Once in the interstitial fluid, the amino acids diffuse into intestinal capillaries for transport to the liver by means of the hepatic portal vein.

Nucleic Acid Digestion and Absorption

Nucleic acids are broken down into their component nucleotides. Brush border enzymes break these nucleotides into sugars, phosphates, and nitrogenous bases that are absorbed by active transport. However, nucleic acids represent only a small fraction of all the nutrients absorbed each day.

Absorption of Water, Ions, and Vitamins

Water, electrolytes (inorganic ions), and vitamins are absorbed through various transport processes as they pass along the small and large intestines. Let's begin by looking at water absorption.

Water Absorption

Cells cannot actively absorb or secrete water. All movement of water across the lining of the digestive tract involves passive water flow down osmotic gradients. The production of glandular secretions also involves passive water flow down osmotic gradients. Recall that when a selectively permeable membrane separates two solutions, water tends to flow into the solution that has the higher concentration of solutes. Osmotic movements are rapid, so interstitial fluid and the fluids in the intestinal lumen always have the same osmotic concentration of solutes, or *osmolarity*.

Intestinal epithelial cells continuously absorb nutrients and ions. These activities gradually lower the solute concentration in the lumen. As the solute concentration drops, water moves into the surrounding tissues, maintaining osmotic equilibrium.

Each day, about 2200 mL of water enters the digestive tract in the form of food and drink. Saliva, gastric secretions, bile, intestinal secretions, and mucus provide an additional 7200 mL. Of that total, only about 150 mL is lost in feces. The sites of secretion and absorption of water are shown in **Figure 24–28**.

Ion Absorption

Osmosis does not distinguish among solutes. All that matters is the total concentration of solutes. To maintain homeostasis, however, the concentrations of specific ions must be closely regulated. Thus, each ion must be handled individually, and the rate of intestinal absorption of each must be tightly controlled (**Table 24–2**). Many of the regulatory mechanisms controlling the rates of absorption are poorly understood.

Sodium ions (Na^+) are usually the most abundant cations in food. They may enter intestinal cells by diffusion, by cotransport with another nutrient, or by active transport. These ions are then pumped into interstitial fluid across the base of the cell.

The rate of Na^+ uptake from the lumen is generally proportional to the concentration of Na^+ in the intestinal contents. As a result, eating heavily salted foods leads to increased sodium ion absorption and an associated gain of water through osmosis. The rate of sodium ion absorption by the digestive tract is increased by *aldosterone*, a steroid hormone from the adrenal cortex.

Calcium ion (Ca^{2+}) absorption involves active transport at the epithelial surface. Calcitriol speeds up the rate of transport.

As other solutes move out of the lumen, the concentration of potassium ions (K^+) increases. These ions can diffuse into the epithelial cells, driven by the concentration gradient. The absorption of magnesium (Mg^{2+}), iron (Fe^{2+}), and other cations involves specific carrier proteins. The cell must use ATP to

Figure 24–28 Digestive Secretion and Water Reabsorption in the Digestive Tract. The purple arrows indicate secretion, and the blue arrows show water ingestion and reabsorption.

obtain and transport these ions to interstitial fluid. Regulatory factors controlling their absorption are poorly understood.

The anions chloride (Cl^-), iodide (I^-), bicarbonate (HCO_3^-), and nitrate (NO_3^-) are absorbed by diffusion or carrier-mediated transport. Phosphate (PO_4^{3-}) and sulfate (SO_4^{2-}) ions enter epithelial cells only by active transport.

Vitamin Absorption

As we have already discussed, **vitamins** are organic compounds required in very small quantities. However, their role in the body is crucial, as they are important cofactors or coenzymes in many metabolic pathways.

There are two major groups of vitamins: water-soluble and fat-soluble vitamins. The nine **water-soluble vitamins** include the B vitamins, common in milk and meats, and vitamin C, found in citrus fruits. All but one of the water-soluble vitamins are easily absorbed by diffusion across the digestive epithelium. The exception is vitamin B_{12} , which is essential for normal erythropoiesis. By itself vitamin B_{12} cannot be absorbed by the intestinal mucosa in adequate amounts. This vitamin must be bound to intrinsic factor, a glycoprotein secreted by the parietal cells of the stomach. The combination is then absorbed through active transport.

Vitamins A, D, E, and K are **fat-soluble vitamins**, which as their name suggests can dissolve in lipids. Fat-soluble vitamins in the diet enter the duodenum in fat droplets, mixed with triglycerides. The vitamins remain in association with these lipids as they form emulsion droplets and, after further digestion, micelles. The fat-soluble vitamins are then absorbed from the micelles along with the fatty acids and monoglycerides. As discussed, vitamin K produced in the colon is absorbed with other lipids released through bacterial action. Taking supplements of fat-soluble vitamins on an empty stomach, during fasting, or while on a low-fat diet is relatively ineffective. The reason is that proper absorption of these vitamins requires the presence of other lipids.

32. Name the nutrients the body requires.
33. What component of food would increase the number of chylomicrons in the lacteals?
34. The absorption of which vitamin would be impaired by the removal of the stomach?
35. Why is diarrhea potentially life threatening, but constipation (infrequent defecation) is not?

See the blue Answers tab at the back of the book.

24-9 Many age-related changes affect digestion and absorption

Learning Outcome Summarize the effects of aging on the digestive system.

Many changes in the digestive system parallel age-related changes already discussed in connection with other body systems. These changes include:

- *The Division Rate of Epithelial Stem Cells Decreases.* The digestive epithelium becomes more susceptible to damage by abrasion, acids, or enzymes. Peptic ulcers therefore become more likely. Stem cells in the epithelium divide less frequently with age, so tissue repair is less efficient. In the mouth, esophagus, and anus, the stratified epithelium becomes thinner and more fragile.
- *Smooth Muscle Tone Decreases.* General motility decreases, and peristaltic contractions are weaker because of a decrease in smooth muscle tone. These changes slow the

Table 24-2 The Absorption of Ions and Vitamins

Ion or Vitamin	Transport Mechanism	Regulatory Factors
Na ⁺	Channel-mediated diffusion, cotransport, or active transport	Increased when sodium-linked cotransport is under way; stimulated by aldosterone
Ca ²⁺	Active transport	Stimulated by calcitriol and PTH
K ⁺	Channel-mediated diffusion	Follows concentration gradient
Mg ²⁺	Active transport	
Fe ²⁺	Active transport	
Cl ⁻	Channel-mediated diffusion or carrier-mediated transport	
I ⁻	Channel-mediated diffusion or carrier-mediated transport	
HCO ₃ ⁻	Channel-mediated diffusion or carrier-mediated transport	
NO ₃ ⁻	Channel-mediated diffusion or carrier-mediated transport	
PO ₄ ³⁻	Active transport	
SO ₄ ²⁻	Active transport	
Water-soluble vitamins (except B ₁₂)	Channel-mediated diffusion	Follows concentration gradient
Vitamin B ₁₂	Active transport	Must be bound to intrinsic factor prior to absorption
Fat-soluble vitamins	Diffusion	Absorbed from micelles along with dietary lipids

rate of fecal movement and promote constipation. Sagging and inflammation of the haustra in the colon can occur. Straining to eliminate compacted feces can stress the less resilient walls of blood vessels, producing hemorrhoids. Problems are not restricted to the lower digestive tract. For example, weakening of muscular sphincters can lead to esophageal reflux and frequent bouts of heartburn.

- **The Effects of Cumulative Damage Become Obvious.** A familiar example is the gradual loss of teeth due to *dental caries* (cavities) or gingivitis. Cumulative damage can involve internal organs as well. Toxins such as alcohol and other injurious chemicals that are absorbed by the digestive tract are transported to the liver for processing. The cells of the liver are not immune to these toxic compounds, and chronic exposure can lead to cirrhosis or other types of liver disease.
- **Cancer Rates Increase.** Cancers are most common in organs in which stem cells divide to maintain epithelial cell populations. Rates of colon cancer and stomach cancer rise with age. Oral, esophageal, and pharyngeal cancers are particularly common among older smokers.
- **Dehydration Is Common Among Older People.** One reason is that osmoreceptor sensitivity decreases with age.
- **Changes in Other Systems Have Direct or Indirect Effects on the Digestive System.** For example, reductions in bone mass and calcium content in the skeleton are associated with erosion of the tooth sockets and eventual tooth loss. The decrease in olfactory and gustatory sensitivities with age can lead to dietary changes that affect the entire body.

✓ Checkpoint

36. Identify general digestive system changes that occur with aging.

See the blue Answers tab at the back of the book.

24-10 The digestive system is extensively integrated with other body systems

Give examples of interactions between the digestive system and other body systems studied so far.

Build Your Knowledge **Figure 24-29** summarizes the functional relationships between the digestive system and other body systems we have studied so far. The digestive system has particularly extensive anatomical and physiological connections to the nervous, cardiovascular, endocrine, and lymphatic systems. Recall that the digestive tract is also an endocrine organ that produces a variety of hormones. Many of these hormones, and some of the neurotransmitters produced by the digestive system, can enter the circulation, cross the blood-brain barrier, and alter CNS activity. In this way, a continual exchange of chemical information takes place among these systems.

✓ Checkpoint

37. Identify the functional relationships between the digestive system and other body systems.
38. What body systems may be affected by inadequate calcium ion absorption?

See the blue Answers tab at the back of the book.

Figure 24–29 Integration of the DIGESTIVE system with the other body systems presented so far.

24 Chapter Review

Study Outline

An Introduction to the Digestive System

1. The digestive system supplies both the fuel that keeps all the body's cells functioning and the building blocks needed for cell growth and repair.

24-1 The digestive system, consisting of the digestive tract and accessory organs, functions primarily to break down and absorb nutrients from food and to eliminate wastes

2. The **digestive system** consists of the muscular **digestive tract** and various **accessory organs**. (Figure 24-1)
3. The general functions of the digestive system are **ingestion**, **mechanical digestion** and **propulsion**, **chemical digestion**, **secretion**, **absorption**, and **defecation**.
4. Double sheets of peritoneal membrane called **mesenteries** suspend the digestive tract. The **greater omentum** lies anterior to the abdominal viscera. Its adipose tissue provides padding, protection, insulation, and an energy reserve. (Figure 24-2)
5. The epithelium, *lamina propria*, and *muscularis mucosae* form the **mucosa** (mucous membrane) that lines the lumen of the digestive tract. Deep to the mucosa is the **submucosa**, the **muscular layer**, and a fibrous layer of connective tissue called the *adventitia*. For viscera projecting into the peritoneal cavity, the muscular layer is covered by a serous membrane called the **serosa**. (Figure 24-3)
6. The muscular layer propels materials through the digestive tract by the contractions of **peristalsis**. **Segmentation** movements in the small intestine churn digestive materials. (Figure 24-4)
7. Local factors, neural mechanisms, and hormonal mechanisms control digestive tract activities. (Figure 24-5)

24-2 The oral cavity, which contains the tongue, teeth, and salivary glands, functions in the ingestion and mechanical digestion of food

8. The functions of the **oral cavity** are (1) *sensory analysis* of foods; (2) *mechanical digestion* by the teeth, tongue, and palatal surfaces; (3) *lubrication*, by mixing with mucus and salivary gland secretions; and (4) limited *chemical digestion* of carbohydrates and lipids.
9. The oral cavity is lined by the **oral mucosa**. The *hard* and *soft palates* form the roof of the oral cavity, and the *tongue* forms its floor. (Figure 24-6)
10. **Intrinsic** and **extrinsic tongue muscles** are controlled by the hypoglossal nerves. (Figure 24-6)
11. **Mastication** (chewing) of the **bolus** occurs through the contact of the **occlusal** (opposing) **surfaces** of the **teeth**. The **periodontal ligament** anchors each tooth in an *alveolus*, or bony socket. **Dentin** forms the basic structure of a tooth. The **crown** is coated with **enamel**, the **root** with **cement**. (Figure 24-7)
12. During childhood and early adulthood, the 20 **deciduous teeth** are replaced by 32 **permanent teeth**. (Figure 24-8)
13. The **parotid**, **sublingual**, and **submandibular salivary glands** discharge their secretions into the oral cavity. (Figure 24-9)

24-3 The pharynx and esophagus are passageways that transport the food bolus from the oral cavity to the stomach

14. The **pharynx** serves as a common passageway for solid food, liquid, and air.
15. The **esophagus** carries solids and liquids from the pharynx to the stomach through the **esophageal hiatus**, an opening in the diaphragm. (Figure 24-10)
16. The esophageal mucosa consists of a stratified epithelium. Mucous secretion by esophageal glands of the submucosa reduces friction during the passage of foods. The proportions of skeletal and smooth muscle of the muscular layer change from the pharynx to the stomach. (Figure 24-10)
17. Swallowing, or **deglutition**, can be divided into **buccal**, **pharyngeal**, and **esophageal phases**. Swallowing begins with the compaction of a bolus and its movement through the pharynx, from contractions of the *pharyngeal constrictor* and the *palatal muscles*, followed by the elevation of the larynx, reflection of the *epiglottis*, and closure of the *glottis*. After the *upper esophageal sphincter* is opened, peristalsis moves the bolus down the esophagus to the *lower esophageal sphincter*. (Figure 24-11)

24-4 The stomach is a J-shaped organ that receives the bolus and aids in its chemical and mechanical digestion

18. The four regions of the stomach are the **cardia**, **fundus**, **body**, and **pyloric part**. The **pyloric sphincter** guards the exit from the stomach. In a relaxed state, the stomach lining contains numerous **rugae** (ridges and folds). (Figure 24-12)
19. The **stomach** functions include the following: (1) storage of ingested food, (2) mechanical breakdown of food, and (3) disruption of chemical bonds by acid and enzymes.
20. Within the **gastric glands**, *parietal cells* secrete *intrinsic factor* and the ions of *hydrochloric acid*. **Chief cells** secrete **pepsinogen**, which is converted by acids in the gastric lumen to the enzyme **pepsin**. **Enteroendocrine** cells of the stomach secrete several compounds, notably the hormone **gastrin**. (Figures 24-13, 24-14)
21. Gastric control involves (1) the **cephalic phase**, which prepares the stomach to receive ingested materials; (2) the **gastric phase**, which begins with the arrival of food in the stomach; and (3) the **intestinal phase**, which controls the rate of gastric emptying. Vomiting, or **emesis**, is reverse peristalsis. (Spotlight Figure 24-15)

24-5 Accessory digestive organs, such as the pancreas and liver, produce secretions that aid in chemical digestion

22. The **pancreas** has a slender **body** and a short tail. The **pancreatic duct** penetrates the wall of the duodenum, the first section of the small intestine. Within each lobule, ducts branch repeatedly before ending in the **pancreatic acini** (pockets). (Figure 24-16)
23. The pancreas has two functions: endocrine (secreting insulin and glucagon into the blood) and exocrine (secreting **pancreatic juice** into the small intestine). Pancreatic enzymes include **carbohydrases**, **lipases**, **nucleases**, and **proteases**.
24. The **liver** performs metabolic and hematological regulation and produces **bile**. The bile ducts from all the **liver lobules** unite to form the **common hepatic duct**. That duct meets the **cystic duct** to form the **bile duct**, which empties into the duodenum. (Figures 24-17 to 24-19)
25. The liver lobule is the organ's basic functional unit. **Hepatocytes** form irregular plates arranged in the form of spokes of a wheel. **Bile canaliculi** carry bile to the **bile ductules**, which lead to **portal triads**. (Figure 24-18)
26. In **emulsification**, **bile salts** break apart large drops of lipids, making the lipids accessible to lipases secreted by the pancreas.
27. The liver is the primary organ involved in regulating the composition of circulating blood. All the blood leaving the absorptive surfaces of the digestive tract flows into the liver before entering the systemic circulation. The liver regulates metabolism as it removes and stores excess nutrients, vitamins, and minerals from the blood; mobilizes stored reserves; synthesizes needed nutrients; and removes wastes.
28. The liver's hematological activities include the monitoring of circulating blood by phagocytes and antigen-presenting cells; the synthesis of plasma proteins; the removal of circulating hormones and antibodies; and the removal or storage of toxins.
29. The liver synthesizes bile, which is composed of water, ions, bilirubin, cholesterol, and bile salts (an assortment of lipids).
30. The **gallbladder** stores, modifies, and concentrates bile. (Figure 24-19)

24-6 The small intestine primarily functions in the chemical digestion and absorption of nutrients

31. Most of the important digestive and absorptive functions occur in the **small intestine** (*small bowel*). The pancreas, liver, and gallbladder provide digestive secretions and buffers.
32. The small intestine consists of the **duodenum**, the **jejunum**, and the **ileum**. A sphincter, the **ileocecal valve**, marks the transition between the small and large intestines. (Figure 24-20)
33. The intestinal mucosa has transverse folds called **circular folds** (*plicae circulares*) and small projections called **intestinal villi**. These folds and projections increase the surface area for absorption. Each villus contains a terminal lymphatic called a **lacteal**. Pockets called **intestinal glands** are lined by enteroendocrine, mucous, paneth, and stem cells. (Figures 24-20, 24-21)
34. **Intestinal juice** moistens chyme, helps buffer acids, and holds digestive enzymes and digestive products in solution.
35. The **duodenal submucosal glands** of the duodenum produce mucus, bicarbonate ions, and the hormone **urogastrone**. The ileum contains masses of lymphoid tissue called **aggregated lymphoid nodules**, or *Peyer's patches*, near the entrance to the large intestine.
36. The **gastroenteric reflex**, initiated by stretch receptors in the stomach, stimulates motility and secretion along the entire small intestine. The **gastroileal reflex** triggers the relaxation of the ileocecal valve.

37. Neural and hormonal mechanisms coordinate the activities of the digestive glands. Gastrointestinal activity is stimulated by parasympathetic innervation and inhibited by sympathetic innervation. The **enterogastric**, **gastroenteric**, and **gastroileal reflexes** coordinate movement from the stomach to the large intestine.
38. Intestinal hormones include **secretin**, **cholecystokinin (CCK)**, **gastric inhibitory peptide (GIP)**, **vasoactive intestinal peptide (VIP)**, **gastrin**, and **enterocrinin**. (Figures 24-22, 24-23)

24-7 The large intestine, which is divided into three parts, absorbs water from digestive materials and eliminates the remaining waste as feces

39. The main functions of the **large intestine** are to (1) reabsorb water and compact materials into feces, (2) absorb vitamins produced by bacteria, and (3) store fecal material prior to defecation. The large intestine (*large bowel*) consists of the *cecum*, *colon*, and *rectum*. (Figure 24-24)
40. The **cecum** collects and stores material from the ileum and begins the process of compaction. The **appendix** is attached to the cecum. (Figure 24-24)
41. The **colon** has a larger diameter and a thinner wall than the small intestine. The colon bears **haustra** (pouches), **teniae coli** (longitudinal bands of muscle), and sacs of fat called **omental appendices**. (Figure 24-24)
42. The four regions of the colon are the **ascending colon**, **transverse colon**, **descending colon**, and **sigmoid colon**. (Figure 24-24)
43. The **rectum** terminates in the **anal canal**, leading to the **anus**. (Figure 24-24)
44. Histological characteristics of the colon include the absence of villi and the presence of goblet cells and deep intestinal glands. (Figure 24-25)
45. The large intestine reabsorbs water and other substances such as vitamins, urobilinogen, bile salts, and toxins. Most of the gut bacteria of the human *microbiome* live in the large intestine. Bacteria are responsible for intestinal gas, or **flatus**.
46. During eating, the gastroileal reflex moves materials from the ileum into the cecum. Distension of the stomach and duodenum stimulates **mass movements** of materials from the transverse colon through the rest of the large intestine and into the rectum. Muscular sphincters control the passage of fecal material to the anus. Distension of the rectal wall triggers the **defecation reflex**. (Figure 24-26)

24-8 Chemical digestion is the enzyme-mediated hydrolysis of food into nutrients that can be absorbed and used by the body

47. The digestive system first breaks down the physical structure of the ingested material and then disassembles the component molecules into smaller fragments by *hydrolysis*. (Spotlight Figure 24-27; Table 24-1)
48. Salivary and pancreatic amylases break down complex carbohydrates into *disaccharides* and *trisaccharides*. These in turn are broken down into *monosaccharides* by enzymes at the epithelial surface. The monosaccharides are then absorbed by the intestinal epithelium by facilitated diffusion or cotransport. (Spotlight Figure 24-27)
49. *Triglycerides* are emulsified into lipid droplets that interact with bile salts to form **micelles**. The fatty acids and monoglycerides resulting from the action of pancreatic lipase diffuse from the micelles across the intestinal epithelium. Triglycerides are then synthesized and released into the interstitial fluid for transport to the general circulation by way of the lymphatic system. (Spotlight Figure 24-27)

50. Protein digestion involves a low pH (which breaks down tertiary and quaternary structure), the gastric enzyme pepsin, and various pancreatic proteases. Peptidases liberate amino acids that are absorbed and exported to interstitial fluid. (*Spotlight Figure 24–27*)
51. About 2200 mL of water is ingested each day, and digestive secretions provide another 7200 mL. Nearly all is reabsorbed by osmosis. (*Figure 24–28*)
52. Various processes, including diffusion, cotransport, and carrier-mediated and active transport, are responsible for the movements of cations (sodium, calcium, potassium, and so on) and anions (chloride, iodide, bicarbonate, and so on) into epithelial cells. (*Table 24–2*)
53. The **water-soluble vitamins** (except B₁₂) diffuse easily across the digestive epithelium. **Fat-soluble vitamins** are enclosed

within fat droplets and absorbed with the products of lipid digestion. (*Table 24–2*)

24-9 Many age-related changes affect digestion and absorption

54. Age-related changes include a thinner and more fragile epithelium due to a reduction in epithelial stem cell divisions, weaker peristaltic contractions as smooth muscle tone decreases, the effects of cumulative damage, increased cancer rates, and increased dehydration.

24-10 The digestive system is extensively integrated with other body systems

55. The digestive system has extensive anatomical and physiological connections to the nervous, endocrine, cardiovascular, and lymphatic systems. (*Figure 24–29*)

Review Questions

See the blue Answers tab at the back of the book.

LEVEL 1 Reviewing Facts and Terms

1. All of the following organs are accessory organs of the digestive system *except* (a) stomach, (b) teeth, (c) liver, (d) pancreas.
2. The layer of the mucosa that provides defense against swallowed bacteria is the (a) digestive epithelium, (b) lamina propria, (c) serosa, (d) muscularis mucosae.
3. A remnant of the ventral mesentery that persists in adults is the (a) peritoneum, (b) transverse mesocolon, (c) lesser omentum, (d) greater omentum.
4. A branch of the hepatic portal vein, hepatic artery proper, and branch of the bile duct form (a) a liver lobule, (b) the sinusoids, (c) a portal triad, (d) the hepatic duct, (e) the pancreatic duct.
5. Label the digestive system structures in the following figure.

- | | |
|-----------|-----------|
| (a) _____ | (b) _____ |
| (c) _____ | (d) _____ |
| (e) _____ | (f) _____ |
| (g) _____ | (h) _____ |
| (i) _____ | (j) _____ |
| (k) _____ | |

6. Label the four layers of the digestive tract in the following figure.

- | | |
|-----------|-----------|
| (a) _____ | (b) _____ |
| (c) _____ | (d) _____ |

7. The P/D1 cells lining the fundic region of the stomach produce (a) somatostatin, (b) ghrelin, (c) gastrin, (d) pepsin, (e) rennin.
8. The primary function of the small intestine is the (a) reabsorption of water, (b) chemical digestion of chyme, (c) storage of digestive wastes, (d) absorption of vitamins produced by bacteria.
9. Bile salts help in the digestion of (a) large polysaccharides, (b) glucose, (c) proteins, (d) lipids.

10. Label the three segments of the small intestine in the following figure.

(a) _____ (b) _____ (c) _____

11. The major function(s) of the large intestine is (are) **(a)** reabsorption of water and compaction of feces, **(b)** absorption of vitamins liberated by bacterial action, **(c)** storage of fecal material prior to defecation, **(d)** all of these.
12. The absorption of the ions HCO_3^- , NO_3^- , and Cl^- by epithelial cells occurs through **(a)** active transport, **(b)** channel-mediated diffusion, **(c)** cotransport, **(d)** simple diffusion.
13. Which source of digestive secretion(s) is/are responsible for the largest amount of water ingestion into the system? **(a)** saliva, **(b)** intestinal secretions, **(c)** gastric secretions, **(d)** bile.
14. What are the six main processes of the digestive system?
15. Name and describe the layers of the digestive tract, proceeding from the innermost layer nearest the lumen to the outermost layer.
16. What three basic mechanisms regulate the activities of the digestive tract?
17. What are the three phases of swallowing, and how are they controlled?
18. What are the primary digestive functions of the pancreas, liver, and gallbladder?
19. Which hormones produced by duodenal enteroendocrine cells effectively coordinate digestive functions?
20. What are the three primary functions of the large intestine?
21. What two positive feedback loops are involved in the defecation reflex?

LEVEL 2 Reviewing Concepts

22. During defecation, **(a)** stretch receptors in the rectal wall initiate a series of peristaltic contractions in the colon and rectum, **(b)** stretch receptors in the rectal wall activate parasympathetic centers in the sacral region of the spinal cord, **(c)** the internal anal sphincter relaxes while the external anal sphincter contracts, **(d)** all of these occur, **(e)** only a and b occur.
23. The small intestine is protected from bacteria living in the large intestine by the **(a)** ileocecal valve, **(b)** villi, **(c)** Peyer's patches, **(d)** submucosal plexus, **(e)** circular folds.
24. An enzyme that contributes to the breakdown of proteins in the small intestine is **(a)** amylase, **(b)** lipase, **(c)** trypsin, **(d)** lactase.
25. What does an oral surgeon mean when he or she tells you that you need surgery because of an impacted wisdom tooth?
26. How is the stomach protected from digestion?
27. How does each of the three phases of gastric secretion promote and facilitate gastric control?
28. Nutritionists have found that after a heavy meal, the pH of blood increases slightly, especially in the veins that carry blood away from the stomach. What causes this increase in blood pH?

LEVEL 3 Critical Thinking and Clinical Applications

29. Jim has developed cirrhosis of the liver as a result of heavy drinking. What does this mean?
30. Henry has an obstruction in his colon. He notices that when he urinates, the color of his urine is much darker than normal, and he wonders if there is any relationship between the color of his urine and his intestinal obstruction. What would be an appropriate response?
31. A condition known as lactose intolerance is characterized by painful abdominal cramping, gas, and diarrhea. The cause of the problem is an inability to digest the milk sugar lactose. How would this cause the observed signs and symptoms?
32. Recently, more people have turned to surgery to help them lose weight. One form of weight control surgery involves stapling a portion of the stomach shut, creating a smaller volume. How would such a surgery result in weight loss?

CLINICAL CASE Wrap-Up An Unusual Transplant

Normally the lining of the colon is slimy with mucus and covered with millions of beneficial bacteria. These “good” bacteria generate vitamins K, B₅, and biotin. They convert bilirubin (the breakdown product of blood) to urobilinogens and stercobilinogens for excretion. The bacteria also break down any remaining peptides in feces.

When these normal, beneficial intestinal bacteria have been killed by antibiotics, they are replaced by other bacteria. Often the replacement bacteria do harm by producing toxins, irritating the intestinal lining, and causing colitis. This is the case with *Clostridium difficile* (*C. difficile*) infections.

One way of treating *C. difficile* infections is with a fecal transplant, as Mirasol's doctor suggests. Normal feces from a healthy donor contain populations of beneficial bacteria that usually colonize large intestines. With a minimal amount of processing, the

donated feces can be infused through a nose tube (nasogastric tube). Then the normal intestinal bacteria inhabit the recipient's large intestine, crowd out the harmful *C. difficile* bacteria, and resume their usual work of protecting the lining of the large intestine, producing vitamins, and recycling nutrients.

After overcoming her initial disgust, Mirasol agrees to the transplant. She recovers completely and leaves the hospital 2 days after her treatment.

1. If Mirasol's *Clostridium difficile* colitis were not treated with a fecal transplant, what kind of health problems might she continue to experience?
2. What would a person see by viewing the inside of Mirasol's large intestine with a colonoscope before the transplant?

See the blue Answers tab at the back of the book.

Related Clinical Terms

borborygmus: A rumbling or gurgling sound made by the movement of fluids and gases in the intestines.

cathartics: Drugs that promote defecation.

cholelithiasis: The presence of gallstones in the gallbladder.

cholera: A bacterial infection of the digestive tract that causes massive fluid losses through diarrhea.

colitis: A general term for a condition characterized by inflammation of the colon.

Crohn's disease: An incurable chronic inflammatory bowel disease that can affect any part of the digestive tract, from the mouth to the anus. The presence of strictures, fistulas, and fissures is common.

diverticulitis: An infection and inflammation of mucosal pockets of the large intestine (diverticula).

diverticulosis: The formation of diverticula, generally along the sigmoid colon.

dysphagia: Difficulty or discomfort in swallowing due to disease.

esophageal varices: Swollen and fragile esophageal veins that result from portal hypertension.

fecal occult blood test: Test to check for hidden blood in feces.

gastrectomy: The surgical removal of the stomach, generally to treat advanced stomach cancer.

gastroesophageal reflux disease (GERD): Chronic condition in which the lower esophageal sphincter allows gastric acids to backflow into the esophagus, causing heartburn, acid indigestion, and possible injury to the esophageal lining.

gastroscope: A fiberoptic instrument inserted into the mouth and directed along the esophagus and into the stomach; used to examine the interior of the stomach and to perform minor surgical procedures.

halitosis: Bad breath that may be due to poor oral hygiene, an infection, diabetes, or other disease.

insoluble fiber: Indigestible plant carbohydrates that do not dissolve in water and pass through the GI tract unchanged. Found in many vegetables and the skins of fruits, insoluble fiber speeds up the passage of material in the GI tract. Individuals consuming diets rich in insoluble fiber decrease their risk for developing diabetes, atherosclerosis, and colorectal cancers, among other diseases.

irritable bowel syndrome (IBS): A common disorder affecting the large intestine, accompanied by cramping, abdominal pain, bloating, gas, diarrhea, and constipation.

pancreatic cancer: Malignancy of the pancreas that does not cause symptoms in its early stages, leading to late detection and a survival rate of only four percent.

periodontal disease: A loosening of the teeth within the alveolar sockets caused by erosion of the periodontal ligaments by acids produced through bacterial action.

polyps: Small growths with a stalk protruding from a mucous membrane that is usually benign.

pulpitis: An infection of the pulp of a tooth; treatment may involve a root canal procedure.

pyloric stenosis: A condition in which the muscle of the lower end of the stomach enlarges and prevents food from entering the small intestine. It occurs most often in babies under 6 months.

pylorospasm: Spasm of the pyloric sphincter, accompanied by pain and vomiting.

root canal: Removal of the alveolar nerve in a severely damaged tooth.

soluble fiber: Indigestible plant carbohydrates found in beans, oats, and citrus fruits that dissolve in water when eaten, forming a gel within the digestive tract to slow the passage of material. Diets rich in soluble fiber lower blood cholesterol levels.

Metabolism, Nutrition, and Energetics

Learning Outcomes

These Learning Outcomes correspond by number to this chapter's sections and indicate what you should be able to do after completing the chapter.

- 25-1 ■ Explain the relationship among metabolism, catabolism, and anabolism, and describe the energetics of an oxidation–reduction reaction.
- 25-2 ■ Describe the basic steps in glycolysis, the citric acid cycle, the electron transport chain, and chemiosmosis, and summarize the energy yield of cellular respiration (glycolysis and aerobic metabolism).
- 25-3 ■ Describe the pathways involved in lipid metabolism and summarize the mechanisms of lipid transport and distribution.
- 25-4 ■ Summarize the main processes of protein metabolism and discuss the use of protein as an energy source.
- 25-5 ■ Differentiate between the absorptive and postabsorptive metabolic states and summarize the characteristics of each.
- 25-6 ■ Explain what makes up a balanced diet and why such a diet is important.
- 25-7 ■ Define metabolic rate, discuss the factors involved in determining an individual's BMR and discuss the homeostatic mechanisms that maintain a constant body temperature.

CLINICAL CASE

The Miracle Supplement

Justine, a pregnant 30-year-old Kenyan female, is walking home from the clinic after her final prenatal visit. As the sun sets, she realizes she is suddenly no longer able to see. Terrified, she manages to walk home blind, in rural Kenya, after dark. The next morning, her vision returns.

Justine knows children who have experienced night blindness. Many of them died young; in fact, every family in Justine's village has experienced childhood death. Several of the village's children also have stunted growth and delayed skeletal development.

They seem to have weak immunity, and commonly develop malarial, respiratory, and diarrheal infections.

Fortunately, Justine goes on to deliver a healthy baby at the clinic. Shortly after giving birth, doctors treat Justine with a

single high-dose vitamin supplement. She is told this will help her night blindness and ensure that there is enough of this vitamin in her breast milk to keep her baby healthy, too.

When Justine's baby is 6 months old, Justine takes her to get her first dose of vitamin supplement. This dose will be repeated every 6 months until the child is 5 years old. Costing only 2¢ per dose and reducing overall childhood mortality (death rate) by 23%, this

vitamin supplement has been called the best public health investment ever. **What could this critical vitamin be? To find out, turn to the Clinical Case Wrap-Up at the end of the chapter.**

An Introduction to Metabolism, Nutrition, and Energetics

The amount and type of *nutrients*, essential elements and molecules, in food can vary widely. The body builds energy reserves when nutrients are abundant. It mobilizes these reserves when nutrients are in short supply. The nervous and endocrine systems control the storage and mobilization of these energy reserves. These systems adjust and coordinate these reactions as part of their regulation of all the *metabolic* activities of the body's tissues. In this chapter we examine (1) how the body obtains energy from the breakdown of organic molecules, stores it in the form of the energy transfer molecule *ATP*, and uses it to support intracellular processes such as the construction of new organic molecules; (2) the role of diet in physiological function; and (3) the *energetics* of how the body balances heat gains and losses to maintain homeostasis.

vitamins, mineral ions, and organic substrates. Substrates are the substances acted on by an enzyme.

Metabolism

Metabolism is the sum of all chemical and physical changes that occur in body tissues. It consists of **catabolism** (catabolic reactions) and **anabolism** (anabolic reactions). Catabolism converts large molecules into smaller ones, and anabolism converts small molecules into larger ones. Energy-rich macromolecules are obtained in our diet—namely, the fats, carbohydrates, and proteins we eat. The pathways making up these reactions extract energy from nutrients, transfer and use energy, and build and store excesses for later use. Nutrients, the components in food, such as water, vitamins, mineral ions, carbohydrates, fats, and proteins, are necessary for normal physiological function. All the available nutrient molecules distributed in the blood form a **nutrient pool** (Figure 25–1).

Catabolism

Catabolism proceeds in a series of steps. In general, the first steps take place in the cytosol. Fats are broken down into fatty acids and glycerol; carbohydrates are broken down into glucose; and proteins are catabolized into amino acids. Different processes are involved in the catabolism of each nutrient. For example, fat catabolism involves *lipolysis* (fat breakdown), and carbohydrate catabolism involves *glycogenolysis* (breakdown of glycogen into glucose) and *glycolysis* (breakdown of glucose into pyruvate). Every day the lungs absorb oxygen, and the digestive tract absorbs nutrients. The cardiovascular system then carries these substances throughout the body in the blood, where our cells can absorb and use them to generate ATP. Figure 25–1 shows the relationships of the various metabolic pathways, which we discuss in greater detail later in the chapter.

25

25-1 Metabolism is the sum of all the catabolic and anabolic reactions in the body, and energetics is the flow and transformation of energy

Learning Outcome Explain the relationship among metabolism, catabolism, and anabolism, and describe the energetics of an oxidation–reduction reaction.

Cells are chemical factories that break down organic molecules to obtain energy. Our cells can then use this energy to generate adenosine triphosphate (ATP) from adenosine diphosphate (ADP) and an inorganic phosphate group (P_i). Reactions within mitochondria provide most of the energy a typical cell needs. To carry out these reactions, cells must have a reliable supply of oxygen and nutrients, including *water*,

Figure 25–1 Metabolism of Organic Nutrients and Nutrient Pools. This flowchart illustrates the major organic macromolecules in the diet and the relationships among the metabolic pathways and nutrient pools of their building blocks (monomers)—free fatty acids, glucose, and amino acids.

Anabolism

The ATP produced by mitochondria provides energy to support both *anabolism*, which is the synthesis of new organic molecules, and other cell functions. For example, muscle fibers need ATP to provide energy for contraction, but gland cells need ATP to synthesize and transport secretions. Here we focus on anabolism.

In terms of energy, anabolism is an “uphill” process that involves the formation of new chemical bonds. Cells synthesize new organic components for four basic reasons:

- **To Carry Out Structural Maintenance or Repairs.** All cells must expend energy for ongoing maintenance and repairs because most structures in the cell are temporary rather than permanent. Cells continuously replace membranes, organelles, enzymes, and structural proteins in the process of *metabolic turnover* (see Appendix C).
- **To Support Growth.** Cells preparing to divide increase in size and synthesize extra proteins and organelles.

- **To Produce Secretions.** Secretory cells must synthesize their products and deliver them to the interstitial fluid.
- **To Store Nutrient Reserves.** Most cells “prepare for a rainy day”—a period of emergency, an interval of extreme activity, or a time when the supply of nutrients in the bloodstream is inadequate. Cells prepare for such times by building up nutrient reserves in a form that can be mobilized as needed. For example, in the process of *lipogenesis*, or fat formation, *triglycerides* (consisting primarily of *fatty acids*) are the most abundant storage form. In the process of *glycogenesis* (glycogen formation), carbohydrates are stored as *glycogen*, a branched chain of glucose molecules. If glucose is unavailable, it may be synthesized through the process of *gluconeogenesis*. Muscle cells and liver cells, for example, store glucose in the form of glycogen, but adipocytes and liver cells store triglycerides. Proteins are the most abundant organic components in the body. They perform a variety of vital functions for the cell. Anabolic activities require more

amino acids than lipids, and few carbohydrates. Therefore, when energy is available, cells synthesize additional proteins. When glucose and fatty acids are unavailable, cells can break down proteins into their component amino acids and use the amino acids as an energy source. Proteins are so abundant and accessible that they represent an important “last-ditch” nutrient reserve (**Figure 25-1**).

Mitochondria provide the energy that supports cellular operations. The cell “feeds” its mitochondria from its nutrient pool. In return, the cell gets the ATP it needs. However, mitochondria are picky eaters: They accept only specific organic molecules for processing and energy production. For this reason, chemical reactions in the cytosol take whichever organic nutrients are available and break them down into smaller fragments that the mitochondria can process. The mitochondria then break the fragments down further, generating carbon dioxide, water, and ATP. Most of the ATP is formed as the result of a metabolic process called *oxidative phosphorylation*. This mitochondrial activity involves the *oxidation* of high-energy carrier molecules from the *citric acid cycle* and the phosphorylation of ADP to form ATP.

Energetics

Each tissue contains a unique mixture of various kinds of cells. As a result, the energy and nutrient requirements of any two tissues, such as loose connective tissue and cardiac muscle, can be quite different. Also, activity levels can change rapidly within a tissue, and such changes affect the body’s requirements. For example, when skeletal muscles start contracting, oxygen demand increases dramatically. Thus, the energy and nutrient requirements vary from moment to moment (resting versus exercising), hour to hour (asleep versus awake), and year to year (growing child versus adult). Understanding energy requirements is one aspect of **energetics**, the study of the flow of energy and its transformation, or change, from one form to another.

Oxidation and Reduction

Most of the important energy changes in cells involve chemical reactions known as oxidation and reduction. Oxidation and reduction reactions may be described as transfers of oxygen, hydrogen, or electrons, but for our purposes the most important are those involving the transfer of electrons. A gain of oxygen, or a loss of hydrogen or electrons, is a form of **oxidation**, and the net result is a *decrease* in potential energy of the atom or molecule. A loss of oxygen, or a gain of hydrogen or electrons, is a form of **reduction**, and the net result is an *increase* in potential energy of the atom or molecule. The two reactions are always paired. When electrons pass from one molecule to another, the electron donor is *oxidized* and

the electron recipient is *reduced*. Oxidation and reduction are important because electrons carry chemical energy. In a typical oxidation–reduction reaction, often called a *redox reaction*, the reduced atom or molecule gains energy at the expense of the oxidized atom or molecule.

Tips

To remember what occurs with electron transfer in oxidation and reduction reactions, think **OIL RIG** for **oxidation is loss** and **reduction is gain**.

In such an exchange, the reduced molecule does not gain all the energy released by the oxidized molecule. Some energy is always released as heat. The remaining energy may be used to do physical or chemical work, such as forming ATP. By passing electrons through a series of oxidation–reduction reactions, cells can capture and use much of the energy that is released.

Mitochondria contain a series of protein complexes, called the *electron transport chain*, which pass electrons through a series of oxidation–reduction reactions. To maintain such a flow of electrons, a final electron acceptor is necessary. In mitochondria, this role is played by oxygen. Water is formed as the electrons ultimately combine with oxygen atoms and hydrogen ions.

Coenzymes play a key role in the flow of energy within a cell and its mitochondria. A **coenzyme** acts as an intermediary that accepts electrons from one molecule and transfers them to another molecule. For example, the coenzymes **NAD** (*nicotinamide adenine dinucleotide*) and **FAD** (*flavin adenine dinucleotide*) can remove hydrogen atoms from organic molecules. Each hydrogen atom consists of an electron (e^-) and a proton (a hydrogen ion, H^+). Thus, when a coenzyme accepts hydrogen atoms, the coenzyme is reduced and gains energy. The donor molecule loses electrons and energy as it gives up its hydrogen atoms.

The coenzyme FAD can accept 2 hydrogen atoms, gaining 2 electrons and forming $FADH_2$. The oxidized form of the coenzyme NAD has a positive charge (NAD^+). This coenzyme also gains 2 electrons as 2 hydrogen atoms are removed from the donor molecule, resulting in the formation of NADH and the release of a proton (H^+). For this reason, the reduced form of NAD is often described as “ $NADH + H^+$.”

In summary, the coenzymes $NADH + H^+$ and $FADH_2$ provide electrons to the electron transport chain. Oxygen accepts, or gains, those electrons. In other words, the coenzymes are oxidized and oxygen is reduced.

Checkpoint

1. Define metabolism, catabolism, and anabolism.
2. Compare oxidation and reduction.

See the blue Answers tab at the back of the book.

25-2 Carbohydrate metabolism generates ATP by glucose catabolism and forms glucose by gluconeogenesis

Learning Outcome Describe the basic steps in glycolysis, the citric acid cycle, the electron transport chain, and chemiosmosis, and summarize the energy yield of cellular respiration (glycolysis and aerobic metabolism).

Carbohydrate metabolism is primarily concerned with glucose metabolism because most carbohydrates are converted to glucose. The steps involved in glucose catabolism and ATP production include glycolysis, the citric acid cycle, the electron transport chain, and chemiosmosis, whereas glucose anabolism involves gluconeogenesis and glycogenesis. In this section, we describe the important catabolic and anabolic cellular reactions involving glucose.

Overview of Glucose Catabolism

Most cells generate ATP and other high-energy compounds by breaking down carbohydrates, especially glucose. The complete oxidation of glucose to CO_2 and H_2O involves three major biochemical pathways: glycolysis, the citric acid cycle, and the electron transport chain. We can summarize the complete reaction as follows:

This overall reaction is called **cellular respiration**. The breakdown of glucose takes place in a series of small steps. Several of these steps release sufficient energy to convert ADP to ATP. The complete catabolism of 1 molecule of glucose provides a typical body cell a net gain of 30–32 molecules of ATP.

Most ATP production occurs inside the mitochondria, but the first steps take place in the cytosol. In Chapter 10 we introduced the process of *glycolysis*, which breaks down glucose in the cytosol into smaller molecules that mitochondria can absorb and use. These reactions are *anaerobic* because glycolysis does not require oxygen. The subsequent reactions take place in mitochondria and are *aerobic*. The mitochondrial activity responsible for ATP production is called *aerobic metabolism*. (The terms *cellular respiration* and *aerobic metabolism* are often considered interchangeable; however, cellular respiration includes both anaerobic and aerobic reactions.)

Glucose Catabolism: Glycolysis

Glycolysis (glī-KOL-ih-sis; *glykus*, sweet + *lysis*, a loosening) is the breakdown of glucose. In this process, a series of enzymatic steps breaks the 6-carbon glucose molecule ($\text{C}_6\text{H}_{12}\text{O}_6$) into two 3-carbon molecules of **pyruvic acid** ($\text{CH}_3\text{—CO—COOH}$). (At the physiologically normal pH inside cells [7.0–7.4], each pyruvic acid molecule loses a hydrogen ion and exists as the negatively charged anion $\text{CH}_3\text{—CO—COO}^-$. This ionized form is called **pyruvate**.)

Glycolysis requires (1) glucose molecules; (2) appropriate cytosolic enzymes; (3) ATP and ADP; (4) inorganic phosphate groups (P_i); and (5) NAD, a coenzyme that removes hydrogen atoms during one of the enzymatic reactions. Recall from Chapter 2 that coenzymes are organic molecules that are essential to enzyme function. If any of these participants is missing, glycolysis cannot take place.

Figure 25-2 provides an overview of the steps in glycolysis. The beginning of glycolysis “costs” the cell 2 ATP molecules. Glycolysis begins with **phosphorylation**, a process in which a phosphate group is attached to the last (sixth) carbon atom of a **glucose** molecule. This uses 1 ATP molecule and creates **glucose-6-phosphate**. It has two main results: (1) It traps the glucose molecule within the cell, because phosphorylated glucose cannot cross the plasma membrane, and (2) it prepares the glucose molecule for further biochemical reactions. A second phosphorylation, using one more ATP molecule, takes place in the cytosol before the 6-carbon chain is broken into two 3-carbon fragments.

Energy benefits then begin to appear as these fragments are converted to pyruvate. Two of the steps release enough energy to generate ATP from ADP and inorganic phosphate (P_i). In addition, 2 molecules of NAD are reduced to $\text{NADH} + \text{H}^+$. (For convenience, we will use NAD for NAD^+ and NADH for $\text{NADH} + \text{H}^+$ in our discussion.) The net reaction of glycolysis looks like this:

This reaction sequence is anaerobic (without oxygen) and provides the cell a net gain of 2 molecules of ATP for each glucose molecule converted to 2 pyruvate molecules.

A few highly specialized cells, such as red blood cells, lack mitochondria and derive all their ATP through glycolysis. Skeletal muscle fibers rely on glycolysis for ATP production during periods of active contraction. Most cells can survive for brief periods using the ATP provided by glycolysis alone.

Here is a summary of the glycolytic pathway, which prepares glucose for the citric acid cycle:

1. One 6-carbon glucose molecule enters the pathway.
2. Two 3-carbon pyruvate molecules are produced.
3. Two molecules of ATP are produced from 2 ADP and 2 P_i .
4. Two pairs of high-energy electrons are passed to 2 NAD to form 2 NADH.
5. Specific enzymes catalyze each step of the process.

Glucose Catabolism: Fate of Pyruvate

A great deal of additional energy is still stored in the chemical bonds of pyruvate. The cell’s ability to capture that energy depends on the availability of oxygen. If oxygen supplies are inadequate, pyruvate is reduced to form lactate and NAD is oxidized from NADH. Lactate formation from pyruvate does not occur without the presence of NAD.

Figure 25-2 Glycolysis. Glycolysis breaks down a 6-carbon glucose molecule into two 3-carbon molecules of pyruvate through a series of enzymatic steps.

?

Glycolysis produces how many pyruvate molecules and how many ATP molecules from one glucose molecule?

If oxygen is readily available, mitochondrial activity provides most of the ATP that cells need.

Glucose Catabolism: Aerobic Metabolism

When oxygen supplies are adequate, mitochondria absorb the pyruvate molecules. Recall that a double membrane surrounds each mitochondrion. The *outer membrane* contains large pores that are permeable to ions and small organic molecules such

as pyruvate. Ions and molecules easily enter the *intermembrane space* separating the outer membrane from the *inner membrane*. The inner membrane contains a carrier protein that moves pyruvate into the mitochondrial matrix.

Within the mitochondria, in the process of **aerobic metabolism**, pyruvate is broken down and the energy released is used to produce a large amount of ATP. This process involves two pathways: the *citric acid cycle* and the *electron transport chain*.

Citric Acid Cycle

The citric acid cycle begins with pyruvate, the product of glycolysis, and it occurs in the mitochondria. This cycle involves oxidation, reduction, and decarboxylation reactions. Each pyruvate molecule ($\text{CH}_3\text{—CO—COO}^-$) is oxidized as its hydrogen atoms are removed by coenzymes, which are then reduced. These hydrogen atoms are ultimately the source of most of the cell's energy gain. The carbon and oxygen atoms are removed and released as carbon dioxide in a process called **decarboxylation** (dē-kar-boks-i-LĀ-shun). In total, each molecule of pyruvate in this cycle produces 3 molecules of CO_2 , 3 molecules of H_2O , 4 molecules of NADH, 1 molecule of FADH_2 , and 1 molecule of GTP (equivalent to ATP in terms of energy). Let's look at the cycle in detail.

Upon entering the mitochondrion, a pyruvate molecule participates in a complex reaction involving NAD and another coenzyme called **coenzyme A (CoA)**. This reaction yields 1 molecule of CO_2 , 1 of NADH, and 1 of **acetyl-CoA** (a-SĒ-til KŌ-ā)—a 2-carbon **acetyl group** (CH_3CO) bound to coenzyme A.

This sets the stage for a sequence of enzymatic reactions called the **citric acid cycle**. This cycle is also known as the *tricarboxylic* (trī-kar-bok-SIL-ik) *acid cycle* (TCA cycle) and the *Krebs cycle*. Because citric acid is the first substrate of the cycle, we will use citric acid cycle as the preferred term. The function of the citric acid cycle is to remove hydrogen atoms from organic molecules and transfer them to coenzymes. The overall pattern of the citric acid cycle is shown in **Figure 25-3**. (At physiologically normal pH, the organic acids exist in their dissociated, ionized form.)

At the start of the citric acid cycle, the 2-carbon acetyl group carried by CoA is transferred to a 4-carbon oxaloacetate molecule to make the 6-carbon compound citric acid (citrate). Coenzyme A is released intact and can thus bind another acetyl group. A complete revolution or “turn” of the citric acid cycle removes 2 carbon atoms, regenerating the 4-carbon chain. (This is why the reaction sequence is called a *cycle*.) In the citric acid cycle, the coenzymes NAD and FAD remove hydrogen atoms from organic molecules, becoming reduced to NADH and FADH_2 , respectively. We can summarize the fate of the atoms in the acetyl group as follows:

- The 2 carbon atoms are removed in enzymatic reactions that incorporate 4 oxygen atoms and form 2 molecules of carbon dioxide, a waste product.
- The hydrogen atoms are removed by the coenzymes NAD or FAD (**Figure 25-3**).

Several of the steps in a turn of the citric acid cycle involve more than one reaction and require more than one enzyme. Water molecules are tied up in two of those steps. We can summarize the entire sequence as follows:

The only immediate energy benefit of one turn of the citric acid cycle is the formation of a single molecule of GTP (*guanosine triphosphate*) from GDP (*guanosine diphosphate*) and P_i . In practical terms, GTP is the equivalent of ATP, because GTP readily transfers a phosphate group to ADP, producing ATP:

The formation of GTP from GDP in the citric acid cycle is an example of **substrate-level phosphorylation**. In this process, an enzyme uses the energy released by a chemical reaction to transfer a phosphate group to a suitable acceptor molecule. GTP is formed in the citric acid cycle, but many reaction pathways in the cytosol phosphorylate ADP and form ATP directly. For example, the ATP produced during glycolysis is generated through substrate-level phosphorylation. Normally, however, substrate-level phosphorylation provides a relatively small amount of energy compared with *oxidative phosphorylation*, which we discuss next.

Oxidative Phosphorylation and the Generation of ATP

Oxidative phosphorylation is the generation of ATP as the result of the transfer of electrons from the coenzymes NADH and FADH_2 to oxygen by a sequence of electron carriers within mitochondria. The process produces more than 90% of the ATP used by body cells. The basis of oxidative phosphorylation is the formation of water, a very simple reaction:

Cells can easily obtain the ingredients for this reaction. Hydrogen is a component of all organic molecules, and oxygen is an atmospheric gas. The only drawback is that the reaction releases a tremendous amount of energy all at once. In fact, this reaction releases so much energy that it is used to launch space shuttles into orbit. Cells cannot handle energy explosions. Instead, energy release must be gradual, as it is in oxidative phosphorylation. This reaction proceeds in a series of small, enzymatically controlled oxidation–reduction reactions. These key reactions take place in the electron transport chain, a series of integral and peripheral protein complexes in the inner mitochondrial membrane. Under these controlled conditions, energy is captured safely in molecules of ATP.

Electron Transport Chain. The **electron transport chain (ETC)** is embedded in the inner mitochondrial membrane (**Spotlight Figure 25-4**). The ETC consists of four respiratory protein complexes, coenzyme Q, and electron carriers made up of a series of **cytochrome** (SĪ-tō-krōm; *cyto-*, cell + *chroma*, color) molecules (*b*, *c*, *a*, and *a*₃). Each cytochrome has two parts: a protein and a pigment. The protein is embedded in the inner membrane of a mitochondrion. The protein surrounds the pigment portion, which contains a metal ion, either iron (Fe^{3+}) or copper (Cu^{2+}).

Figure 25-3 The Citric Acid Cycle.**a** An overview of the citric acid cycle, showing the distribution of carbon, hydrogen, and oxygen atoms through one complete turn**b** A detailed view of the citric acid cycle, showing its specific reactants and products beginning with citrate, the ionized form of citric acid

The final step in aerobic ATP production involves the indirect transfer of energy from the high-energy electrons carried by NADH and FADH₂ to ATP molecules. This energy transfer involves the electron transport chain and chemiosmosis along the inner mitochondrial membrane.

The electron transport chain consists of four respiratory complexes (I–IV), coenzyme Q, and cytochrome molecules (*b*, *c*, *a*, and *a*₃). Except for cytochrome *c* (Cyt *c*), these molecules are associated with respiratory complexes III and IV. The hydrogen atoms delivered by NADH and FADH₂ are first split into electrons (e[−]) and protons (H⁺). The high-energy electrons are passed along by redox reactions, such that their energy is released in a series of small steps. This energy is used to pump H⁺ into the intermembrane space. The result is a proton (H⁺) electrochemical gradient across the inner membrane. Chemiosmosis uses this proton (H⁺) gradient to generate ATP through ATP synthase. The red line with the arrowhead indicates the paths and destination of the electrons.

1

The electrons from NADH pass from respiratory complex I to coenzyme Q. The energy released by the electrons is used to pump protons (H⁺) from the matrix into the intermembrane space.

2

The electrons from FADH₂ are transferred to respiratory complex II and then directly to coenzyme Q.

3

The electrons are transferred from coenzyme Q to respiratory complex III. More electron energy is released and used to pump H⁺ into the intermembrane space.

4

The electrons transferred to respiratory complex IV release their remaining energy to pump H⁺ into the intermembrane space. The electrons are released into the matrix and combine with oxygen and H⁺ to form water molecules.

5

H⁺ pass through hydrogen ion channels into the matrix. Their movement provides the energy for the ATP synthase complex to combine ADP and P into ATP.

The Process of Oxidative Phosphorylation. During the citric acid cycle, hydrogen atoms are passed to the coenzymes NAD and FAD. The hydrogen atoms from the citric acid cycle do not enter the ETC intact. Only the electrons enter the electron transport chain. The protons (H^+) that accompany them are released into the mitochondrial matrix. The electrons, which carry the chemical energy, enter a sequence of oxidation–reduction reactions in the electron transport chain. This sequence ends with the transfer of electrons to oxygen and the formation of a water molecule. The electrons that travel along the electron transport chain gradually release energy as they pass from *coenzyme Q* and along the series of cytochrome molecules. That energy is used to *indirectly* support the synthesis of ATP from ADP.

The red lines in **Spotlight Figure 25–4** show the paths and destinations of electrons. Those from NADH are transferred from respiratory protein complex I to coenzyme Q (*ubiquinone*). The electrons from $FADH_2$ enter the ETC at respiratory protein complex II and are passed to coenzyme Q. As a result, the electrons carried by NADH enter the ETC at a higher energy level than those carried by $FADH_2$. The electrons from both paths are passed from coenzyme Q to respiratory protein complex III, which contains cytochrome *b*. From there, the electrons are shuttled by cytochrome *c* to additional cytochromes within respiratory protein complex IV.

Notice that this reaction sequence starts with the removal of 2 hydrogen atoms from a substrate molecule and ends with the formation of water from 2 hydrogen ions and 1 oxygen ion (O^{2-}). This is the reaction we described earlier as releasing too much energy if performed in a single step. However, because the reaction takes place in a series of small steps, the hydrogen and oxygen combine safely rather than explosively.

ATP Generation by Chemiosmosis. As we noted in Chapter 3, concentration gradients across membranes represent a form of potential energy that can be harnessed by the cell. The electron transport chain does not produce ATP directly. Instead, it creates the conditions necessary for ATP production. It creates a steep concentration gradient of hydrogen ions (protons) across the inner mitochondrial membrane. The electrons that travel along the electron transport chain release energy as they pass from coenzyme to cytochrome and from cytochrome to cytochrome. The energy released at each of several steps drives proton, or hydrogen ion, pumps. These pumps move hydrogen ions from the mitochondrial matrix into the intermembrane space between the inner and outer mitochondrial membranes. The pumps create a large electrochemical gradient for hydrogen ions across the inner membrane. This electrochemical gradient provides the energy to convert ADP to ATP.

Despite the electrochemical gradient, hydrogen ions cannot diffuse into the matrix because they are not lipid soluble. However, hydrogen ion channels in the inner membrane do permit H^+ to diffuse into the matrix. These ion channels and their attached *coupling factors* make up a protein complex called

ATP synthase. The kinetic energy of passing hydrogen ions generates ATP in a process known as **chemiosmosis** (*kem-ē-oz-MŌ-sis*), or *chemiosmotic phosphorylation*.

Spotlight Figure 25–4 diagrams the mechanism of ATP generation by chemiosmosis. Hydrogen ions are pumped into the intermembrane space at three places: (1) as respiratory complex I reduces coenzyme Q, (2) as cytochrome *b* reduces cytochrome *c*, and (3) as electrons are passed from cytochrome *a* to cytochrome *a₃*. For each pair of electrons removed from a substrate in the citric acid cycle by NAD, 6 hydrogen ions are pumped across the inner membrane of the mitochondrion and into the intermembrane space. Their reentry into the matrix provides the energy to generate 2.5 molecules of ATP. Alternatively, for each pair of electrons removed from a substrate in the citric acid cycle by $FADH_2$, 4 hydrogen ions are pumped across the inner membrane and into the intermembrane space. Their reentry into the matrix provides the energy to generate 1.5 molecules of ATP.

The Importance of Oxidative Phosphorylation. Oxidative phosphorylation is the most important cellular mechanism for generating ATP. It provides about 95% of the ATP needed to keep our cells alive. In most cases, if oxidative phosphorylation slows or stops, the cell dies. If many cells are affected, the individual may die. Oxidative phosphorylation requires both oxygen and electrons. For this reason, the rate of ATP generation is limited by the availability of either oxygen or electrons.

Cells obtain oxygen by diffusion from the extracellular fluid. If the supply of oxygen is cut off, mitochondrial ATP production stops, because reduced cytochrome *a₃* will have no acceptor for its electrons. With the last reaction stopped, the entire ETC comes to a halt, like cars at a washed-out bridge. Oxidative phosphorylation can no longer take place, and cells quickly succumb to energy starvation. Because neurons have a high demand for energy, the brain is one of the first organs to be affected.

Hydrogen cyanide gas is sometimes used as a pesticide to kill rats or mice. The cyanide ion (CN^-) binds to iron atoms in cytochrome *a₃* and prevents the transfer of electrons to oxygen. As a result, cells die from energy starvation, that is, a lack of ATP.

Glucose Catabolism: Energy Yield of Glycolysis and Aerobic Metabolism

For most cells, the main method of generating ATP is the complete reaction pathway that begins with glucose and ends with carbon dioxide and water. **Figure 25–5** summarizes the process in terms of energy production:

- **Glycolysis.** During glycolysis, the cell gains a net 2 molecules of ATP for each glucose molecule broken down anaerobically to 2 molecules of pyruvate. Two molecules of NADH are also produced. In most cells, electrons are passed from NADH to FAD by an intermediate electron carrier in the intermembrane space, producing $FADH_2$, and then to the electron transport chain.

Figure 25–5 A Summary of the Energy Yield of Glycolysis and Aerobic Metabolism. For each glucose molecule broken down by glycolysis, only 2 molecules of ATP (net) are produced. However, glycolysis, the formation of acetyl-CoA, and the citric acid cycle all yield molecules of reduced coenzymes (NADH or FADH_2). Many additional ATP molecules are produced when electrons from these coenzymes pass through the electron transport chain. In most cells, the 2 NADH molecules produced in glycolysis provide another 3–5 ATP molecules. The 8 NADH molecules produced in the mitochondria yield 20 ATP molecules, for a total of 23–25. Another 3 ATP molecules are gained from the 2 FADH_2 molecules generated in the mitochondria. The citric acid cycle generates an additional 2 ATP molecules in the form of GTP.

The energy produced from aerobic metabolism comes from what two sources?

- **The Citric Acid Cycle.** Each of the two revolutions of the citric acid cycle required to break down the 2 pyruvate molecules completely yields 1 molecule of ATP by way of GTP. This cycling provides an additional gain of 2 molecules of ATP. This cycle also transfers hydrogen atoms to NADH and FADH_2 . These coenzymes provide electrons to the electron transport chain.
- **The Electron Transport Chain.** For each molecule of glucose broken down, a total of 10 NADH and 2 FADH_2 deliver their high-energy electrons to the electron transport

chain. Each NADH yields 2.5 ATP and each FADH_2 yields 1.5 ATP. The 2 FADH_2 molecules from glycolysis yield 3 ATP molecules and 2 water molecules. Each of the 8 molecules of NADH from the citric acid cycle yields 2.5 molecules of ATP and 1 water molecule. Thus, the shuffling from the citric acid cycle to the electron transport chain yields 23 molecules of ATP.

Summing up, for each glucose molecule processed, the cell gains 30–32 molecules of ATP: 2 from glycolysis, 3–5 from the NADH generated in glycolysis, 2 from the citric acid cycle (by

means of GTP), and 23 from the electron transport chain. All but 2 of them are produced in the mitochondria.

Cardiac muscle cells and liver cells can gain an additional 2 ATP molecules for each glucose molecule broken down. They do so by increasing the energy yield from the 2 NADH generated during glycolysis. Although the NADH produced during glycolysis does not enter mitochondria in these cells, each NADH molecule passes its electrons to an intermediate molecule that can cross the mitochondrial membrane. Inside the matrix, NAD strips electrons from the intermediate molecule, forming NADH. The subsequent transfer of electrons to the electron transport chain results in the production of 5 ATP molecules, just as if the 2 NADH molecules formed during glycolysis had been generated in the citric acid cycle.

Glucose Anabolism: Gluconeogenesis

Some of the steps in the breakdown of glucose, or glycolysis, are essentially irreversible. For this reason, cells cannot generate glucose simply by using the same enzymes and reversing the steps of glycolysis. Glycolysis and the production of glucose, called *gluconeogenesis*, involve different sets of regulatory enzymes. As a result, the two processes are regulated independently.

When too little glucose is available, liver cells can form glucose from noncarbohydrate molecules in a process known as **gluconeogenesis** (glū-kō-nē-JEN-eh-sis). Fatty acids and two ketogenic amino acids (leucine and lysine) cannot be used for gluconeogenesis, because their catabolic pathways produce acetyl-CoA. Cells cannot use acetyl-CoA to make glucose, because the decarboxylation step (removal of CO₂) between pyruvate and acetyl-CoA cannot be reversed. So, some 3-carbon molecules other than pyruvate are used to synthesize glucose.

Glycogenesis and Glycogenolysis

Glucose molecules formed by gluconeogenesis can be used to manufacture other simple sugars, complex carbohydrates, proteoglycans, or nucleic acids. In the liver and in skeletal muscle, glucose molecules are stored as **glycogen**. Glycogen is an important energy reserve that can be broken down when the cell cannot obtain enough glucose from interstitial fluid. Glycogen molecules are large, but glycogen reserves take up very little space because they form compact, insoluble granules.

When the amount of available glucose exceeds cellular needs, cells can form glycogen from excess glucose in a process known as **glycogenesis** (glī-kō-JEN-e-sis). It involves several steps and requires the high-energy compound *uridine triphosphate* (UTP). The breakdown of glycogen to monomers of glucose is called **glycogenolysis** (glī-kō-je-NOL-i-sis). It takes place quickly and involves a single enzymatic step (Figure 25-6).

Figure 25-6 Glycolysis and Gluconeogenesis. Many of the reactions are freely reversible, but separate regulatory enzymes control the key steps, which are indicated by colored arrows. Certain amino acids, carbohydrates, lactate, and glycerol can be converted to glucose. The enzymatic reaction that converts pyruvate to acetyl-CoA cannot be reversed.

Clinical Note Carbohydrate Loading

Eating carbohydrates just before exercise does not improve performance. In fact, it can decrease endurance by slowing the mobilization of existing energy reserves. Generally, runners or swimmers preparing for lengthy endurance events, such as a marathon or 5K swim, do not eat immediately before participating. For 2 hours before the event, they also limit their intake to just drinking water.

However, performance in endurance sports improves if muscles have large stores of glycogen. Endurance athletes try to build these stores by eating carbohydrate-rich diets for 3 days before competing. This practice is called *carbohydrate loading*. Studies have shown that attempts to deplete stores by exercising to exhaustion before carbohydrate loading, a practice called *carbohydrate depletion/loading*, are less effective than 3 days of rest or minimal exercise during carbohydrate loading. The less intense approach improves mood and reduces the risks of muscle and kidney damage.

Tips

To make several similar-sounding terms easier to distinguish between, learn these word parts: *genesis* means “the formation of,” *lysis* means “a loosening,” *glyco* and *gluco* refer to glucose, and *neo* means “new.” So, **gluconeogenesis** is the formation of new glucose, **glycogenesis** is the formation of glycogen (the storage form of glucose), **glycogenolysis** is the breakdown of glycogen to glucose, and **glycolysis** is the breakdown of glucose to pyruvate.

Checkpoint

3. What is the primary role of the citric acid cycle in the production of ATP?
4. What process in the mitochondrion provides the conditions necessary for the synthesis of ATP by chemiosmosis?
5. How would a decrease in the level of NAD in the cytosol affect ATP production in mitochondria?

25-3 Lipid metabolism provides long-term storage and release of energy

Learning Outcome Describe the pathways involved in lipid metabolism and summarize the mechanisms of lipid transport and distribution.

Like carbohydrates, lipid molecules contain carbon, hydrogen, and oxygen, but the atoms are present in different proportions.

Triglycerides are the most abundant lipid in the body, so our discussion focuses on pathways for triglyceride breakdown and synthesis (**Figure 25-1**).

Lipid Catabolism: Lipolysis

Lipid metabolism involves the breakdown of fats into glycerol, fatty acids, and monoglycerides. During lipid catabolism, or **lipolysis**, lipids are broken down into pieces that can be either converted to pyruvate or channeled directly into the citric acid cycle (**Figure 25-7**). A triglyceride is split into its component parts by hydrolysis, yielding 1 molecule of glycerol and 3 fatty acid molecules. This catabolism occurs under the influence of growth hormone and thyroid hormone.

Conversion of Glycerol

Enzymes in the cytosol convert glycerol to pyruvate. Assuming the presence of sufficient oxygen, the pyruvate is converted to acetyl-CoA and then enters the citric acid cycle.

Beta-Oxidation of Fatty Acids

The catabolism of fatty acids involves a process that generates acetyl-CoA directly. In the process of **beta-oxidation**, fatty acid molecules are broken down in a sequence of reactions into 2-carbon acetic acid fragments, and FAD and NAD⁺ are reduced. **Figure 25-7** diagrams one step in the process of beta-oxidation. Each step generates molecules of acetyl-CoA, NADH, and FADH₂, and leaves a shorter carbon chain bound to coenzyme A. This process takes place inside mitochondria, so the acetyl-CoA produced can enter the citric acid cycle immediately.

Beta-oxidation has substantial energy benefits. For example, 9 acetyl-CoA can be produced from one 18-carbon fatty acid. During the creation of an acetyl-CoA from a fatty acid, 1 NADH and 1 FADH₂ result. For an 18-carbon fatty acid, eight steps of beta-oxidation result in 9 acetyl-CoA and the formation of 8 NADH and 8 FADH₂. The breakdown of one acetyl-CoA yields 3 NADH, 1 GTP/ATP, and 1 FADH₂ in the citric acid cycle. So, the breakdown of 9 acetyl-CoA yields 27 NADH, 9 GTP/ATP, and 9 FADH₂. Recall that each NADH produces 2.5 ATP, and each FADH₂ produces 1.5 ATP. The 35 NADH and 17 FADH₂ produce 113 ATP. Adding the 9 GTP/ATP makes a total of 122 ATP. Although 1 ATP was required for activation, it counts as 2 ATP, because the result was an AMP, not an ADP. The cell can therefore gain 120 ATP molecules from the breakdown of one 18-carbon fatty acid molecule. By comparison, this yield of ATP molecules is almost 1.3 times the energy obtained by the complete breakdown of three 6-carbon glucose molecules (90–96 ATP). The catabolism of other lipids follows similar patterns, generally ending with the formation of acetyl-CoA.

Figure 25-7 Lipolysis and Beta-Oxidation. Triglycerides are broken down into 1 glycerol and 3 fatty acid molecules. During beta-oxidation, the carbon chains of fatty acids are broken down to yield molecules of acetyl-CoA, which can be used in the citric acid cycle. The reaction also donates hydrogen atoms to coenzymes, which deliver them to the electron transport chain.

Where does beta-oxidation take place in a cell?

Lipid Anabolism: Lipogenesis

Lipogenesis (lip-Ō-JEN-e-sis) is the synthesis of lipids (Figure 25-1). It is stimulated by a diet high in carbohydrates and several hormones, including insulin. Glycerol is synthesized from *dihydroxyacetone phosphate*, one of the 3-carbon intermediate products shared by the pathways of glycolysis and gluconeogenesis. The synthesis of most types of lipids, including nonessential fatty acids and steroids, begins with acetyl-CoA. Lipogenesis can use almost any organic substrate because lipids, amino acids, and carbohydrates can be converted to acetyl-CoA. In other words, the body can turn just about anything we eat into fat.

Fatty acid synthesis involves a reaction sequence quite distinct from that of beta-oxidation. Body cells cannot *build* every fatty acid they can break down. For example, **linoleic acid** and **linolenic acid** are both 18-carbon unsaturated fatty acids synthesized by plants. They cannot be synthesized in the human body. They are considered **essential fatty acids** because they must be included in the diet. These fatty acids are also needed to synthesize prostaglandins and some of the phospholipids in plasma membranes throughout the body.

Lipid Storage and Energy Release

Lipids are important energy reserves because their breakdown provides large amounts of ATP. Lipids can be stored in compact droplets in the cytosol because they are insoluble in water. This storage method saves space, but when the lipid droplets are large, it is difficult for water-soluble enzymes to reach them. For this reason, lipid reserves are more difficult to access than carbohydrate reserves. Also, most lipids are processed inside mitochondria, and mitochondrial activity is limited by the availability of oxygen.

The net result is that lipids cannot provide large amounts of ATP quickly. However, cells with modest energy demands can shift to lipid-based energy production when glucose supplies are limited. Skeletal muscle fibers normally cycle between lipid metabolism and carbohydrate metabolism. At rest (when energy demands are low), these cells break down fatty acids. During activity (when energy demands are high and immediate), skeletal muscle fibers shift to glucose metabolism.

Lipid Transport and Distribution

Like glucose, lipids are needed throughout the body. For example, all cells need lipids to maintain their plasma membranes, and important steroid hormones must reach target cells in many different tissues. However, free fatty acids make up only a small percentage of the total circulating lipids. Because most lipids are not soluble in water, special transport mechanisms carry them from one region of the body to another. Most lipids, especially *cholesterol*, circulate through the bloodstream as *lipoproteins* (Figure 25-8).

Free Fatty Acids

Free fatty acids are lipids that can diffuse easily across plasma membranes. In the blood, free fatty acids are generally bound to albumin, the most abundant plasma protein. Sources of free fatty acids in the blood include the following:

- Fatty acids that are not used in the synthesis of triglycerides, but diffuse out of the intestinal epithelium and into the blood
- Fatty acids that diffuse out of lipid reserves (such as those in the liver and adipose tissue) when triglycerides are broken down.

Liver cells, cardiac muscle cells, skeletal muscle fibers, and many other body cells can metabolize free fatty acids. These lipids are an important energy source during periods of starvation when glucose supplies are limited.

Lipoproteins and Cholesterol

Lipoproteins are lipid-protein complexes that contain large insoluble glycerides and **cholesterol**. A superficial coating of phospholipids and proteins makes the entire complex soluble. Exposed proteins of the complexes bind to specific membrane receptors. For this reason, these membrane proteins determine which cells absorb the associated lipids.

Lipoproteins are usually classified into the following four major groups according to size and the relative proportions of lipid and protein:

- *Chylomicrons*. Chylomicrons (kī-lō-Mī-kronz) are the largest lipoproteins, ranging in diameter from 0.03 to 0.5 μm . About 95% of the weight of a chylomicron consists of triglycerides. They are produced by intestinal epithelial cells from the fats in food. Chylomicrons carry absorbed lipids from the intestinal tract into the lymph and then to the bloodstream.

The liver is the primary source of all the other groups of lipoproteins, which shuttle lipids among various tissues:

- *Very Low-Density Lipoproteins* (VLDLs). Very low-density lipoproteins contain triglycerides manufactured by the liver, plus small amounts of phospholipids and cholesterol. The primary function of VLDLs is to transport these triglycerides to skeletal muscles and adipose tissues. The VLDLs range in diameter from 25 to 75 nm (0.025–0.075 μm).
- *Low-Density Lipoproteins* (LDLs). Low-density lipoproteins contain cholesterol, lesser amounts of phospholipids, and very few triglycerides. These lipoproteins are about 25 nm in diameter. They deliver cholesterol to peripheral tissues. LDL cholesterol is often called “bad cholesterol” because the cholesterol may end up in arterial plaques.
- *High-Density Lipoproteins* (HDLs). High-density lipoproteins have approximately equal amounts of lipid and protein.

Figure 25-8 Lipid Transport and Use.

Clinical Note Dietary Fats and Cholesterol

Due to concerns about cholesterol, such phrases as “low cholesterol,” “contains no cholesterol,” and “cholesterol free” are now widely used in food packaging. Cholesterol content alone, however, does not adequately explain the complicated relationship among diet, genetics, and health.

- *Cholesterol has many vital functions in the human body.* Cholesterol serves as a lipid component of all plasma membranes, is a key constituent of bile, and is the precursor of several hormones (estrogen and testosterone) and vitamin D.
- *The cholesterol content of the diet is not the only source of circulating cholesterol.* The liver can manufacture cholesterol, accounting for about 20% of the cholesterol in the bloodstream. The remainder comes from metabolism of saturated fats in the diet. If the diet contains an abundance of saturated fats, cholesterol levels in the blood increase because excess lipids are broken down to acetyl-CoA and used to synthesize cholesterol. Consequently, individuals

trying to lower blood—specifically serum—cholesterol levels through diet must also restrict other lipids, especially saturated fats.

- *Genetic factors affect individual cholesterol level.* If dietary cholesterol is reduced, the body synthesizes more to maintain cholesterol concentrations in the blood. Because individuals have different genes, their cholesterol levels can vary, even on similar diets.
- *Cholesterol levels vary with age.* At age 19, males have fasting cholesterol levels (measured 8–12 hours after a meal) below 170 mg/dL, whereas females have levels below 175 mg/dL. As age increases, the cholesterol levels gradually increase. Cholesterol levels are considered unhealthy if they are higher than those of 90% of the population in that age group. For males, this level is 185 mg/dL at age 19 and 250 mg/dL at age 70. For females, the comparable levels are 190 mg/dL at age 19 and 275 mg/dL at age 70.

The lipids are largely cholesterol and phospholipids. HDLs are about 10 nm in diameter. Their primary function is to transport excess cholesterol from peripheral tissues back to the liver for storage or excretion in the bile. HDL cholesterol is called “good cholesterol” because it is returning from peripheral tissues and does not cause circulatory problems. Applying the terms *good* and *bad* to cholesterol can be misleading, for cholesterol metabolism is complex and variable. (For more details, see the Clinical Note: Dietary Fats and Cholesterol.) **Figure 25–8** also shows the relationship between LDL and HDL lipoproteins and the transport of cholesterol.

Exercise may lower cholesterol by several mechanisms. For example, exercise stimulates enzymes that move LDL from the blood into the liver and exercise increases the size of the protein particles that carry cholesterol in the bloodstream. Studies have also shown that vigorous exercise—the equivalent of 20 miles of jogging per week—lowered the LDL level even more than moderate exercise. However, the amount of exercise a person needs to experience the cholesterol-lowering benefit is still uncertain.

Checkpoint

6. Define beta-oxidation.
7. Identify the four major groups of lipoproteins.
8. Why are high-density lipoproteins (HDLs) considered beneficial to health?

See the blue Answers tab at the back of the book.

Clinical Note Blood Testing for Fat

When ordering a blood test for cholesterol, clinicians also request information about circulating triglycerides. In fasting individuals, triglycerides are usually found within the range of 40–150 mg/dL. (After a person has consumed a fatty meal, the triglyceride level may be temporarily elevated.)

When cholesterol levels are high, or when an individual has a family history of atherosclerosis or coronary artery disease (CAD), further tests and calculations are done. The **HDL** level is measured, and the **LDL** level is calculated as follows:

$$\text{LDL} = \text{cholesterol} - \text{HDL} - \frac{\text{triglycerides}}{5}$$

A high total cholesterol value linked to a high LDL level is a risk factor for cardiovascular disease. In effect, too much cholesterol is being exported to peripheral tissues. Problems can also exist in individuals with high total cholesterol—or even normal total cholesterol—but low HDL levels (below 35 mg/dL). In such cases, excess cholesterol delivered to the tissues cannot be returned easily to the liver for excretion. In either event, the amount of cholesterol in peripheral tissues—and especially in arterial walls—is likely to increase.

For years, LDL:HDL ratios were considered valid predictors of the risk of developing atherosclerosis. Risk factor analysis and the LDL level are now thought to be more accurate indicators. For males with more than one risk factor, many clinicians recommend dietary changes and drug therapy if the LDL level exceeds 130 mg/dL, or even 100 mg/dL, regardless of the total cholesterol or HDL level.

25-4 Protein metabolism provides amino acids and synthesizes proteins

Learning Outcome Summarize the main processes of protein metabolism and discuss the use of protein as an energy source.

The body can synthesize 100,000 to 140,000 different proteins. They have various functions and structures. Yet each protein contains some combination of the same 20 **amino acids**. Amino acids enter body cells by active transport, and growth hormone influences the entry of amino acids into cells. The amino acids are synthesized into proteins that function as enzymes, hormones, structural elements, and neurotransmitters. Very little protein is used as an energy source. We begin with amino acid catabolism.

Amino Acid Catabolism

Before protein catabolism occurs, proteins must be converted to substances that can enter the citric acid cycle. This conversion involves transamination (removal of an amino group from an amino acid and its transfer to a keto acid), deamination (removal of an amino group), and the urea cycle (producing urea from ammonium ions derived from deamination reactions and carbon dioxide). Amino acids may be converted into glucose, fatty acids, and ketone bodies. The first step in amino acid catabolism is the removal of the amino group ($-\text{NH}_2$). This step requires a coenzyme derivative of **vitamin B₆** (*pyridoxine*).

Transamination

Transamination (tranz-am-i-NĀ-shun) is a reversible chemical reaction that transfers the amino group of an amino acid to a **keto acid**. Keto acids resemble amino acids except that the second carbon binds to an oxygen atom rather than to an amino group (**Figure 25-9a**). This transfer converts the keto acid into an amino acid that can leave the mitochondrion and enter the cytosol. There it can be used for protein synthesis. In the process, the original amino acid becomes a keto acid that can be broken down in the citric acid cycle.

Cells perform transamination to synthesize many of the amino acids needed for protein synthesis. For example, cells of the liver, skeletal muscles, heart, lung, kidney, and brain are particularly active in protein synthesis, so they carry out many transamination reactions.

Deamination

Deamination (dē-am-i-NĀ-shun) prepares an amino acid for breakdown in the citric acid cycle (**Figure 25-9b**). Deamination is the removal of an amino group and a hydrogen atom in a reaction that generates a toxic ammonium ion (NH_4^+). Liver cells are the primary sites of deamination. They also have

enzymes that remove ammonium ions by synthesizing **urea**, a harmless water-soluble compound excreted in urine. The **urea cycle** is the reaction sequence that produces urea (**Figure 25-9c**).

Several inherited metabolic disorders result from an inability to produce specific enzymes involved in amino acid metabolism. For example, individuals with *phenylketonuria* (fen-il-kē-tō-NŪ-rē-uh), or PKU, have a defect in the enzyme *phenylalanine hydroxylase*. They cannot convert phenylalanine to tyrosine. This reaction is an essential step in the synthesis of norepinephrine, epinephrine, dopamine, and melanin. If the enzyme is absent, phenylalanine undergoes a transamination and makes phenylpyruvic acid, which can be detected in urine. If PKU is not detected in infancy, phenylalanine and its deaminated products build up and central nervous system development is inhibited. Severe brain damage results. The condition is common enough that a warning is printed on the packaging of products that contain phenylalanine, such as diet drinks.

Amino Acids and ATP Production

When glucose supplies are low and lipid reserves are inadequate, mitochondria can generate ATP by breaking down amino acids in the citric acid cycle. Liver cells break down internal proteins and absorb additional amino acids from the blood (**Figure 25-1**). The amino acids are deaminated, and their carbon chains are sent to the mitochondria. Not all amino acids enter the cycle at the same point, however, so the ATP benefits vary. Nonetheless, the average ATP yield per gram is comparable to that of carbohydrate catabolism.

However, three factors make protein catabolism an impractical source of quick energy:

- Proteins are more difficult to break apart than are complex carbohydrates or lipids.
- One of the by-products, ammonium ions, is toxic to cells.
- Proteins form the most important structural and functional components of any cell. Extensive protein catabolism threatens homeostasis at both the cellular and system levels.

Protein Synthesis

We discussed the basic mechanism for protein synthesis in Chapter 3. The body can synthesize about half of the various amino acids needed to build proteins. There are 10 **essential amino acids**, which must come from the diet. The body cannot synthesize eight of them (*isoleucine, leucine, lysine, threonine, tryptophan, phenylalanine, valine, and methionine*). The other two (*arginine* and *histidine*) can be synthesized, but not in the amounts that growing children need.

Figure 25–9 Amino Acid Catabolism and Synthesis.

Other amino acids are called **nonessential amino acids** because the body can make them on demand. Body cells can readily synthesize their carbon frameworks. Then an amino group can be added by **amination**—using an ammonium ion as a reactant (Figure 25–9d).

Checkpoint

- Define transamination and deamination.
- How would a diet that is deficient in pyridoxine (vitamin B_6) affect protein metabolism?

See the blue Answers tab at the back of the book.

25-5 There are two patterns of metabolic activity: energy storage in the absorptive state and energy release in the postabsorptive state

Learning Outcome Differentiate between the absorptive and postabsorptive metabolic states and summarize the characteristics of each.

The nutrient requirements of each tissue vary with the types and quantities of enzymes present in the cytosol of cells. From a metabolic standpoint, we consider the body to have

distinctive components: the liver, adipose tissue, skeletal muscle, nervous tissue, and other peripheral tissues.

- **The Liver.** The liver is the focal point of metabolic regulation and control. Liver cells contain a great diversity of enzymes, so they can break down or synthesize most of the carbohydrates, lipids, and amino acids needed by other body cells. Liver cells have an extensive blood supply, so they are in an excellent position to monitor and adjust the nutrient composition of circulating blood. The liver also contains significant energy reserves in the form of glycogen.
- **Adipose Tissue.** Adipose tissue stores lipids, primarily as triglycerides. Adipocytes are in many areas: in areolar tissue, in mesenteries, within red and yellow bone marrows, in the epicardium, and around the eyes and the kidneys.
- **Skeletal Muscle.** Skeletal muscle accounts for almost half of a healthy person's body weight. Skeletal muscle fibers maintain substantial glycogen reserves. In addition, if other nutrients are unavailable, their contractile proteins can be broken down and the amino acids used as an energy source.
- **Nervous Tissue.** Nervous tissue has a high demand for energy, but the cells do not maintain reserves of carbohydrates, lipids, or proteins. Neurons must have a reliable supply of glucose because they are generally unable to metabolize other molecules. If the blood glucose level becomes too low, nervous tissue in the central nervous system cannot continue to function, and the person falls unconscious.
- **Other Peripheral Tissues.** Other peripheral tissues do not maintain large metabolic reserves, but they are able to metabolize glucose, fatty acids, or other substrates. Their preferred source of energy varies according to instructions from the endocrine system.

25

To understand the interrelationships among these five components, let's consider events over a typical 24-hour period. During this time, the body experiences two broad patterns of metabolic activity: the *absorptive state* and the *postabsorptive state*. In the absorptive state that follows a meal, cells absorb nutrients to be used for growth, maintenance, and energy reserves. Hours later, in the postabsorptive state, metabolic reactions are focused on maintaining the blood glucose level that meets the needs of nervous tissue.

Spotlight Figure 25-10 summarizes the metabolic pathways for lipids, carbohydrates, and proteins. The diagrams show the reactions in a "typical" cell. Note, however, that no one cell can carry out all the anabolic and catabolic operations and interconversions required by the body as a whole. As cells differentiate, each type develops its own set of enzymes. These enzymes determine the cell's metabolic capabilities. In the face of such cellular diversity, homeostasis can be preserved only when the metabolic activities of tissues, organs, and organ systems are coordinated.

Tips

The absorptive state is like harvest time: Food is being gathered and stored. The postabsorptive state corresponds to the time between harvests, when stored food is used for nourishment.

During the postabsorptive state, liver cells conserve glucose and break down lipids and amino acids. Both lipid catabolism and amino acid catabolism generate acetyl-CoA. As the concentration of acetyl-CoA rises, compounds called *ketone bodies* begin to form. A **ketone body** is an organic compound produced by fatty acid metabolism that dissociates in solution, releasing a hydrogen ion. There are three such compounds: (1) **acetoacetate** (as-eh-tō-AS-eh-tāt), (2) **acetone** (AS-eh-tōn), and (3) **betahydroxybutyrate** (bā-tah-hl-droks-ē-BŪ-teh-rāt). Liver cells do not catabolize any of the ketone bodies. Instead, these compounds diffuse through the cytosol and into the general circulation. Cells in peripheral tissues then absorb the ketone bodies and reconvert them to acetyl-CoA for breakdown in the citric acid cycle.

In healthy individuals, the liver continuously produces ketone bodies, but the blood concentration is about 1 mg/dL (normal range 0.3–2.0 mg/dL). Ketone bodies are undetectable by routine urinalysis. During even a brief period of fasting, the increased production of ketone bodies results in *ketosis* (kē-TŌ-sis), a high concentration of ketone bodies in body fluids. The appearance of ketone bodies in the bloodstream—*ketonemia*—lowers blood pH, which must be controlled by buffers. During prolonged starvation, the level of ketone bodies continues to rise. Eventually, buffering capacities are exceeded and a dangerous drop in pH takes place. This acidification of the blood by ketone bodies is called *ketoacidosis* (kē-tō-as-ih-DŌ-sis). In severe ketoacidosis, the circulating concentration of ketone bodies can reach 200 mg/dL, and the pH may drop below 7.05. A pH that low can disrupt tissue activities and cause coma, cardiac arrhythmias, and death.

In summary, during the postabsorptive state, the liver acts to stabilize the blood glucose concentration. It does so first by the breakdown of glycogen reserves and later by gluconeogenesis. Over the remainder of the postabsorptive state, the combination of lipid and amino acid catabolism provides the necessary ATP. These processes generate large quantities of ketone bodies that diffuse into the bloodstream. Amino acid catabolism results in the release of toxic ammonium ions, which become tied up in the formation of urea.

Changes in the activity of the liver, adipose tissue, skeletal muscle, and other peripheral tissues ensure a steady supply of glucose to the nervous system. The supply remains steady despite daily or even weekly changes in nutrient availability. Only after a prolonged period of starvation does nervous tissue begin to metabolize ketone bodies and lactate molecules, as well as glucose.

✓ Checkpoint

11. What process in the liver increases after eating a high-carbohydrate meal?
12. Why does the blood level of urea increase during the postabsorptive state?
13. If a cell accumulates more acetyl-CoA than it can metabolize in the citric acid cycle, what products are likely to form?

See the blue Answers tab at the back of the book.

25-6 Adequate nutrition allows normal physiological functioning

Learning Outcome Explain what makes up a balanced diet and why such a diet is important.

The postabsorptive state can be maintained for a considerable period. For homeostasis to be maintained indefinitely, however, the digestive tract must regularly absorb enough fluids, organic nutrients, minerals, and vitamins to keep pace with cellular demands. The absorption of nutrients from food is called **nutrition**.

The body's requirement for each nutrient varies from day to day and from person to person. *Nutritionists* attempt to analyze a diet in terms of its ability to meet the needs of a specific individual. Food supplies the necessary nutrients to ensure normal functions. Absorbed nutrients enter the bloodstream and lymph and are transported to body tissues. When a person is in good health and maintains a healthy diet, energy needs are met by absorbed nutrients. An important healthy diet consideration is *nitrogen balance*. Since proteins contain a great deal of nitrogen, nitrogen balance equals protein balance, or simply, protein anabolism equals protein catabolism. This section discusses the food groups, positive and negative nitrogen balance, and minerals and vitamins.

Food Groups and a Balanced Diet

A **balanced diet** contains all the ingredients needed to maintain homeostasis. Such a diet must include adequate essential amino acids and fatty acids, minerals and vitamins, and substrates for energy generation. In addition, the diet must include enough water to replace losses in urine, feces, and evaporation. A balanced diet prevents **malnutrition**, an unhealthy state resulting from inadequate or excessive absorption of one or more nutrients.

One way of avoiding malnutrition is to consume a balanced diet. In the United States, the Department of Agriculture establishes Dietary Guidelines for Americans. The guidelines for healthy eating are updated every 5 years. Current guidelines use color-coded food groups in a visual known as MyPlate. These color-coded food groups of fruits (red), vegetables (green), grains (orange), proteins (purple), and dairy (blue) indicate the proportions of food recommended for a healthy diet (**Figure 25-11** and **Table 25-1**).

What is most important for a balanced diet is taking in nutrients in sufficient *quantity* (adequate to meet energy needs) and *quality* (including all nutrients of a balanced diet). If nutritious food is available, it is important to make good choices about what to eat. Poor choices can lead to malnutrition even if all food groups are represented.

For example, consider the essential amino acids. The liver cannot synthesize any of these amino acids, so they must be obtained from the diet. Some foods in the dairy and protein groups—specifically, beef, fish, poultry, eggs, and milk—provide all the essential amino acids in sufficient quantities. They are said to contain **complete proteins**. Many plants also supply adequate *amounts* of protein but contain **incomplete proteins**, which are deficient in one or more of the essential amino acids. People who follow a *vegetarian diet*, which is largely restricted to the grains, vegetables, and fruits groups

Table 25-1 Basic Food Groups and Their General Effects on Health

Nutrient Group	Provides	Health Effects
Grains (recommended: at least half of the total eaten as whole grains)	Carbohydrates; vitamins E, thiamine, niacin, folate; calcium; phosphorus; iron; sodium; dietary fiber	Whole grains prevent rapid rise in blood glucose levels and consequent rapid rise in insulin levels
Vegetables (recommended: especially dark-green and orange vegetables)	Carbohydrates; vitamins A, C, E, folate; dietary fiber; potassium	Reduce risk of cardiovascular disease; protect against colon cancer (folate) and prostate cancer (lycopene in tomatoes)
Fruits (recommended: a variety of fruit each day)	Carbohydrates; vitamins A, C, E, folate; dietary fiber; potassium	Reduce risk of cardiovascular disease; protect against colon cancer (folate)
Dairy (recommended: low-fat or fat-free milk, yogurt, and cheese)	Complete proteins; fats; carbohydrates; calcium; potassium; magnesium; sodium; phosphorus; vitamins A, B ₁₂ , pantothenic acid, thiamine, riboflavin	Whole milk: high in calories, may cause weight gain; saturated fats correlated with heart disease
Protein (recommended: lean meats, fish, poultry, eggs, dry beans, nuts, legumes)	Complete proteins; fats; calcium; potassium; phosphorus; iron; zinc; vitamins E, thiamine, B ₆	Fish and poultry lower risk of heart disease and colon cancer (compared to red meat). Consumption of up to one egg per day does not appear to increase incidence of heart disease; nuts and legumes improve blood cholesterol ratios, lower risk of heart disease and diabetes

Over a typical 24-hour period, the body experiences two broad patterns of metabolic activity: the **absorptive state** and the **postabsorptive state**.

MEALS

The **absorptive state** is the time following a meal, when nutrient absorption is happening. After a typical meal, the absorptive state lasts for about 4 hours. Thus, if 3 meals are eaten in a day, 12 out of every 24 hours are spent in the absorptive state. Insulin is the primary hormone of the absorptive state. Various other hormones stimulate amino acid uptake (growth hormone) and protein synthesis (growth hormone, androgens, and estrogens).

ABSORPTIVE STATE

Figure 25–11 MyPlate. The proportion of each food group is indicated by the relative size of its color-coded area. Foods should be consumed in proportions based on both the food group and the person's level of activity.

(with or without the dairy products group), must become adept at varying their food choices to include combinations of ingredients that meet all their amino acid requirements. Even with a proper balance of amino acids, people who eat a *vegan diet*, which avoids all animal products, face a significant problem, because vitamin B₁₂ is obtained only from animal products or from fortified cereals or tofu.

Nitrogen Balance

Nitrogen balance is the difference between the total nitrogen consumed and the amount excreted in urine and feces. A variety of important compounds in the body contain nitrogen atoms. These include:

- Amino acids, which are part of the framework of all proteins and protein derivatives, such as glycoproteins and lipoproteins
- Purines and pyrimidines, the nitrogenous bases of RNA and DNA
- *Creatine*, important in energy storage in muscle tissue (as creatine phosphate)
- *Porphyryns* (por-FĒR-inz), complex ring-shaped molecules that bind metal ions and are essential to the function of hemoglobin, myoglobin, and the cytochromes.

Despite the importance of nitrogen to these compounds, the body neither stores nitrogen nor maintains nitrogen reserves, as it does carbohydrates (glycogen) and lipids (triglycerides). The body can synthesize the carbon chains of the nitrogen compounds, but nitrogen atoms must be obtained either by recycling nitrogen compounds already in the body

or by absorbing nitrogen from the diet. Nitrogen balance is a normal condition, and it means that the rates of synthesis and breakdown of nitrogen compounds are equivalent.

Growing children, athletes, people recovering from an illness or injury, and pregnant or lactating females actively synthesize nitrogen compounds. These individuals must absorb more nitrogen than they excrete. Such individuals are in a state of **positive nitrogen balance**.

When excretion exceeds ingestion, a **negative nitrogen balance** exists. The body contains only about a kilogram of nitrogen tied up in nitrogen compounds, and a decrease of one-third can be fatal. Even when energy reserves are mobilized (as during starvation), carbohydrates and lipid reserves are broken down first and nitrogen compounds are conserved.

The Role of Minerals and Vitamins

As we explained, a balanced diet includes both minerals and vitamins. However, the body cannot synthesize minerals, and the cells can generate only a small quantity of a very few vitamins.

Minerals

Minerals are inorganic ions released through the dissociation of electrolytes. Minerals are important for three reasons:

- *Ions such as sodium and chloride determine the osmotic concentrations of body fluids.* Potassium ions are important in maintaining the osmotic concentration of the cytosol inside body cells.
- *Ions in various combinations play major roles in important physiological processes.* As noted, these processes include the

maintenance of membrane potentials; the construction and maintenance of the skeleton; muscle contraction; the generation of action potentials; the release of neurotransmitters; hormone production; blood clotting; the transport of respiratory gases; buffer systems; fluid absorption; and waste removal.

- *Ions are essential cofactors in a variety of enzymatic reactions.* For example, calcium-dependent ATPase in skeletal muscle also requires the presence of magnesium ions. This calcium ATPase transports calcium ions from the cytosol back to the sarcoplasmic reticulum after muscle contraction. Another ATPase required for the conversion of glucose to pyruvate needs both potassium and magnesium ions. Carbonic anhydrase is important in CO_2 transport, buffering systems, and gastric acid secretion. This enzyme requires the presence of zinc ions. Finally, components of the electron transport chain require an iron atom. The final cytochrome (a_3) of the electron transport chain must bind a copper ion as well.

The major minerals and a summary of their functional roles are listed in **Table 25–2**. The body contains reserves of several important minerals, and these reserves help reduce the effects of variations in the dietary supply. Chronic dietary reductions can lead to a variety of clinical problems.

Alternatively, a dietary excess of mineral ions can be equally dangerous because storage capabilities are limited.

Problems involving iron are particularly common. The body of a healthy male contains about 3.5 g of iron in the ionic form Fe^{2+} . Of that amount, 2.5 g is bound to hemoglobin in circulating red blood cells. The remainder is stored in the liver and red bone marrow. In females, the total body iron content averages 2.4 g, with about 1.9 g incorporated into red blood cells. Thus, a female's iron reserves are only 0.5 g, which is half that of a typical male. For this reason, if the diet contains inadequate amounts of iron, premenopausal females are more likely to develop signs of iron deficiency than are males.

Vitamins

A **vitamin** is an essential organic nutrient that functions as a coenzyme in vital enzymatic reactions. Vitamins are assigned to either of two groups based on their chemical structure and characteristics: *fat-soluble vitamins* or *water-soluble vitamins*.

Fat-Soluble Vitamins. Vitamins A, D, E, and K are the **fat-soluble vitamins**, which dissolve in lipids. These vitamins are primarily absorbed from the digestive tract, along with the lipid contents of micelles. However, when exposed to sunlight,

Table 25–2 Minerals and Mineral Reserves

Mineral	Significance	Total Body Content	Primary Route of Excretion	Recommended Daily Allowance (RDA) in mg
BULK MINERALS				
Sodium	Major cation in body fluids; essential for normal membrane function	110 g, primarily in body fluids	Urine, sweat, feces	1500
Potassium	Major cation in cytoplasm; essential for normal membrane function	140 g, primarily in cytoplasm	Urine	4700
Chloride	Major anion in body fluids; functions in forming HCl	89 g, primarily in body fluids	Urine, sweat	2300
Calcium	Essential for normal muscle and neuron function and normal bone structure	1.36 kg, primarily in skeleton	Urine, feces	1000–1200
Phosphorus	In high-energy compounds, nucleic acids, and bone matrix (as phosphate)	744 g, primarily in skeleton	Urine, feces	700
Magnesium	Cofactor of enzymes, required for normal membrane functions	29 g (skeleton, 17 g; cytoplasm and body fluids, 12 g)	Urine	310–400
TRACE MINERALS				
Iron	Component of hemoglobin, myoglobin, and cytochromes	3.9 g (1.6 g stored as ferritin or hemosiderin)	Urine (traces)	8–18
Zinc	Cofactor of enzyme systems, notably carbonic anhydrase	2 g	Urine, hair (traces)	8–11
Copper	Required as cofactor for hemoglobin synthesis	127 mg	Urine, feces (traces)	0.9
Manganese	Cofactor for some enzymes	11 mg	Feces, urine (traces)	1.8–2.3
Cobalt	Cofactor for transaminations; mineral in vitamin B_{12} (cobalamin)	1.1 g	Feces, urine	0.0001
Selenium	Antioxidant	Variable	Feces, urine	0.055
Chromium	Cofactor for glucose metabolism	0.0006 mg	Feces, urine	0.02–0.035

Table 25–3 The Fat-Soluble Vitamins

Vitamin	Significance	Sources	Recommended Daily Allowance (RDA) in mg	Effects of Deficiency	Effects of Excess
A	Maintains epithelia; required for synthesis of visual pigments; supports immune system; promotes growth and bone remodeling	Leafy green and yellow vegetables	0.7–0.9	Retarded growth, night blindness, deterioration of epithelial membranes	Liver damage, skin paling, CNS effects (nausea, anorexia)
D	Required for normal bone growth, intestinal calcium and phosphorus absorption, and retention of these ions at the kidneys	Synthesized in skin exposed to sunlight	0.005–0.015*	Rickets, skeletal deterioration	Calcium deposits in many tissues, disrupting functions
E	Prevents breakdown of vitamin A and fatty acids	Meat, milk, vegetables	15	Anemia, other problems suspected	Nausea, stomach cramps, blurred vision, fatigue
K	Essential for liver synthesis of prothrombin and other clotting factors	Vegetables; production by intestinal bacteria	0.09–0.12	Bleeding disorders	Liver dysfunction, jaundice

*Unless exposure to sunlight is inadequate for extended periods and alternative sources are unavailable.

the skin can synthesize small amounts of vitamin D, and intestinal bacteria produce some vitamin K.

The mode of action of these vitamins is an area of active research. Vitamin A has long been recognized as a structural component of the visual pigment retinal. Its more general metabolic effects are not well understood. Vitamin D is ultimately converted to calcitriol. This hormone binds to cytoplasmic receptors within the intestinal epithelium and helps to increase the rate of intestinal absorption of calcium and phosphorus

ions. Vitamin E stabilizes intracellular membranes. Vitamin K is essential to the synthesis of several proteins, including at least three blood clotting factors. Information about the fat-soluble vitamins is summarized in **Table 25–3**.

Water-Soluble Vitamins. Most of the **water-soluble vitamins** (**Table 25–4**) are components of coenzymes. For example, NAD is derived from niacin (vitamin B₃), FAD from vitamin B₂ (riboflavin), and coenzyme A from vitamin B₅

Table 25–4 The Water-Soluble Vitamins

Vitamin	Significance	Sources	Recommended Daily Allowance (RDA) in mg	Effects of Deficiency	Effects of Excess
B₁ (thiamine)	Coenzyme in many pathways	Milk, meat, bread	1.1–1.2	Muscle weakness, CNS and cardiovascular problems, including heart disease; called <i>beriberi</i>	Hypotension
B₂ (riboflavin)	Part of FAD, involved in multiple pathways, including glycolysis and citric acid cycle	Milk, meat, eggs, and cheese	1.1–1.3	Epithelial and mucosal deterioration	Itching, tingling
B₃ (niacin)	Part of NAD, involved in multiple pathways	Meat, bread, potatoes	14–16	CNS, GI, epithelial, and mucosal deterioration; called <i>pellagra</i>	Itching, burning; vasodilation; death after large dose
B₅ (pantothenic acid)	Coenzyme A, in multiple pathways	Milk, meat	10	Retarded growth, CNS disturbances	None reported
B₆ (pyridoxine)	Coenzyme in amino acid and lipid metabolism	Meat, whole grains, vegetables, orange juice, cheese, and milk	1.3–1.7	Retarded growth, anemia, convulsions, epithelial changes	CNS alterations, perhaps fatal
B₉ (folic acid)	Coenzyme in amino acid and nucleic acid metabolism	Leafy vegetables, some fruits, liver, cereal, and bread	0.2–0.4	Retarded growth, anemia, gastrointestinal disorders, developmental abnormalities	Few noted, except at massive doses
B₁₂ (cobalamin)	Coenzyme in nucleic acid metabolism	Milk, meat	0.0024	Impaired RBC production, causing <i>pernicious anemia</i>	Polycythemia
B₇ (biotin)	Coenzyme in many pathways	Eggs, meat, vegetables	0.03	Fatigue, muscular pain, nausea, dermatitis	None reported
C (ascorbic acid)	Coenzyme in many pathways	Citrus fruits	75–90; smokers add 35 mg	Epithelial and mucosal deterioration; called <i>scurvy</i>	Kidney stones

(pantothenic acid). The liver synthesizes niacin from the essential amino acid tryptophan.

Water-soluble vitamins are rapidly exchanged between the fluid compartments of the digestive tract and the circulating blood. Excessive amounts are readily excreted in urine. For this reason, hypervitaminosis involving water-soluble vitamins is relatively uncommon, except among people who take large doses of vitamin supplements. Only vitamins B₁₂ and C are stored in significant quantities. Insufficient intake of other water-soluble vitamins can lead to initial signs and symptoms of vitamin deficiency within a period of days to weeks.

The bacteria that live in the intestines help prevent deficiency diseases. They produce small amounts of five of the nine water-soluble vitamins, in addition to the fat-soluble vitamin K. The intestinal epithelium can easily absorb all the water-soluble vitamins except B₁₂. Because the B₁₂ molecule is large, it must be bound to *intrinsic factor* from the gastric mucosa before absorption can take place.

✓ Checkpoint

14. Identify the two classes of vitamins.
15. Would an athlete in intensive training try to maintain a positive or a negative nitrogen balance?
16. How would a decrease in the amount of bile salts in the bile affect the amount of vitamin A in the body?

See the blue Answers tab at the back of the book.

+ Clinical Note Vitamins

“If a little is good, a lot must be better” is a common—but dangerously incorrect—attitude about vitamins.

Too much of a vitamin can also have harmful effects.

Hypervitaminosis (hī-per-vī-tuh-min-ō-sis) occurs when dietary intake exceeds the body’s ability to use, store, or excrete a particular vitamin. This condition usually involves one of the fat-soluble vitamins because the excess is retained and stored in body lipids. Fat-soluble vitamins normally diffuse into plasma membranes and other lipids in the body, including the lipid inclusions in the liver and adipose tissue. As a result, the body contains a significant reserve of these vitamins. Normal metabolic operations can continue for several months after dietary sources have been eliminated. For this reason, a dietary insufficiency of fat-soluble vitamins rarely causes signs and symptoms of vitamin deficiency, known as **hypovitaminosis** (hī-pō-vi-ta-min-ō-sis). However, other factors can cause hypovitaminosis involving either fat-soluble or water-soluble vitamins. Problems may be due to an inability to absorb a vitamin from the digestive tract, inadequate storage, or excessive demand.

+ Clinical Note Alcohol and Disease

Annual alcoholic beverage sales in the United States are above \$222 billion. Advertisements for alcoholic beverages abound, but alcohol has serious medical consequences.

Consider these statistics provided by the Centers for Disease Control and Prevention (CDC) and the National Institute on Alcohol Abuse and Alcoholism (NIAAA) for people living in the United States:

- 7.5 million children aged 17 and younger live with a parent with alcohol use disorder (AUD)
- 95,000 deaths are attributed to alcohol-related causes every year.
- 25.8% of people aged 18 and older reported binge drinking in the past month,
- Alcohol poisoning, cancer, car accidents, heart failure, liver damage, and violence are causes of alcohol-related deaths.
- 85.6% of people aged 18 and older have had an alcoholic drink.

Alcohol affects many organ systems. Major clinical symptoms of alcoholism include (1) disorientation and confusion (*nervous system*); (2) ulcers, diarrhea, and cirrhosis (*digestive system*); (3) cardiac arrhythmias, cardiomyopathy, and anemia (*cardiovascular system*); (4) depressed sexual drive and testosterone level (*reproductive system*); (5) itching (*integumentary system*); and (6) angiomas, which are benign tumors of blood vessels or lymphatic vessels (*cardiovascular and lymphatic systems*).

Prenatal exposure to alcohol can also affect developing fetuses, leading to fetal alcohol spectrum disorders (FASDs). Fetal alcohol spectrum disorders is an umbrella term for several alcohol-related effects in fetuses exposed to alcohol. These include fetal alcohol syndrome, partial fetal alcohol syndrome, alcohol-related neurodevelopmental disorder, and alcohol-related birth defects.

+ Clinical Note Anorexia

Anorexia means lack of appetite. This is a common symptom of chronic disease. Patients with cancer often lose their appetite and body weight. The presence of anorexia can indicate an underlying disease.

Anorexia nervosa, a similar term, refers to an eating disorder characterized by low body weight, distorted body image, and an intense fear of gaining weight. People with anorexia nervosa restrict their caloric intake, often starving themselves. Repetitive starvation damages both body and brain. More common in females, anorexia nervosa has the highest mortality rate of any psychiatric disease.

+ Clinical Note Superfoods

Superfoods have star status! The health claims and advertisements for superfoods are commonplace: “Eat (*a specific food*) and banish (*a disease*)!” Oat bran is hyped for reversing high serum cholesterol, while pomegranates are touted to promote long life. Are these claims legitimate?

Some foods are more nutrient dense than others. Raw almonds, for example, contain protein, anti-inflammatory omega-3 fats, and fiber. Other foods have high concentrations of a select nutrient. Red peppers, for example, are unusually high in vitamin C. The bright orange color of a sweet potato broadcasts its content of beta-carotene, a precursor of vitamin A. Dark leafy greens are rich plant sources of iron. Different foods confer different, and complementary, benefits.

However, the notion that foods have superpowers is more marketing ploy than nutrition science. A diet that incorporates a wide variety of whole foods is a powerful tool for nutritional health.

25-7 Metabolic rate is the average caloric expenditure, and thermoregulation involves balancing heat-producing and heat-losing mechanisms

Learning Outcome Define metabolic rate, discuss the factors involved in determining an individual's BMR, and discuss the homeostatic mechanisms that maintain a constant body temperature.

25

A person's daily energy expenditures vary widely with activity. For example, a person who leads a sedentary life may have minimal energy demands, but someone who includes a single hour of swimming has a significantly increased daily energy use. Average daily energy use is related to the *metabolic rate*. If the daily energy intake exceeds the total energy demands, the excess energy is stored, primarily as triglycerides in adipose tissue. If daily energy expenditures exceed intake, the result is a net reduction in energy reserves and a corresponding loss in weight. In this section, first we consider aspects of energy intake and expenditure. Then we turn to the topic of *thermoregulation*, how the body maintains a consistent internal temperature.

Energy Gains and Losses

When chemical bonds are broken, energy is released. Inside cells, a significant amount of energy may be used to synthesize ATP, but much of it is lost to the environment as heat.

Measuring Energy and the Energy Content of Food

The process of *calorimetry* (kal-ō-RIM-eh-trē) measures the total amount of energy released when the bonds of organic molecules are broken. The unit of measurement is the **calorie** (KAL-ō-rē) (cal), defined as the amount of energy required to raise the temperature of 1 g of water 1 degree Celsius (°C). One gram of water is not a very practical measure when you are interested in the metabolic processes that keep a 70-kg human alive, so we use the **kilocalorie** (KIL-ō-kal-ō-rē) (kcal), or **Calorie** (with a capital C, also known as the “large calorie,”). One kilocalorie is the amount of energy needed to raise the temperature of 1 kilogram (1 liter) of water 1°C. In human nutrition, the term *calorie* is commonly used instead of kilocalorie or Calorie to refer to a unit of food energy.

In cells, organic molecules are oxidized to carbon dioxide and water. Oxidation also takes place when something burns, and this process can be experimentally controlled. A known amount of food is placed in a chamber called a **calorimeter** (kal-ō-RIM-e-ter), which is filled with oxygen and surrounded by a known volume of water. Once the food is inside, the chamber is sealed and the contents are electrically ignited. When the material has completely oxidized and only ash remains in the chamber, the number of Calories released can be determined by comparing the water temperatures before and after the test.

The energy potential of food is usually expressed in kilocalories per gram (kcal/g). The catabolism of lipids releases a considerable amount of energy, about 9.46 kcal/g. The catabolism of carbohydrates or proteins is not as productive, because many of the carbon and hydrogen atoms are already bound to oxygen. Their average yields are comparable: 4.18 kcal/g for carbohydrates and 4.32 kcal/g for proteins. Most foods are mixtures of fats, proteins, and carbohydrates, so the calculated values listed in a “calorie counter” vary.

Measuring Energy Expenditure: Metabolic Rate

Clinicians can examine a person's metabolic state and determine how many calories they are using. The result can be expressed as calories per hour, calories per day, or calories per unit of body weight per day. The **basal metabolic rate (BMR)** is a measurement of the rate at which the body expends energy while at rest to maintain vital functions, such as breathing and keeping warm. On average, the BMR is 1 kcal of energy per hour for each kilogram of body weight. The metabolic rate changes and is affected by exercise, age, sex, hormones, endocrine activity, and climate. For instance, measurements taken while a person is sprinting are quite different from those taken while a person is sleeping. **Figure 25-12** shows the caloric expenditures for various common activities.

Figure 25–12 Caloric Expenditures for Various Activities.

To reduce the variations in studies of energetics and metabolism, physiologists and clinicians standardize the testing conditions. Ideally, the BMR is the minimum resting energy expenditure of an awake, alert person. A direct method of determining the BMR involves monitoring respiratory activity. In resting individuals, energy use is proportional to oxygen consumption. If we assume that average amounts of carbohydrates, lipids, and proteins are being catabolized, 4.825 kcal are expended per liter of oxygen consumed.

On average, an individual has a BMR of 70 kcal per hour, or about 1680 kcal per day. Although the test conditions are standardized, many uncontrollable factors can influence the BMR. These factors include physical condition, body weight, and genetic differences.

Regulation of Energy Intake

The control of appetite is poorly understood. Stretch receptors along the digestive tract, especially in the stomach, play a role, but other factors are probably more significant. Social factors, psychological pressures, and dietary habits are important. Evidence also indicates that complex hormonal stimuli interact to affect appetite. For example, the hormones *cholecystokinin* (CCK) and *adrenocorticotrophic hormone* (ACTH) suppress appetite. The hormones (adipokines) leptin and ghrelin also interact to affect hunger. *Leptin* is released into the bloodstream by adipose tissues as they synthesize triglycerides. When leptin binds to CNS neurons that function in emotion and appetite control, the result is a sense of satiation and appetite suppression. Leptin levels are lower in thin people and higher in overweight people, who have resistance to

the appetite-suppressing effects of leptin. *Ghrelin* (GREL-in), a hormone secreted from the gastric mucosa, stimulates appetite. The ghrelin level decreases when the stomach is full, and ghrelin level increases during the fasting. Some research suggests that leptin plays a role in regulating ghrelin, showing that these “hunger hormones” are complex and warrant further study.

Obesity is defined as body weight more than 20% above the ideal weight for a given individual. Currently, obesity is considered an epidemic and is taking its toll on the health of adults and children. Diseases associated with obesity include heart disease, cancer, and diabetes. For this reason, calorie counting and exercise are important in a weight-control program.

Thermoregulation

The BMR estimates the rate of energy use by the body. The energy that cells do not capture and harness is released as heat. This heat serves an important homeostatic purpose. Humans are subject to vast changes in environmental temperatures, but our complex biochemical systems have a major limitation. Our enzymes operate over only a relatively narrow temperature range. Accordingly, our bodies have anatomical and physiological mechanisms that keep body temperatures within acceptable limits, regardless of environmental conditions. This homeostatic process is called **thermoregulation**. Failure to control body temperature can result in a series of physiological changes. For example, a body temperature below 36°C (97°F) or above 40°C (104°F) can cause disorientation. A body temperature above 42°C (108°F) can cause convulsions and permanent cell damage.

We continuously produce heat as a by-product of metabolism. When our energy use increases due to physical activity, or when our cells are more active metabolically (as they are during the absorptive state), additional heat is generated. The heat produced by biochemical reactions is retained by water, which makes up nearly two-thirds of body weight. Water is an excellent conductor of heat, so the heat produced in one region of the body is rapidly distributed by diffusion, as well as through the bloodstream. If body temperature is to remain constant, that heat must be lost to the environment at the same rate at which it is generated. When environmental conditions rise above or fall below “ideal,” the body must control the gains or losses to maintain homeostasis.

Mechanisms of Heat Exchange

Heat exchange with the environment involves four basic processes: (1) *radiation*, (2) *convection*, (3) *evaporation*, and

(4) **conduction** (Figure 25–13). Objects warmer than the environment lose heat as **radiation**. When a person feels the heat from the sun, they are experiencing radiant heat. The body loses heat the same way, but in proportionately smaller amounts. More than 50% of body heat lost indoors is lost through radiation. The exact amount varies with both body temperature and skin temperature.

Convection is heat loss to the cooler air that moves across the surface of the body. As the body loses heat to the air next to the skin, that air warms and rises, moving away from the skin surface. Cooler air replaces it, and this air in turn becomes warmed. This pattern then repeats. Convection accounts for about 15% of the body's heat loss indoors but is insignificant as a mechanism of heat gain.

When water evaporates, it changes from a liquid to a vapor. **Evaporation** absorbs energy—about 0.58 kcal per gram of water evaporated—and cools the surface where evaporation occurs. The rate of evaporation at the skin is highly variable. Each hour, 20–25 mL of water crosses epithelia and evaporates from the alveolar surfaces and the surface of the skin. This *insensible water loss* remains relatively constant. At rest, it accounts for about 20% of the body's average indoor heat loss. The sweat glands responsible for *sensible perspiration* have a tremendous scope of activity, ranging from virtual inactivity to secretory rates of 2–4 liters (2.1–4.2 quarts) per hour.

Conduction is the direct transfer of energy through physical contact. When coming into an air-conditioned classroom

and sitting on a cold plastic chair, this process is immediately apparent. Conduction is generally not an effective way of gaining or losing heat. Its impact depends on the temperature of the object and the amount of skin surface area involved. When lying on cool sand in the shade, conductive losses can be considerable. When standing on the same sand, conductive losses are negligible.

The Hypothalamus Regulates Heat Gain and Heat Loss

Heat loss and heat gain involve the activities of many systems. Those activities are coordinated by the **heat-loss center** and **heat-gain center**, respectively, in the pre-optic area of the anterior hypothalamus. These centers modify the activities of other hypothalamic nuclei. The overall effect is to control temperature by influencing two processes: the rate of heat production and the rate of heat loss to the environment. Changes in behavior may also support these processes.

Mechanisms for Increasing Heat Loss. When the temperature at the pre-optic area increases above its set point range, the heat-loss center is stimulated, producing major effects:

- *The inhibition of the vasomotor center causes peripheral vasodilation, and warm blood flows to the surface of the body. The skin and/or mucous membranes take on a reddish color, skin temperatures rise, and radiative and convective losses increase.*
- *As blood flow to the skin increases, sweat glands are stimulated to increase their secretory output. The perspiration flows across the body surface, and evaporative heat losses accelerate. Maximal secretion, if completely evaporated, would remove 2320 kcal per hour.*
- *The respiratory centers are stimulated, and the depth of respiration increases. Often, the individual begins breathing through an open mouth rather than through the nasal passageways. This increases evaporative heat losses through the lungs.*

Mechanisms for Promoting Heat Gain. The function of the heat-gain center of the brain is to prevent **hypothermia** (hī-pō-THER-mē-uh), or below-normal body temperature.

Figure 25–13 Mechanisms of Heat Exchange.

When the temperature at the pre-optic area drops below the acceptable level, the heat-loss center is inhibited, and the heat-gain center is activated.

To conserve heat, the sympathetic vasomotor center decreases blood flow to the dermis, thereby reducing losses by radiation, convection, and conduction and allowing the skin to cool. With blood flow restricted, the skin in lighter-skinned individuals may take on a bluish or pale color. The epithelial cells are not damaged, because they can tolerate extended periods at temperatures as low as 25°C (77°F) or as high as 49°C (120°F).

In addition, blood returning from the limbs is shunted into a network of deep veins. Under warm conditions, blood flows in a superficial venous network (Figure 25–14a). In cold

conditions, blood is diverted to a network of veins that lie deep to an insulating layer of subcutaneous fat (Figure 25–14b). This venous network wraps around the deep arteries, and heat is conducted from the warm blood flowing outward to the limbs to the cooler blood returning from the periphery (Figure 25–14c). This arrangement traps the heat close to the body core and restricts heat loss. Such exchange between fluids that are moving in opposite directions is called *countercurrent exchange*.

The mechanisms for generating heat are divided into two broad categories: shivering thermogenesis and nonshivering thermogenesis. In **shivering thermogenesis** (ther-mō-JEN-eh-sis), a gradual increase in muscle tone increases the energy

Figure 25–14 Vascular Adaptations for Heat Loss and Conservation.

In a warm environment, does more blood return to the trunk through deep or superficial veins? Why?

consumption of skeletal muscle tissue throughout the body. The more energy expended, the more heat is produced. Both agonist and antagonist muscles are involved. The degree of stimulation varies with the demand.

If the heat-gain center is extremely active, muscle tone increases to the point at which stretch receptor stimulation will produce brief, oscillatory contractions of antagonistic muscles. In other words, the body begins to **shiver**. Shivering increases the workload of the muscles and further elevates oxygen and energy consumption. The heat that is produced warms the deep vessels, to which blood has been shunted by the sympathetic vasomotor center. Shivering can elevate body temperature quite effectively, increasing the rate of heat generation by as much as 400%.

In contrast, *nonshivering thermogenesis* is a less immediate heat-gain process. In an adult, heat production increases by only 10–15% after a few weeks. **Nonshivering thermogenesis** involves the release of hormones that increase the metabolic activity of all tissues:

- The heat-gain center stimulates the adrenal medullae through the sympathetic division of the autonomic nervous system. As a result, epinephrine is released. It increases the rates of glycogenolysis in liver and skeletal muscle, and the metabolic rate of most tissues. The effects are immediate.

Clinical Note Hypothermia in the Operating Room

Hypothermia may be intentionally produced during surgery. The goal is to reduce the metabolic rate of a particular organ or of the patient's entire body. In controlled hypothermia, the patient is first anesthetized to prevent shivering, which would act to fight off hypothermia.

During open-heart surgery, the body is typically cooled to 25°C–32°C (79°F–89°F). This cooling reduces the metabolic demands of the body, which will be receiving blood from an external pump or oxygenator. The heart must be stopped completely during the operation, and it cannot be well supplied with blood during this time. For this reason, the heart is perfused with an *arresting solution* at 0°C–4°C (32°F–39°F) and maintained at a temperature below 15°C (60°F) during the operation. At these temperatures, the cardiac muscle can tolerate several hours of ischemia (inadequate blood supply) without damage.

When cardiac surgery is performed on infants, a deep hypothermia may be produced by cooling the entire body to temperatures as low as 11°C (52°F) for an hour or more. In effect, these conditions are similar to those experienced by victims of accidental drowning.

- The pre-optic area regulates the production of thyrotropin-releasing hormone (TRH) by the hypothalamus. In children, when body temperatures are below normal, additional TRH is released. This hormone stimulates the release of thyroid-stimulating hormone (TSH) by the anterior lobe of the pituitary gland. In response to this release of TSH, the thyroid gland increases the rate of thyroxine release into the blood. Thyroxine increases not only the rate of carbohydrate catabolism, but also the rate of catabolism of all other nutrients. These effects develop gradually, over a period of days to weeks.

Sources of Individual Variation in Thermoregulation

The timing of thermoregulatory responses differs from person to person. A person may undergo **acclimatization** (ah-klī-mah-tih-ZA-shun)—a physiological adjustment to a particular environment over time. For example, residents of Tierra del Fuego (off the southernmost tip of South America) once lived naked in the snow, but Hawaii residents often put on their sweaters when the temperature drops below 22°C (72°F).

Another source of variation is body size. Although heat *production* takes place within the mass of the body, heat *loss* takes place across a body surface. As an object (or person) gets larger, its surface area increases at a much slower rate than does its total volume. This relationship affects thermoregulation, because heat generated by the “volume” (that is, by internal tissues) is lost at the body surface. For this reason, small individuals lose heat more readily than do large individuals.

Brown Adipose Tissue and Thermoregulation. Brown adipose tissue, also called **brown fat**, is thermogenic tissue with fat cells characterized by multiple small lipid droplets and numerous heme-containing mitochondria. Together, these characteristics give the tissue a deep, rich color and an increased capacity to generate heat. Found in the mitochondria of brown adipose tissue is an inner membrane uncoupling protein called *thermogenin* that catalyzes thermogenesis. It does this by uncoupling the protons (H⁺) from ATP synthesis in the electron transport chain. The energy is then lost as heat, which radiates into the surrounding tissues. This heat quickly warms the blood passing through the surrounding network of vessels, and it is then distributed throughout the body.

It was once thought that brown fat was only present in infants; however, it is also found in adults. In newborns and infants, brown fat is important for thermoregulation, because their temperature-regulating mechanisms are not fully functional and they cannot shiver. Consequently, newborns must be dried promptly and kept bundled up. Babies born prematurely need a thermally regulated incubator. Infants also lose heat quickly because of their small size. So, the brown fat can very quickly speed up metabolic heat generation by 100%.

With increasing age and size, an infant's body temperature becomes more stable. As a result, brown fat becomes less important. With increased body size, skeletal muscle mass, and insulation, shivering thermogenesis becomes more effective in raising body temperature.

While we tend to lose brown fat as we age, everyone has brown fat nestled between areas of white adipose tissue (white fat), predominantly in the neck, upper chest, and shoulders. Interestingly, people who live in colder climates seem to have more brown fat than do people living in warmer climes, and thinner, younger people have more brown fat than do older, obese people. Hence, the role of brown fat—particularly its role in metabolism—is an area of active research.

Thermoregulatory Variations among Adults. Adults of a given body weight may differ in their thermal responses due to variations in body mass and tissue distribution. Adipose tissue is an excellent insulator. It conducts heat at only about one-third the rate of other tissues. As a result, people with a more substantial layer of subcutaneous fat may not begin to shiver until long after their thinner companions.

Two otherwise similar individuals may also differ in their response to temperature changes because their hypothalamic

“thermostats” are at different settings. We all experience daily oscillations in body temperature. Temperatures peak during the day or early evening. They fall 1°C–2°C (1.8°F–3.6°F) at night. The ovulatory cycle also causes temperature fluctuations in females, as described in Chapter 28.

Individuals vary in the timing of their maximum temperature setting. Some have a series of peaks, with an afternoon low. The origin of these patterns is unclear. The patterns do not result from daily activity regimens. For example, the temperatures of people who work at night still peak during the same range of times as the rest of the population.

+ Clinical Note Excess Body Heat

Heat exhaustion and heat stroke are malfunctions of thermoregulatory mechanisms. With **heat exhaustion**, also known as *heat prostration*, excessive fluids are lost in sweat, and the individual has difficulty maintaining blood volume. The heat-loss center in the hypothalamus stimulates sweat glands, whose secretions moisten the surface of the skin to provide evaporative cooling. As fluid losses increase, blood volume decreases. The resulting decrease in blood pressure is not countered by peripheral vasoconstriction, because the heat-loss center is actively stimulating peripheral vasodilation. As blood flow to the brain decreases, headache, nausea, and eventual collapse follow. Treatment is straightforward: provide fluids, salts, and a cooler place to be.

In **heat stroke**, body temperature increases uncontrollably because the thermoregulatory center stops functioning. The sweat glands are inactive, and the skin becomes hot and dry. Heat stroke is more serious than heat exhaustion and can follow an untreated case of heat exhaustion. Predisposing factors include any preexisting condition that affects peripheral circulation, such as heart disease or diabetes. Unless the problem is recognized in time, body temperature may increase to 41°C–45°C (106°F–113°F). Temperatures in this range quickly disrupt a variety of vital physiological systems and destroy brain, liver, skeletal muscle, and kidney cells. Effective treatment involves decreasing the body temperature as rapidly as possible.

+ Clinical Note Deficient Body Heat

Hypothermia is below-normal body temperature. If body temperature decreases significantly below the normal level, thermoregulatory mechanisms become less sensitive and less effective. Cardiac output and respiratory rate decrease. If the core temperature falls below 28°C (82°F), cardiac arrest is likely. The individual then has no heartbeat, no respiratory rate, and no response to external stimuli—even painful ones. The body temperature continues to decrease, and the skin and/or mucous membranes turn blue or pale and cold.

At this point, people commonly assume that the person has died. But because metabolic activities have decreased system-wide, the person may still be saved, even after several hours. Treatment consists of cardiopulmonary support and gradual rewarming, both external and internal. The skin can be warmed up to 45°C (113°F) without damage. Warm baths or blankets can be used. One effective method of raising internal temperatures involves the introduction of warm saline solution into the peritoneal cavity.

Hypothermia is a significant risk for people engaged in water sports and may complicate the treatment of a drowning person. Water absorbs heat about 27 times as fast as air does, and the body's heat-gain mechanisms are unable to keep pace over long periods or when faced with a large temperature gradient. But hypothermia in cold water does have a positive side. On several occasions, small children who have been submerged (“drowned”) in cold water have been successfully revived after time periods of up to 4 hours. Children lose body heat quickly, and their systems soon stop functioning as their body temperature decreases. This rapid decrease in temperature prevents the oxygen starvation and tissue damage that would otherwise take place when breathing stops.

Resuscitation is not attempted if the person has frozen. Because water expands about 7% during ordinary freezing, plasma membranes throughout the body are destroyed. However, very small organisms can be frozen and subsequently thawed without ill effects, because their surface-to-volume ratio is enormous, and the freezing process occurs so rapidly that ice crystals never form.

Fevers

A **fever** is a body temperature greater than 37.2°C (99°F). We discussed fevers in Chapter 22 when we examined innate (non-specific) immunity. Fevers occur for a variety of reasons, not all of them pathological. In young children, transient fevers with no ill effects can result from exercise in warm weather. Similar exercise-related elevations were rarely recognized in adults until running marathons became popular. Temperatures from 39°C to 41°C (103°F to 109°F) may result. For this reason, competitions are usually held when the air temperature is below 28°C (82°F).

Fevers can also result from the following factors:

- Abnormalities that affect the entire thermoregulatory mechanism, such as heat exhaustion or heat stroke
- Clinical problems that restrict blood flow, such as congestive heart failure
- Conditions that impair sweat gland activity, such as drug reactions and some skin conditions
- The resetting of the hypothalamic “thermostat” by circulating *pyrogens*—most notably, interleukin-1.

Checkpoint

17. How would the BMR of a pregnant female compare with her BMR before becoming pregnant?
18. What effect does peripheral vasoconstriction on a hot day have on an individual's body temperature?
19. Why do infants have greater problems with thermoregulation than adults?

See the blue Answers tab at the back of the book.

25 Chapter Review

Study Outline

An Introduction to Metabolism, Nutrition, and Energetics

1. The nutrients in food support the metabolic activities of the body. The body builds energy reserves when nutrients are abundant and mobilizes them when nutrients are in short supply.

25-1 Metabolism is the sum of all the catabolic and anabolic reactions in the body, and energetics is the flow and transformation of energy

2. All the available nutrients distributed in the blood form a **nutrient pool**. **Catabolism** converts larger molecules into smaller ones, and **anabolism** converts small molecules into larger ones. Various metabolic pathways are involved with catabolism and anabolism. (Figure 25-1)
3. Anabolic reactions (1) perform structural maintenance or repairs, (2) support growth, (3) produce secretions, and (4) build and store nutrient reserves. (Figure 25-1)
4. **Energetics** is the study of the flow of energy and its transformation, or change, from one form to another.
5. Energy changes in cells involve chemical reactions known as oxidation and reduction. **Oxidation** is the gain of oxygen, or loss of hydrogen or electrons, and **reduction** is the loss of oxygen, or gain of hydrogen or electrons. Oxidation–reduction reactions occur together and are referred to as *redox reactions*.

25-2 Carbohydrate metabolism generates ATP by glucose catabolism and forms glucose by gluconeogenesis

6. Most cells generate ATP and other high-energy compounds by the catabolism of carbohydrates, especially glucose.
7. **Glycolysis** and **aerobic metabolism**, or **cellular respiration**, provide most of the ATP used by typical cells. In the anaerobic

Media Resources:

- Chapter Quizzes, Chapter Practice Test, MP3 Tutor Sessions, and Clinical Case Studies
- Practice Anatomy Lab
- A&P Flix
- Interactive Physiology
- PhysioEx

process of glycolysis, each molecule of glucose yields 2 molecules of **pyruvic acid** (as **pyruvate** ions), a net gain of 2 molecules of ATP, and 2 **NADH** molecules. (Figure 25-2)

8. In the presence of oxygen, pyruvate enters the mitochondria, where it is broken down completely in the **citric acid cycle**. Carbon and oxygen atoms are lost as carbon dioxide (**decarboxylation**); hydrogen atoms are passed to coenzymes, which initiate the oxygen-consuming and ATP-generating reaction **oxidative phosphorylation**. (Figure 25-3)
9. The **electron transport chain (ETC)** is embedded in the inner mitochondrial membrane. It is made up of four respiratory protein complexes, coenzyme Q, and cytochromes that eventually pass along electrons to oxygen to form water. Energy released by the passage of the electrons is used to pump H^+ from the matrix to the intermembrane space. (Spotlight Figure 25-4)
10. ATP is formed through **chemiosmosis**. During this process, H^+ pass through proton (H^+) channels in the inner membrane from the intermembrane space to the mitochondrial matrix. Energy from the passage of protons (H^+) is used by **ATP synthase** to form ATP from ADP and P_i . (Spotlight Figure 25-4)
11. For each glucose molecule processed through glycolysis, the citric acid cycle, and the electron transport chain, most cells gain 30–32 molecules of ATP. (Figure 25-5)

12. **Gluconeogenesis**, the synthesis of glucose from noncarbohydrate molecules, enables a liver cell to synthesize glucose molecules when carbohydrate reserves are depleted. Glucose molecules are stored as **glycogen** in liver and skeletal muscle cells. **Glycogenesis** is the process of glycogen formation. Glycogen is an important energy reserve. **Glycogenolysis** is the breakdown of glycogen to glucose molecules. (Figures 25–1, 25–6)

25-3 Lipid metabolism provides long-term storage and release of energy

13. During **lipolysis** (lipid catabolism), lipids are broken down into pieces that can be converted into pyruvate or channeled into the citric acid cycle.
14. **Triglycerides**, the most abundant lipids in the body, are split into glycerol and fatty acids. The glycerol is converted to pyruvate, and the fatty acids enter the mitochondria.
15. **Beta-oxidation** is the breakdown of a fatty acid molecule into 2-carbon fragments that enter the citric acid cycle. The steps of beta-oxidation cannot be reversed, and the body cannot manufacture all the fatty acids needed for normal metabolic operations. (Figure 25–7)
16. Lipids cannot provide large amounts of ATP quickly. However, cells can shift to lipid-based energy production when glucose reserves are limited.
17. In **lipogenesis** (the synthesis of lipids), almost any organic substrate can be used to form glycerol. **Essential fatty acids** are those that cannot be synthesized and must be included in the diet.
18. Most lipids circulate as **lipoproteins** (lipid–protein complexes that contain large glycerides and cholesterol). The largest lipoproteins, chylomicrons, carry absorbed lipids from the intestinal tract to the bloodstream. All other lipoproteins are derived from the liver and carry lipids to and from various tissues of the body. (Figure 25–8)
19. Capillary walls of adipose tissue, skeletal muscle, cardiac muscle, and the liver contain **lipoprotein lipase**, an enzyme that breaks down lipids, releasing a mixture of fatty acids and monoglycerides into the interstitial fluid. (Figure 25–8)

25-4 Protein metabolism provides amino acids and synthesizes proteins

20. If other energy sources are inadequate, mitochondria can break down amino acids in the citric acid cycle to generate ATP. In the mitochondria, the amino group can be removed by either **transamination** or **deamination**. (Figure 25–9)
21. Protein catabolism is impractical as a source of quick energy.
22. About half the amino acids needed to build proteins can be synthesized. There are 10 **essential amino acids**, which must be acquired through the diet. **Amination**, the attachment of an amino group to a carbon framework, is an important step in the synthesis of **nonessential amino acids**. (Figure 25–9)

25-5 There are two patterns of metabolic activity: energy storage in the absorptive state and energy release in the postabsorptive state

23. No one cell of a human can perform all the anabolic and catabolic operations necessary to support life. Homeostasis can be preserved only when metabolic activities of different tissues are coordinated.
24. The body has five metabolic components: the liver, adipose tissue, skeletal muscle, nervous tissue, and other peripheral tissues. The liver is the focal point for metabolic regulation and control. Adipose tissue stores lipids, primarily in the form of triglycerides.

Skeletal muscle contains substantial glycogen reserves, and the contractile proteins can be degraded and the amino acids used as an energy source. Nervous tissue does not contain energy reserves; glucose must be supplied to it for energy. Other peripheral tissues can metabolize glucose, fatty acids, or other substrates under the direction of the endocrine system.

25. For about 4 hours after a meal, nutrients enter the blood as intestinal absorption proceeds. (Spotlight Figure 25–10)
26. The liver closely regulates the circulating levels of glucose and amino acids.
27. The **absorptive state** exists when nutrients are being absorbed by the digestive tract. Adipocytes remove fatty acids and glycerol from the bloodstream and synthesize new triglycerides to be stored for later use. (Spotlight Figure 25–10)
28. During the absorptive state, glucose molecules are catabolized and amino acids are used to build proteins. Skeletal muscles may also catabolize circulating fatty acids, and the energy obtained is used to increase glycogen reserves.
29. The **postabsorptive state** extends from the end of the absorptive state to the next meal. (Spotlight Figure 25–10)
30. When blood glucose levels fall, the liver begins breaking down glycogen reserves and releasing glucose into the bloodstream. As the time between meals increases, liver cells synthesize glucose molecules from smaller carbon fragments and from glycerol molecules. Fatty acids undergo beta-oxidation; the fragments enter the citric acid cycle or combine to form **ketone bodies**. (Spotlight Figure 25–10)
31. Some amino acids can be converted to pyruvate and used for gluconeogenesis; others, including most of the essential amino acids, are converted to acetyl-CoA and are either catabolized or converted to ketone bodies.
32. Nervous tissue continues to be supplied with glucose as an energy source until blood glucose levels become very low.

25-6 Adequate nutrition allows normal physiological functioning

33. **Nutrition** is the absorption of nutrients from food. A **balanced diet** contains all the ingredients needed to maintain homeostasis; a balanced diet prevents **malnutrition**.
34. The **basic food groups** include grains, vegetables, fruits, dairy, and protein. These are arranged on a *plate* to reflect the recommended daily food consumption balanced with daily physical activity. (Figure 25–11; Table 25–1)
35. Amino acids, purines, pyrimidines, creatine, and porphyrins are **nitrogen compounds**, which contain nitrogen atoms. An adequate dietary supply of nitrogen is essential, because the body does not maintain large nitrogen reserves. **Nitrogen balance** is a state in which the amount of nitrogen absorbed equals that lost in urine and feces.
36. **Minerals** act as cofactors in a variety of enzymatic reactions. They also contribute to the osmotic concentration of body fluids and play a role in membrane potentials, action potentials, the release of neurotransmitters, muscle contraction, skeletal construction and maintenance, gas transport, buffer systems, fluid absorption, and waste removal. (Table 25–2)
37. Vitamins are needed in very small amounts. Vitamins A, D, E, and K are **fat-soluble vitamins**; taken in excess, they can lead to **hypervitaminosis**. **Water-soluble vitamins** are not stored in the body; a lack of adequate dietary supplies may lead to **hypovitaminosis**, or vitamin insufficiency. (Tables 25–3, 25–4)
38. A balanced diet can improve one's general health.

25-7 Metabolic rate is the average caloric expenditure, and thermoregulation involves balancing heat-producing and heat-losing mechanisms

39. The energy content of food is usually expressed in **kilocalories (kcal)** per gram (kcal/g) or as **Calories** per gram (Cal/g).
40. The catabolism of lipids releases 9.46 kcal/g, about twice the amount released by equivalent weights of carbohydrates or proteins.
41. The **basal metabolic rate (BMR)** is a measurement of the rate at which the body expends energy while at rest to maintain vital functions, such as breathing and keeping warm. (Figure 25–12)
42. The homeostatic regulation of body temperature is **thermoregulation**. Heat exchange with the environment involves four processes: **radiation**, **convection**, **evaporation**, and **conduction**. (Figure 25–13)
43. The *pre-optic area* of the hypothalamus acts as the body's thermostat, affecting the **heat-loss center** and the **heat-gain center**.
44. Mechanisms for increasing heat loss include both physiological mechanisms (peripheral vasodilation, increased perspiration, and increased respiration) and behavioral modifications.
45. Responses that conserve heat include a decreased blood flow to the dermis and *countercurrent exchange*. (Figure 25–14)
46. Heat is generated by **shivering thermogenesis** and **nonshivering thermogenesis**.
47. Thermoregulatory responses differ among individuals. One important source of variation is **acclimatization** (a physiological adjustment to an environment over time).
48. **Fever**, a body temperature above 37.2°C (99°F), can result from problems with the thermoregulatory mechanism, circulation, or sweat gland activity, or from the resetting of the hypothalamic “thermostat” by circulating pyrogens.

Review Questions

See the blue Answers tab at the back of the book.

LEVEL 1 Reviewing Facts and Terms

1. Anabolism refers to the **(a)** conversion of small molecules into larger ones, **(b)** conversion of large molecules into smaller ones, **(c)** creation of a nutrient pool, **(d)** sum of all chemical and physical changes that occur in body tissues.
2. The breakdown of glucose to pyruvate is an _____ process.
(a) anaerobic, **(b)** aerobic, **(c)** anabolic, **(d)** oxidative, **(e)** both a and d.
3. The process that produces more than 90% of the ATP used by body cells is **(a)** glycolysis, **(b)** the citric acid cycle, **(c)** substrate-level phosphorylation, **(d)** oxidative phosphorylation.
4. The sequence of reactions responsible for the breakdown of fatty acid molecules is **(a)** beta-oxidation, **(b)** the citric acid cycle, **(c)** lipogenesis, **(d)** all of these.
5. For the breakdown of one glucose molecule by glycolysis and aerobic metabolism, a cell gains _____ ATP molecules. **(a)** 2–4, **(b)** 5, **(c)** 20–22, **(d)** 30–32, **(e)** 50.
6. Ketone bodies are organic compounds produced by the metabolism of **(a)** fatty acids, **(b)** proteins, **(c)** carbohydrates, **(d)** purines, **(e)** low-density lipoproteins.
7. Fill in the missing terms for the different mechanisms of heat transfer.

8. A water-soluble vitamin that the intestinal epithelium cannot easily absorb is **(a)** vitamin C, **(b)** vitamin B₉, **(c)** vitamin B₁₂, **(d)** vitamin B₂.
9. What is a lipoprotein? What are the major groups of lipoproteins, and how do they differ?

LEVEL 2 Reviewing Concepts

10. What is oxidative phosphorylation? Explain how the electron transport chain and chemiosmosis are involved in this process.
11. When do cells use amino acids to generate ATP? Why isn't the ATP yield of all amino acids the same?
12. How do the absorptive and postabsorptive states maintain normal blood glucose levels?
13. Why is maintaining a healthy nitrogen balance important for your body?
14. Why are vitamins and minerals essential components of the diet?
15. Articles in the popular media often refer to “good cholesterol” and “bad cholesterol.” To which types and functions of cholesterol do these terms refer? Explain your answer.

LEVEL 3 Critical Thinking and Clinical Applications

16. A deficiency of _____ results in impaired RBC production and pernicious anemia. **(a)** vitamin B₁, **(b)** vitamin B₃, **(c)** vitamin B₉, **(d)** vitamin B₁₂, **(e)** vitamin C.
17. Armondo has a blood test that shows a normal level of LDLs but an elevated level of HDLs in his blood. Given that his family has a history of cardiovascular disease, he wonders if he should modify his lifestyle. What should his clinician tell him?
18. Patricia was diagnosed with anorexia nervosa. One afternoon she is rushed to the emergency room because of cardiac arrhythmias. Her breath smells fruity, and her blood and urine samples contain high levels of ketone bodies. Why is she having the arrhythmias?

CLINICAL CASE Wrap-Up The Miracle Supplement

Vitamin A is the miracle vitamin supplement that can reduce overall childhood mortality by 23% in high-risk areas like rural Kenya. Preschool-age children and pregnant individuals in their last trimester are the most vulnerable to vitamin A deficiency.

Like other fat-soluble vitamins, vitamin A is an essential organic nutrient that functions as a coenzyme in vital enzymatic reactions. In the retina of the eye, *retinal* (made from vitamin A) combines with *opsin* to form *rhodopsin*, which is necessary for low-light and color vision. Vitamin A deficiency is the leading cause of preventable childhood blindness, affecting as many as half a million children worldwide. As a coenzyme, vitamin A is critical for immune system functions. Vitamin A deficiency leads to a decreased immune response and increased vulnerability to malaria, respiratory infections, and diarrhea. Vitamin A is also critical for normal bone growth and development, and its deficiency can lead to stunting and skeletal deformities.

Vitamin A is found naturally in leafy green, yellow, and orange vegetables and fruits. Vitamin A is also available in milk, liver, eggs, and some fatty fish. None of these foods are available to Justine, who is among the very poor living in sub-Saharan Africa. But thanks to inexpensive vitamin A supplements, Justine's daughter will be protected from the health problems caused by vitamin A deficiency.

1. Other than diet and vitamin supplementation, is there any other available source of vitamin A?
2. If Justine's diet—which includes very little milk, liver, eggs, fish, leafy green, yellow, and orange vegetables, and fruits—is deficient in vitamin A, what other vitamin deficiencies might be expected?

See the blue Answers tab at the back of the book.

Related Clinical Terms

anorexia: Persistent loss of appetite.

anorexia nervosa: An eating disorder occurring primarily among females characterized by a desire to lose weight or to not gain weight, through starvation, due to a distorted view of the person's own body.

binge-purge syndrome: An eating disorder characterized by excessive eating followed by periods of fasting or self-induced vomiting.

bulimia: An eating disorder usually characterized by episodic binge eating that is followed by feelings of guilt, depression, and self-condemnation. It is often associated with steps taken to lose weight, such as self-induced vomiting, the use of laxatives, dieting, or fasting.

eating disorders: Psychological problems that result in inadequate or excessive food consumption. Examples include anorexia nervosa and bulimia.

familial hypercholesterolemia: The most common inherited type of hyperlipidemia characterized by high levels of lipids in one's blood. It affects 1 in every 500 children born, who then present with LDL levels more than 190.

heat cramps: A condition that usually follows heavy sweating due to strenuous activity that causes a loss of salt in the body and results in painful muscle spasms in the abdomen, arms, or legs.

hyperuricemia: A condition in which the plasma uric acid level exceeds 7.4 mg/dL. It can result in the condition called *gout*.

ketonuria: The presence of ketone bodies in the urine.

kwashiorkor: A form of malnutrition due to a protein deficiency in the diet that typically affects young children in tropical regions.

marasmus: Severe malnourishment that causes a child's weight to decrease significantly below the standards set for children of similar age.

orexigenic: Having a stimulating effect on the appetite.

pica: Tendency or craving for substances other than normal food. Possible organic causes are iron deficiency, lead encephalopathy, pregnancy, and zinc deficiency.

protein-calorie malnutrition: A severe deficiency of protein in the diet in addition to inadequate caloric intake. It results in the condition termed *kwashiorkor*.

skin-fold test: Test to estimate the amount of body fat on a person.

26

The Urinary System

Learning Outcomes

These Learning Outcomes correspond by number to this chapter's sections and indicate what you should be able to do after completing the chapter.

- 26-1 ■ Identify the organs of the urinary system and describe the functions of the system.
- 26-2 ■ Describe the location and structures of the kidneys, identify major blood vessels associated with each kidney, trace the path of blood flow through a kidney, and describe the structure of a nephron.
- 26-3 ■ Describe the basic processes that form urine.
- 26-4 ■ Describe the factors that influence glomerular filtration pressure and the rate of filtrate formation.
- 26-5 ■ Identify the types and functions of transport mechanisms found along each segment of the nephron and collecting system.
- 26-6 ■ Explain the role of countercurrent multiplication, describe hormonal influence on the volume and concentration of urine, and describe the characteristics of a normal urine sample.
- 26-7 ■ Describe the structures and functions of the ureters, urinary bladder, and urethra, discuss the voluntary and involuntary regulation of urination, and describe the urinary reflexes.
- 26-8 ■ Describe the effects of aging on the urinary system.
- 26-9 ■ Give examples of interactions between the urinary system and other organ systems studied so far.

CLINICAL CASE

A Case of “Hidden” Bleeding

The motorcycle accident scene is horrific. The driver is dead, and his passenger—a 14-year-old high school freshman named Waylen—is unconscious, flung more than 50 feet from the wreckage. When emergency responders deliver Waylen to the trauma center, he has no measurable blood pressure, despite the 4 liters of fluids they have infused. The trauma team begins administering whole blood transfusions, but Waylen is bleeding faster than replacement blood can be supplied.

Noting Waylen’s bloated abdomen and the abrasions on his left posterior chest and flank, the trauma team suspects that the massive blood loss is due to intra-abdominal injuries. An x-ray of Waylen’s chest and abdomen shows fractured left 8th through 12th ribs and fractures of the left

transverse processes of L₁, L₂, and L₃ vertebrae. A nurse inserts a urinary catheter into Waylen’s bladder, which drains clear urine.

When the surgeon opens Waylen’s abdomen through a midline incision, he encounters a copious amount of free blood. Clearing this blood quickly, and moving the abdominal structures out of the way, he finds a ruptured spleen that is bleeding profusely. The surgeon performs an emergency splenectomy. Rinsing the abdominal structures reveals no further visible bleeding, but the surgical team cannot stabilize Waylen’s

blood pressure, no matter how quickly they transfuse blood.

Something is still bleeding, but what is it? To find out, turn to the Clinical Case Wrap-Up at the end of the chapter.

An Introduction to the Urinary System

The **urinary system** removes most of the metabolic wastes produced by the body’s cells. This chapter describes the organs that make up the urinary system and explains how the *kidneys* remove metabolic wastes from the circulation to produce *urine*. The major regulatory mechanisms controlling urine production, concentration, and elimination are also presented.

26-1 The organs of the urinary system function in excreting wastes and regulating body fluids

Learning Outcome Identify the organs of the urinary system and describe the functions of the system.

This section introduces the organs of the urinary system, as well as their major functions.

Organs of the Urinary System

The organs of the urinary system are shown in **Figure 26-1**. The paired **kidneys** have excretory functions in the urinary system. These organs produce **urine**, which is a fluid that contains water, ions, and small soluble compounds. Urine leaving the kidneys flows along the *urinary tract*. The **urinary tract** consists of paired tubes called **ureters** (yū-RE-terz); the **urinary bladder**, a muscular sac for temporary urine storage; and a tube called the **urethra** (yū-RE-thrah).

When the bladder is full, urine is eliminated from the body in the process of **urination**, or **micturition** (mik-chū-RISH-un).

Figure 26-1 An Overview of the Urinary System. An anterior view of the urinary system, showing the positions of its organs.

In this process, the urinary bladder contracts and forces urine through the urethra, which conducts the urine to the exterior.

Urinary System Functions

The major functions of the urinary system are excretion and elimination. *Excretion* is the removal of metabolic wastes from body fluids, and *elimination* is the discharge of these wastes out of the body. However, the urinary system also has a third major function: *homeostatic regulation* of the volume and solute concentration of blood. Essential to such homeostatic regulation are the following:

- *Regulating blood volume and blood pressure*, by adjusting the volume of water lost in urine, secreting erythropoietin, and releasing renin.
- *Regulating plasma concentrations of sodium, potassium, chloride, and other ions*, by influencing the quantities in urine. The kidneys also control the calcium ion level through the synthesis of calcitriol.
- *Helping to stabilize blood pH*, by controlling the concentrations of hydrogen and bicarbonate ions in urine.
- *Conserving valuable nutrients*, by preventing their loss in urine while removing metabolic wastes—especially the nitrogenous wastes *urea* and *uric acid*.
- *Assisting the liver in detoxifying poisons* and, during starvation, the deamination of amino acids for their metabolic use by other tissues.

These activities are carefully regulated to keep the composition of blood within acceptable limits. A disruption of any one of them has immediate consequences and can be fatal.

✓ Checkpoint

1. Name the major functions of the urinary system.
2. Identify the organs of the urinary system.

See the blue Answers tab at the back of the book.

26-2 Kidneys are highly vascular organs containing functional units called nephrons

Learning Outcome Describe the location and structures of the kidneys, identify major blood vessels associated with each kidney, trace the path of blood flow through a kidney, and describe the structure of a nephron.

The kidneys are major excretory organs located retroperitoneally in the superior lumbar region. Kidneys contain many functional units called nephrons.

Position and Associated Structures of the Kidneys

The kidneys are located on either side of the vertebral column, between vertebrae T₁₂ and L₃ (**Figure 26-2a**). The left kidney

Figure 26-2 The Position and Associated Structures of the Kidneys.

lies slightly superior to the right kidney. The right kidney is slightly inferior due to the position of the right lobe of the liver.

The superior surface of each kidney is capped by an adrenal gland. The kidneys and adrenal glands lie between the muscles of the posterior body wall and the parietal peritoneum, in a retroperitoneal position (**Figure 26-2b**).

Tips

To visualize the kidneys' retroperitoneal positions, think of each kidney as a picture on the body wall that got covered over by wallpaper (the parietal peritoneum). To remember all the organs located entirely or partially retroperitoneally, use the mnemonic **SAD PUCKER** for **S**uprarenal (adrenal) glands, **A**orta and inferior vena cava, **D**uodenum, **P**ancreas, **U**reters, **C**olon, **K**idneys, **E**sophagus, **R**ectum.

The kidneys are held in position within the abdominal cavity by (1) the overlying peritoneum, (2) contact with adjacent visceral organs, and (3) supporting connective tissues. Three concentric layers of connective tissue protect and stabilize each kidney, which are, from deep to superficial (**Figure 26-2b**):

1. The **fibrous capsule**, a layer of collagen fibers that covers the outer surface of the entire organ

2. The **perinephric fat**, a cushioning, thick layer of adipose tissue that surrounds the fibrous capsule
3. The **renal fascia**, a dense, fibrous outer layer that anchors the kidney to surrounding structures. Collagen fibers extend outward from the fibrous capsule through the perinephric fat to this layer. Posteriorly, the renal fascia fuses with the deep fascia surrounding the muscles of the body wall. Anteriorly, the renal fascia forms a thick layer that fuses with the peritoneum.

In effect, each kidney hangs suspended by collagen fibers from the renal fascia and is packed in a soft cushion of adipose tissue. This arrangement prevents the jolts and shocks of day-to-day living from disturbing normal kidney function. If the suspensory fibers break or become detached, a slight bump or hit can displace the kidney and stress the attached vessels and ureter. This condition is called a *floating kidney*. It may cause pain or other problems from the distortion of the ureter or blood vessels.

Gross Anatomy of the Kidneys

Figure 26-3 shows the bean-shaped kidneys and adjacent renal blood vessels, ureters, and bladder.

Figure 26-3 The Gross Anatomy of the Urinary System. The abdominopelvic cavity (with the digestive organs and parietal peritoneum removed), showing the kidneys, ureters, urinary bladder, and blood supply to the urinary structures.

External Anatomy of the Kidneys

A typical adult kidney is reddish-brown and about 10 cm (4 in.) long, 5.5 cm (2.2 in.) wide, and 3 cm (1.2 in.) thick (**Figure 26–3**). Each kidney weighs about 150 g (5.25 oz). The **hilum**, a prominent medial indentation, is the point of entry for the *renal artery* and *renal nerves*. The hilum is also the point of exit for the *renal vein* and the *ureter*.

Internal Anatomy of the Kidneys

The fibrous capsule covering the outer surface of the kidney also lines the **renal sinus**, an internal cavity within the kidney (**Figure 26–4**). The fibrous capsule is bound to the outer surfaces of the structures within the renal sinus. In this way, it stabilizes the positions of the ureter, renal blood vessels, and nerves.

The kidney has an outer *cortex* and an inner *medulla*. The **renal cortex** is the superficial region of the kidney, which is in contact with the fibrous capsule. The cortex is reddish-brown and granular.

The **renal medulla** consists of 6 to 18 distinct triangular structures called **renal pyramids**. The base of each pyramid touches the cortex. The tip of each pyramid—a region known as the **renal papilla**—projects into the renal sinus. Each pyramid has a series of fine grooves that converge at the papilla. Bands of cortical tissue called **renal columns** extend into the medulla and separate adjacent renal pyramids. The columns have a distinctly granular texture, similar to that of the cortex. A **kidney lobe** consists of a renal pyramid, the overlying area of renal cortex, and adjacent tissues of the renal columns.

Urine is produced in the kidney lobes. Ducts within each renal papilla discharge urine into a cup-shaped drain called a **minor calyx** (KĀ-lik-s). Four or five minor calyces (KAL-ih-sēz) merge to form a **major calyx**, and two or three major calyces combine to form the **renal pelvis**, a large, funnel-shaped chamber. The renal pelvis fills most of the renal sinus and is connected to the ureter, which drains the kidney.

Urine production begins in microscopic, tubular structures called *nephrons* (NEF-ronz). Two types of nephrons found in the kidney are *cortical nephrons* (in the renal cortex) and *juxtamedullary nephrons* (in the renal medulla). Each kidney has about 1.25 million nephrons, with a combined length of about 145 km (85 miles).

Blood Supply and Innervation of the Kidneys

The kidneys receive 20–25% of the total cardiac output. In healthy individuals, about 1200 mL of blood flow through the kidneys each minute—a phenomenal amount of blood for organs with a combined weight of less than 300 g (10.5 oz)!

Each kidney receives blood through a **renal artery**. This vessel originates along the lateral surface of the abdominal aorta near the level of the superior mesenteric artery (look back at **Figure 21–23a**). As it enters the renal sinus, the renal artery provides blood to the five **segmental arteries** (**Figure 26–5a**). Segmental arteries further divide into a series of **interlobar arteries**. These arteries radiate outward through the renal columns between the renal pyramids. The interlobar arteries supply

Figure 26–4 The Internal Anatomy of the Kidney.

Figure 26-5 The Blood Supply to the Kidneys.

In which region of the kidney is a glomerulus located?

blood to the **arcuate** (AR-kyū-āt) **arteries**, which arch along the boundary between the cortex and medulla of the kidney. Each arcuate artery gives rise to several **cortical radiate arteries**, also called *interlobular arteries*. They supply the cortical regions of the adjacent kidney lobes. Branching from each cortical radiate artery

are numerous **afferent arterioles**. These vessels deliver blood to the capillaries supplying individual nephrons (**Figure 26-5b,c**).

After passing through the capillaries of the nephrons, blood enters a network of venules and small veins that converge on the **cortical radiate veins**, also called *interlobular veins*

(Figure 26–5a,c). The cortical radiate veins deliver blood to **arcuate veins**. These veins in turn empty into **interlobar veins**, which drain directly into the **renal vein**. There are no segmental veins.

Renal nerves innervate the kidneys and ureters. Most of the nerve fibers involved are sympathetic postganglionic fibers from the celiac plexus and the inferior splanchnic nerves. A renal nerve enters each kidney at the hilum and follows the branches of the renal arteries to reach individual nephrons. The sympathetic innervation (1) adjusts rates of urine formation by

changing blood flow at the nephron and (2) influences urine composition by stimulating release of the hormone *renin*.

Microscopic Anatomy of the Kidneys: The Nephron and Collecting System

In the kidneys, the functional units—the smallest structures that can carry out all the functions of the system—are the **nephrons**. Each nephron consists of a renal corpuscle and a renal tubule (Figure 26–6a). The *renal corpuscle* (KOR-pus-ul)

Figure 26–6 The Anatomy of a Representative Nephron and the Collecting System. The characteristic cells of each segment of (a) the nephron (purple) and (b) the collecting system (tan) are noted. In this representative figure, the nephron has been significantly shortened and some parts rearranged.

What structure connects the proximal convoluted tubule to the distal convoluted tubule?

is a spherical structure containing a capillary network that filters blood. The *renal tubule*, a long tubular passageway, begins at the renal corpuscle. Each renal tubule empties into the *collecting system*, a series of tubes that carry tubular fluid away from the nephron (Figure 26-6b). Let's examine the structure and basic functions of each segment of a representative nephron.

The Renal Corpuscle

Each **renal corpuscle** is 150–250 μm in diameter (Figure 26-7). It is made up of the *glomerular* (Bowman's) *capsule*, a cup-shaped chamber that envelopes the capillary network called the *glomerulus*.

The Glomerular Capsule and the Glomerulus. The outer wall of the renal corpuscle is formed by the **glomerular capsule**. This structure encapsulates the glomerular capillaries and is continuous with the initial segment of the renal tubule. The **glomerulus** (glo-MER-yū-lus; plural, *glomeruli*) consists of about 50 intertwined capillaries. Blood is delivered to the

glomerulus by an **afferent arteriole**, and blood leaves the glomerulus in an **efferent arteriole** (Figures 26-6, 26-7a).

The outer wall of the capsule is made up of a simple squamous epithelium and is called the **capsular outer layer** (Figure 26-7a). This layer ends at the **visceral layer**, which covers the glomerular capillaries. The **capsular space** (*urinary space*) separates the capsular outer layer and visceral layer. The two layers are continuous where the glomerular capillaries are connected to the afferent arteriole and efferent arteriole. The capsular space is continuous with the lumen of the renal tubule (Figure 26-6a).

The visceral layer of the glomerulus consists of large cells with complex processes, or "feet," that wrap around the *dense layer*, a specialized basement membrane of the glomerular capillaries. These visceral cells of the capsule are called **podocytes** (PŌ-dō-sīts; *podos*, foot + *-cyte*, cell). Their feet are known as **foot processes**, or *pedicels* (Figure 26-7b). There are narrow gaps called **filtration slits** between adjacent foot processes. These slits are only 6–9 nm wide.

Figure 26-7 The Renal Corpuscle.

a Important structural features of a renal corpuscle.

b This cross section through a portion of the glomerulus shows the components of the filtration membrane of the nephron.

+ Clinical Note Glomerulonephritis

Glomerulonephritis (glo-mer-yū-lō-nef-Rĭ-tis) is inflammation of the glomeruli that impairs filtration in the kidneys. The condition is often an *immune complex disorder*, developing after an infection with *Streptococcus* bacteria. The kidneys are not the sites of infection, but as the immune system responds, the number of circulating antigen–antibody complexes rapidly increases. These complexes are small enough to pass through the basement membrane, but too large to fit between podocyte foot processes of the filtration membrane. The complexes clog up the filtration mechanism. As a result, filtrate production decreases. Any condition that leads to a massive immune response, including viral infections and autoimmune disorders, can cause glomerulonephritis.

Intraglomerular mesangial cells are located among the glomerular capillaries (Figure 26-7b). They are specialized cells derived from smooth muscle. Functions of these contractile cells include structural support, filtration, and phagocytosis. Their contraction decreases the luminal diameter of the capillaries. Their phagocytic activities help clear debris from the filtration membrane (discussed next).

The glomerular capillaries are fenestrated capillaries. That is, their endothelium contains pores ranging from 60 to 80 nm (0.06 to 0.08 μm) in diameter. The basement membrane of the endothelium differs from that in other capillary networks in that it may encircle more than one capillary.

The Filtration Membrane. Together, the fenestrated endothelium, the basement membrane, and the foot processes of podocytes form the **filtration membrane** (Figure 26-7b). During *filtration*, which takes place in the renal corpuscle, blood pressure forces water and small dissolved solutes out of the glomerular capillaries through this membrane and into the capsular space. The larger solutes, especially plasma proteins, do not pass through. Filtration produces an essentially protein-free solution, known as a *filtrate*, that is otherwise similar to blood plasma. From the renal corpuscle, filtrate enters the renal tubule.

The Renal Tubule

The **renal tubule** may be 50 mm (1.97 in.) in length. This tubule has two convoluted (coiled or twisted) segments—the *proximal convoluted tubule* (PCT) and the *distal convoluted tubule* (DCT). They are separated by a simple U-shaped tube, the *nephron loop*, also called the *loop of Henle* (HEN-lē). The convoluted segments lie in the cortex of the kidney, and the nephron loop dips at least partially into the medulla. For clarity, the nephron shown in Figure 26-6a has been shortened and straightened.

Tips

In the nephron, the terms *proximal tubule* and *distal tubule* refer to how far along the renal tubule these structures are located from the renal corpuscle. Think of *proximal* (nearer the renal corpuscle) as being first, and *distal* (farther from the renal corpuscle) as being last.

As the filtrate travels along the renal tubule, it is now called *tubular fluid*, and it gradually changes in composition. This is because the main functions of the renal tubule are reabsorption and secretion. When a substance is *reabsorbed*, it is “reclaimed,” eventually reentering the blood. When a substance is *secreted*, it enters the tubular fluid from the blood. The changes that take place in the tubular fluid, and the characteristics of the urine that result, are due to the activities under way in each segment of the nephron.

The Proximal Convoluted Tubule. The **proximal convoluted tubule (PCT)** is the first segment (Figure 26-6a). Its entrance lies almost directly opposite the point where the afferent and efferent arterioles connect to the glomerulus. The lining of the PCT is a simple cuboidal epithelium whose apical surfaces have microvilli. Reabsorption of critical ions is the primary function of the PCT.

The Nephron Loop. The PCT makes an acute bend that turns the renal tubule toward the renal medulla. This turn leads to the **nephron loop** (Figure 26-6a). It is divided into a **descending limb** and an **ascending limb**. Fluid in the descending limb flows toward the renal pelvis. Fluid in the ascending limb flows toward the renal cortex. The limbs contain thin and thick segments: the *descending thin limb* (DTL), the *ascending thin limb* (ATL), and the *thick ascending limb* (TAL). The terms *thick* and *thin* refer to the height of the epithelium, not to the diameter of the lumen. Thick limbs have cuboidal epithelium. Thin limbs are lined with squamous epithelium.

The Distal Convoluted Tubule. The thick ascending limb (TAL) of the nephron loop ends where it forms a sharp angle near the renal corpuscle. The **distal convoluted tubule (DCT)**, the third segment of the renal tubule, begins there. The initial portion of the DCT passes between the afferent and efferent arterioles (Figure 26-7a).

In sectional view, the DCT differs from the PCT in that the DCT has a smaller luminal diameter and its epithelial cells lack microvilli. The primary function of the DCT is to reabsorb water and selected ions, as well as active secretion of undesirable substances.

The Juxtaglomerular Complex

The **juxtaglomerular complex (JGC)** is a structure that helps regulate blood pressure and filtrate formation. It consists of the

macula densa, *juxtaglomerular cells* (granular cells), and *extraglomerular mesangial cells*. The **macula densa** (MAK-yū-luh DEN-suh) is a group of tall, closely packed epithelial cells in the distal tubular epithelium. They function as either chemoreceptors or baroreceptors. The **juxtaglomerular cells** are modified smooth muscle cells in the wall of the afferent arteriole that secrete renin. These cells function as baroreceptors that monitor blood pressure in the afferent arteriole. **Extraglomerular mesangial cells** are in the triangular space between the afferent and efferent glomerular arterioles. These cells provide feedback control between the macula densa and the juxtaglomerular cells (**Figure 26-7a**).

The Collecting System

The distal convoluted tubule, the last segment of the nephron, opens into the **collecting system** (**Figure 26-6b**). Many individual nephrons drain their tubular fluid into a nearby **collecting duct**. Each collecting duct begins in the cortex and descends into the medulla. Several collecting ducts then converge into a larger **papillary duct**, which in turn empties into a *minor calyx*. The epithelium lining the papillary duct is typically columnar.

Two main types of cells are found in the collecting duct: *intercalated cells* and *principal cells*. Intercalated cells are

cuboidal cells with microvilli. Type A intercalated cells and Type B intercalated cells make up the population of intercalated cells. Together, these cells regulate the acid–base balance in the blood. Principal cells are cuboidal cells that lack microvilli and reabsorb water and secrete potassium ions.

The collecting system transports tubular fluid from the nephrons to the renal pelvis. Along the way, it also adjusts the fluid's composition and determines the final osmotic concentration and volume of urine, the final product. These activities of the collecting system are considered later in the chapter.

Table 26-1 summarizes the regional specializations and general functions of the parts of the nephron and the collecting system.

Types of Nephrons

Nephrons from different locations within a kidney differ slightly in structure. Approximately 85% of all nephrons are **cortical nephrons**, located almost entirely within the superficial cortex of the kidney (**Figure 26-8a,b**). In a cortical nephron, the nephron loop is relatively short, and the efferent arteriole delivers blood to a network of **peritubular capillaries**, which surround the entire renal tubule. These

Figure 26-8 The Locations and Structures of Cortical and Juxtamedullary Nephrons.

Table 26–1 The Organization of the Nephron and Collecting System

Region	Histological Characteristics	Length	Diameter	Primary Function
NEPHRON				
Renal corpuscle Capsular space 	Glomerulus (capillary knot), intraglomerular mesangial cells, and basement membrane, enclosed by the glomerular capsule; visceral layer (podocytes) and capsular outer layer (simple squamous epithelium) separated by capsular space	150–250 μm (spherical)	150–250 μm	Filtration of blood plasma
Renal tubule Proximal convoluted tubule (PCT) 	Cuboidal cells with microvilli	14 mm	60 μm	Reabsorption of ions, organic molecules, vitamins, water; secretion of drugs, toxins, acids
Nephron loop 	Squamous or cuboidal cells	30 mm	15 μm 30 μm	Descending limb: reabsorption of water from tubular fluid Ascending limb: reabsorption of ions; assists in creation of a concentration gradient in the renal medulla
Distal convoluted tubule (DCT) 	Cuboidal cells with few if any microvilli	5 mm	30–50 μm	Reabsorption of sodium ions and calcium ions; secretion of acids, ammonia, drugs, toxins
COLLECTING SYSTEM				
Collecting duct 	Cuboidal cells	15 mm	50–100 μm	Reabsorption of water, sodium ions; secretion or reabsorption of bicarbonate ions or hydrogen ions
Papillary duct 	Columnar cells	5 mm	100–200 μm	Conduction of tubular fluid to minor calyx; contributes to concentration gradient of the medulla

capillaries drain into small venules that carry blood to the cortical radiate veins (look back at **Figure 26–5c**).

The remaining 15% of nephrons, termed **juxtamedullary** (juks-tuh-MED-yū-lār-ē; *juxta*, near) **nephrons**, have long nephron loops that extend deep into the renal pyramids of the medulla (**Figure 26–8a,c**). The efferent arterioles of juxtamedullary nephrons connect to the **vasa recta** (*vasa*, vessel + *recta*, straight), long, straight capillaries that parallel the nephron loop.

Checkpoint

26-3 Different segments of the nephron form urine by filtration, reabsorption, and secretion

Learning Outcome Describe the basic processes that form urine.

The primary function of urine production is to maintain homeostasis by regulating the volume and composition of blood. This process involves the excretion of solutes—specifically, **metabolic wastes**.

Metabolic Wastes

The body forms three important metabolic wastes:

- **Urea.** **Urea** is the most abundant organic waste. Approximately 21 g of urea are generated each day, most of it through the breakdown of amino acids.
- **Creatinine.** Skeletal muscle tissue generates **creatinine** through the breakdown of *creatine phosphate*, a high-energy compound that plays an important role in muscle contraction. The body generates about 1.8 g of creatinine each day. Virtually all of it is excreted in urine.
- **Uric Acid.** **Uric acid** is a waste formed during the recycling of the nitrogenous bases from RNA molecules. Approximately 480 mg of uric acid are produced each day.

These wastes are dissolved in the bloodstream. They can be eliminated only when dissolved in urine. For this reason, their removal involves an unavoidable water loss. The kidneys are usually capable of producing urine with an osmotic concentration more than four times that of plasma. If the kidneys were unable to concentrate the filtrate produced by filtration, fluid losses would lead to fatal dehydration in a matter of hours.

The kidneys also ensure that the fluid that is lost does not contain potentially useful substances that are present in blood plasma, such as sugars or amino acids. These valuable materials must be reabsorbed and retained for use by other tissues.

Basic Processes of Urine Formation

Let's look at the three distinct processes each nephron uses to produce urine:

1. **Filtration.** In **filtration**, blood pressure forces water and solutes across the walls of the glomerular capillaries and into the capsular space. Solute molecules small enough to pass through the filtration membrane are carried by the surrounding water molecules.
2. **Reabsorption.** **Reabsorption** is the removal of water and solutes from the filtrate, and their movement across the tubular epithelium and into the **peritubular fluid**, the interstitial fluid surrounding the renal tubule. Reabsorption takes place after the filtrate has left the renal corpuscle. Most of the reabsorbed substances are nutrients the body can use. Filtration

is based solely on particle size, but reabsorption is a selective process. Reabsorption involves either simple diffusion or carrier proteins in the tubular epithelium. The reabsorbed substances in the peritubular fluid eventually reenter the blood. Water reabsorption takes place passively, through osmosis.

3. **Secretion.** **Secretion** is the transport of solutes from the peritubular fluid, across the tubular epithelium, and into the tubular fluid. Secretion is necessary because filtration does not force all the dissolved substances out of the plasma. Tubular secretion, which removes substances from the blood, can further lower the plasma concentration of undesirable materials. It provides a backup process for filtration. Secretion is often the primary method of preparing substances, including many drugs, for excretion.

Figure 26-9 summarizes where these processes occur in the various segments of the nephron and collecting system. Most regions carry out a combination of reabsorption and secretion. Note that the balance between the two processes shifts from one region to another.

Together, these processes produce urine, a fluid that is very different from other body fluids. **Table 26-2** shows the functional efficiency of the kidneys by comparing the concentrations of solutes in urine and plasma.

Normal kidney physiology can continue only if filtration, reabsorption, and secretion function within relatively narrow limits. A disruption in kidney function has immediate effects on the composition of the circulating blood. If both kidneys are affected, death follows within a few days unless medical assistance is provided.

Table 26-2 Normal Laboratory Values for Solutes in Plasma and Urine

Solute	Plasma	Urine
IONS (mEq/L)		
Sodium (Na⁺)	135–145	40–220
Potassium (K⁺)	3.5–5.0	25–100
Chloride (Cl⁻)	100–108	110–250
Bicarbonate (HCO₃⁻)	20–28	1–9
METABOLITES AND NUTRIENTS (mg/dL)		
Glucose	70–110	0.009
Lipids	450–1000	0.002
Amino acids	40	0.188
Proteins	6–8 g/dL	0.000
NITROGENOUS WASTES (mg/dL)		
Urea	8–25	1800
Creatinine	0.6–1.5	150
Uric acid	2–6	40
Ammonia	<0.1	60

Figure 26–9 An Overview of Urine Formation.

The next sections proceed along the nephron to consider the formation of filtrate and how it changes in composition and concentration as it passes along the individual segments of the renal tubule. Most of what follows applies equally to cortical and juxtamedullary nephrons. The functions of the renal corpuscle and of the proximal and distal convoluted tubules are the same in all nephrons. Cortical nephrons do most of the reabsorption and secretion in the kidneys because they are more numerous than juxtamedullary nephrons.

However, as described later in the chapter, it is the juxtamedullary nephrons that enable the kidneys to produce

concentrated urine. Their long nephron loops play a key role in water conservation and the formation of concentrated urine. This process is vitally important, affecting the tubular fluid produced by every nephron in the kidney. For this reason, a juxtamedullary nephron is used as an example.

✓ Checkpoint

6. Identify the three distinct processes that form urine in the kidney.

See the blue Answers tab at the back of the book.

26-4 The glomerulus filters blood through the filtration membrane to produce filtrate; several pressures determine the glomerular filtration rate

Learning Outcome Describe the factors that influence glomerular filtration pressure and the rate of filtrate formation.

In the body, the heart pushes blood around the cardiovascular system and generates *hydrostatic pressure*. Recall that this pressure causes filtration to occur across the walls of capillaries as water and dissolved materials are pushed into the interstitial fluids of the body (look back at **Figure 21–10**). In kidney nephrons, this hydrostatic pressure drives *glomerular filtration*. Glomerular filtration is the vital first step for all other kidney functions. If filtration does not take place, wastes are not excreted, pH control is jeopardized, and an important mechanism for regulating blood volume is lost.

This section describes the pressures that affect the glomerular filtration and how that filtration is regulated. But first we revisit the filtration membrane and learn more about how this process occurs.

Function of the Filtration Membrane

In **glomerular filtration**, blood plasma is forced through the pores of the specialized filtration membrane, and solute molecules small enough to pass through those pores are carried along. The filtration membrane restricts the passage of larger solutes and suspended materials from the plasma, producing filtrate.

An example of filtration in action occurs in a drip coffee machine. Gravity pulls hot water through the filter, and the water carries a variety of dissolved substances into the pot. The large coffee grounds never reach the pot, because they cannot fit through the pores of the filter. In other words, they are “filtered out” of the solution; the coffee people drink is the filtrate.

Recall that the filtration membrane has three parts: (1) the fenestrated endothelium, (2) the basement membrane, and (3) the foot processes of podocytes (**Figures 26–7b** and **26–10a**). In glomerular filtration, water from the blood plasma is forced through all three parts of this membrane, with each filtering solutes of smaller size out of the final filtrate. The glomerular capillaries are made up of fenestrated endothelium with pores small enough to prevent the passage of blood cells, but too large to restrict the diffusion of solutes, even those the size of plasma proteins. The basement membrane is more selective: Only small plasma proteins, nutrients, and ions can cross it. The foot processes are the finest filters of all. The narrow gaps between the foot processes prevent the passage of most small plasma proteins. As a result, under normal circumstances only a few plasma proteins—such as albumin molecules, with an average diameter of 7 nm—can cross the filtration membrane and

enter the capsular space. Because plasma proteins are all that stay behind, the filtrate contains dissolved ions and small organic molecules in about the same concentrations as in plasma.

Filtration Pressures

The major forces that act across capillary walls were discussed in Chapters 21 and 22. (It may be helpful to review **Figures 21–10** and **21–11** before proceeding.) The primary factor involved in glomerular filtration is basically the same one that regulates fluid and solute movement across capillaries throughout the body. This factor is the balance between **hydrostatic pressure**, or fluid pressure, and **colloid osmotic pressure**, or pressure due to materials in solution, on each side of the capillary walls.

Hydrostatic Pressure

Blood pressure is low in typical systemic capillaries. The reason is that capillary blood flows into the venous system, where resistance is low. However, at the glomerulus, blood leaving the glomerular capillaries flows into an efferent glomerular arteriole, whose luminal diameter is *smaller* than that of the afferent glomerular arteriole. For this reason, the efferent arteriole offers considerable resistance. Relatively high pressures are needed to force blood into it. As a result, glomerular pressures are similar to those of small arteries. *Glomerular hydrostatic pressure* (GHP) averages about 50 mm Hg, instead of the 35 mm Hg typical of peripheral capillaries. GHP is shown with other pressures affecting glomerular filtration in **Figure 26–10b**.

Capsular hydrostatic pressure (CsHP) opposes glomerular hydrostatic pressure. The CsHP results from the resistance to flow along the nephron and the conducting system. (Before additional filtrate can enter the capsule, some of the filtrate already present must be forced into the PCT.) The CsHP averages about 15 mm Hg.

The *net hydrostatic pressure* (NHP) is the difference between the glomerular hydrostatic pressure, which tends to push water and solutes out of the bloodstream, and the capsular hydrostatic pressure, which tends to push water and solutes into the bloodstream. Net hydrostatic pressure can be calculated as follows:

$$\begin{aligned} \text{NHP} &= (\text{GHP} - \text{CsHP}) = (50 \text{ mm Hg} - 15 \text{ mm Hg}) \\ &= 35 \text{ mm Hg} \end{aligned}$$

Colloid Osmotic Pressure

The *blood colloid osmotic pressure* (BCOP) is the osmotic pressure resulting from suspended proteins in the blood (**Figure 26–10b**). Under normal conditions, very few plasma proteins enter the capsular space, so no opposing colloid osmotic pressure exists within the capsule. However, if the glomeruli are damaged by disease or injury, and plasma proteins begin passing into the capsular space, a *capsular colloid osmotic pressure* is created that promotes filtration and increases fluid losses in urine.

Figure 26–10 Glomerular Filtration.

Net Filtration Pressure

The **net filtration pressure (NFP)** in the glomerulus is the difference between the net hydrostatic pressure and the blood colloid osmotic pressure acting across the glomerular capillaries. Under normal circumstances, this relationship is summarized as

$$\text{NFP} = \text{NHP} - \text{BCOP}$$

or, using the values in **Figure 26–10b**,

$$\text{NFP} = 35 \text{ mm Hg} - 25 \text{ mm Hg} = 10 \text{ mm Hg}$$

This is the average pressure forcing water and dissolved substances out of the glomerular capillaries and into the capsular spaces (**Figure 26–10b**). Problems that affect the net filtration pressure can seriously disrupt kidney function and cause a variety of clinical signs and symptoms.

The Glomerular Filtration Rate (GFR)

The **glomerular filtration rate (GFR)** is the amount of filtrate the kidneys produce each minute. Each kidney contains

about 6 m^2 —approximately 64 square feet—of filtration surface, and the GFR averages an astounding $125 \text{ mL per minute}$. This means that nearly 10% of the fluid delivered to the kidneys by the renal arteries leaves the bloodstream and enters the capsular spaces. In a single day, the glomeruli generate about 180 liters (48 gal) of filtrate, approximately 70 times the total plasma volume.

The glomerular filtration rate depends on the net filtration pressure across the glomerular capillaries. Any factor that alters the net filtration pressure also alters the GFR and affects kidney function. One of the most significant factors would be a decrease in renal blood pressure. If blood pressure at the glomeruli decreases by 20% (from 50 mm Hg to 40 mm Hg), kidney filtration stops, because the net filtration pressure falls to 0 mm Hg. For this reason, the kidneys are sensitive to changes in blood pressure that have little or no effect on other organs. Hemorrhaging, shock, and dehydration are relatively common clinical conditions that can cause a dangerous decrease in the GFR and lead to *acute renal failure* (loss of kidney function).

Regulation of the GFR

Filtration depends on adequate blood flow to the glomerulus and on the maintenance of normal filtration pressures. Three interacting levels of control ensure that the GFR remains within normal limits: (1) *autoregulation* occurring at the local level, (2) *hormonal regulation* initiated by the kidneys, and (3) *autonomic regulation* maintained primarily by the sympathetic division of the autonomic nervous system.

Autoregulation of the GFR

Autoregulation (local blood flow regulation) maintains an adequate GFR despite changes in local blood pressure and blood flow. *Myogenic mechanisms*—how the smooth muscle of arteries and arterioles react to an increase or decrease in blood pressure—play a role in the autoregulation of blood flow. Changes to the luminal diameters of afferent arterioles, efferent arterioles, and glomerular capillaries maintain GFR.

The most important regulatory mechanisms stabilize the GFR when systemic blood pressure decreases. One of these mechanisms relies on the supporting intraglomerular mesangial cells. Actin-like filaments in these cells enable them to contract. In this way, these cells control capillary luminal diameter and the rate of glomerular capillary blood flow.

The GFR also remains relatively constant when systemic blood pressure increases. An increase in renal blood pressure stretches the walls of afferent glomerular arterioles, and the smooth muscle cells respond by contracting. The reduction in the luminal diameter of afferent glomerular arterioles decreases glomerular blood flow and keeps the GFR within normal limits.

If autoregulation is ineffective, the kidneys call for a wider response to increase the GFR (**Figure 26–11**).

Hormonal Regulation of the GFR

The GFR is regulated by the hormones of the **renin-angiotensin-aldosterone system** (RAAS) and the *natriuretic peptides*. These hormones and their actions were introduced in Chapters 18 and 21. The release of **renin** ultimately restricts water and salt loss in the urine by stimulating reabsorption by the nephron. There are three triggers for the release of renin by the juxtaglomerular complex (JGC): (1) a decrease in blood pressure at the glomerulus as the result of a decrease in blood volume, a decrease in systemic pressures, or a blockage in the renal artery or its branches; (2) stimulation of juxtaglomerular cells by sympathetic innervation; or (3) a decrease in the osmotic concentration of the tubular fluid at the macula densa.

These triggers are often interrelated. For example, a decrease in systemic blood pressure reduces the glomerular filtration rate, while baroreceptor reflexes cause sympathetic activation. Meanwhile, a decrease in the GFR slows the movement of tubular fluid along the nephron. As a result, the tubular fluid is in the ascending limb of the nephron loop longer, and the concentration of sodium and chloride ions in the tubular fluid reaching the macula densa and DCT becomes abnormally low.

Figure 26–11 shows how the renin-angiotensin-aldosterone system responds to a decrease in GFR. A decrease in GFR leads to the release of renin by the juxtaglomerular complex. Renin converts the inactive plasma protein angiotensinogen to angiotensin I. Angiotensin I is also inactive but is then converted to angiotensin II by **angiotensin-converting enzyme (ACE)**. This conversion takes place primarily in the capillaries of the lungs. Angiotensin II acts at the nephron, at the adrenal glands, and in the CNS. Angiotensin II stimulates contraction of vascular smooth muscle in peripheral capillary beds, promotes aldosterone production, and stimulates the sympathetic nervous system to increase arterial pressures throughout the body. The combined effect is an increase in systemic blood pressure and blood volume and the restoration of normal GFR.

If blood volume increases, the GFR increases automatically. This increase promotes fluid losses that help return blood volume to the normal level. If the increase in blood volume is severe, hormonal factors further increase the GFR and speed up fluid losses in the urine. As noted in Chapter 18, the heart releases natriuretic peptides when increased blood volume or blood pressure stretches the walls of the heart. For example, the atria release *atrial natriuretic peptide* (ANP). Among its other effects, this hormone triggers the dilation of afferent glomerular arterioles and the constriction of efferent glomerular arterioles. This mechanism increases glomerular pressures and increases the GFR. ANP also decreases sodium reabsorption at

Renin-Angiotensin-Aldosterone System

The diagram illustrates the RAAS pathway and its effects on restoring blood pressure and volume. It is organized into three main sections: **Endocrine response** and **Neural responses**.

Stimulus: Homeostasis is disturbed by decreasing blood flow to kidneys, leading to decreased filtration pressure, decreased filtrate, and decreased urine production.

Endocrine response:

- Effector:** Juxtaglomerular complex releases renin into the bloodstream.
- Renin triggers the formation of angiotensin I. Angiotensin-converting enzyme (ACE) in the capillaries of the lungs converts angiotensin I to angiotensin II.
- Angiotensin II constricts peripheral arterioles and further constricts the efferent arterioles.

Neural responses started by angiotensin II:

- Angiotensin II increases aldosterone secretion by the adrenal glands.
- Aldosterone increases Na^+ retention.
- Angiotensin II stimulates the nervous system (brain).

Effects of the nervous system:

- Increased stimulation of thirst centers leads to increased fluid consumption.
- Increased ADH production leads to increased fluid retention.
- Increased sympathetic activation leads to constriction of systemic veins and increased cardiac output.
- Together, angiotensin II and sympathetic activation stimulate peripheral vasoconstriction.

Restoration of Homeostasis:

- Increased blood volume and increased blood pressure are the result of the combined effects of increased fluid consumption, increased fluid retention, increased cardiac output, and peripheral vasoconstriction.
- Homeostasis is restored by increasing blood flow to kidneys.

What four factors shown result in an increased blood volume?

Most of the autonomic innervation of the kidneys consists of sympathetic postganglionic fibers. Sympathetic activation has a direct effect on the GFR. It produces powerful

vasoconstriction of afferent glomerular arterioles, which decreases the GFR and slows the production of filtrate. In this way, the sympathetic activation triggered by an acute decrease in blood pressure or a heart attack overrides the local regulatory mechanisms that act to stabilize the GFR. As the crisis passes and sympathetic tone decreases, the filtration rate gradually returns to normal.

When the sympathetic division alters regional patterns of blood circulation, blood flow to the kidneys is often affected. For example, the dilation of superficial dermal blood vessels in warm weather shunts blood away from the kidneys. As a result, glomerular filtration decreases temporarily. The effect becomes especially pronounced during strenuous exercise. As blood flow to the skin and skeletal muscles increases, kidney perfusion gradually decreases.

At a maximal level of exertion, renal blood flow may be less than 25% of the normal resting level. This reduction can create problems for endurance athletes. Metabolic wastes build up over the course of a long event. *Proteinuria* (protein in the urine) commonly occurs after such events because the glomerular cells have been injured by prolonged *hypoxia* (a low oxygen level). If the damage is substantial, *hematuria* (blood in the urine) occurs. Hematuria develops in about 18% of marathon runners. The cause is trauma to the bladder epithelium from the shocks of running. Proteinuria and hematuria generally disappear within 48 hours as the glomerular tissues are repaired. However, a small number of marathon and ultramarathon runners experience acute renal failure.

26-5 The renal tubule reabsorbs nutrients, ions, and water and secretes ions and wastes; the collecting system reabsorbs ions and water

Learning Outcome Identify the types and functions of transport mechanisms found along each segment of the nephron and collecting system.

Filtration by the renal corpuscle is both effective and energy efficient, but it has one major drawback: Useful substances such as glucose, free fatty acids, amino acids, vitamins, and other solutes enter the capsular space, in addition to metabolic wastes and excess ions.

The renal tubule has three specific functions: (1) reabsorbing all the useful organic nutrients in the filtrate; (2) reabsorbing more than 90% of the water in the filtrate; and (3) secreting into the tubule lumen any wastes that did not pass into the filtrate at the glomerulus. As filtrate passes through the renal tubules, about 99% of it is reabsorbed. Both reabsorption and secretion take place in every segment of the

renal tubule and in the collecting system. However, their relative importance changes from segment to segment. Let's take a more detailed look at these critical processes, starting with the principles behind them.

Principles of Reabsorption and Secretion

The processes of reabsorption and secretion alter the composition of the filtrate produced by glomerular filtration. Tubular reabsorption returns nutrients, such as glucose, amino acids, water, and salt, from the tubular fluid to the blood. Tubular secretion is the reverse of reabsorption: It adds substances from the blood to the tubular fluid.

Review of Carrier-Mediated Transport Mechanisms

The processes of reabsorption and secretion by the kidneys involve a combination of diffusion, osmosis, leak channels (channel-mediated diffusion), and carrier-mediated transport. Here is a brief review of *carrier-mediated transport* mechanisms.

- In *facilitated diffusion*, a carrier protein transports a molecule across the plasma membrane without expending energy. Such transport always follows the concentration gradient for the ion or molecule transported.
- *Active transport* is driven by the hydrolysis of ATP to ADP on the inner plasma membrane surface. Exchange pumps and other carrier proteins are active along the renal tubules. Active transport can operate despite an opposing concentration gradient.
- In *cotransport*, carrier protein activity is not directly linked to the hydrolysis of ATP. Instead, two substrates (ions, molecules, or both) cross the membrane while bound to the carrier protein. The movement of the substrates always follows the concentration gradient of at least one of the transported substances. Cotransport is used for the reabsorption of organic and inorganic compounds from the tubular fluid.
- *Countertransport* resembles cotransport, except that the two transported ions move in *opposite* directions. Countertransport operates in the PCT, DCT, and collecting system.

All carrier-mediated processes share the following characteristics, which are important to understanding kidney physiology:

- A specific substrate binds to a carrier protein that facilitates movement across the membrane. The movement may be active or passive.
- A given carrier protein typically works in one direction only. In facilitated diffusion, the concentration gradient of the

substance being transported determines that direction. In active transport, cotransport, and countertransport, the location and orientation of the carrier proteins determine whether a particular substance is reabsorbed or secreted. The carrier protein that transports amino acids from the tubular fluid to the cytosol of the tubule cells, for example, will not carry amino acids back into the tubular fluid.

- *The distribution of carrier proteins can vary in different regions of the cell surface.* Transport between tubular fluid and peritubular fluid involves two steps. First, the material enters the cell at its apical surface. Then the material leaves the cell at its basolateral surface and enters the peritubular fluid. Each step involves a different carrier protein. For example, the apical surfaces of cells along the proximal convoluted tubule contain carrier proteins that bring amino acids, glucose, and many other nutrients into these cells by sodium ion–linked cotransport. In contrast, the basolateral surfaces contain carrier proteins that move those nutrients out of the cell by facilitated diffusion.
- *The membrane of a single tubular cell contains many types of carrier proteins.* Each cell can have multiple functions. A cell that reabsorbs one compound can secrete another.

The Transport Maximum (T_m) and the Renal Threshold

Recall that when an enzyme is *saturated*, further increases in substrate concentration have no effect on the rate of reaction. Likewise, when a carrier protein is saturated, further increases in substrate concentration have no effect on the rate of transport across the plasma membrane. For any substance, the concentration at saturation is called the **transport maximum** (T_m), or *tubular maximum*. The T_m reflects the number of available carrier proteins in the renal tubules. In healthy people, carrier proteins involved in tubular secretion seldom become saturated. However, carriers involved in tubular reabsorption are often at risk of saturation, especially during the absorptive state following a meal. When the carrier proteins are saturated, excesses of that substrate are excreted.

Normally, any plasma proteins and nutrients, such as amino acids and glucose, are removed from the tubular fluid by cotransport or facilitated diffusion. If the concentrations of these nutrients rise in the tubular fluid, the rate of reabsorption increases until the carrier proteins are saturated. A concentration higher than the transport maximum exceeds the reabsorption abilities of the nephron. In this case, some of the material will remain in the tubular fluid and appear in the urine. The transport maximum thus determines the **renal threshold**—the plasma concentration at which a specific substance or ion begins to appear in the urine.

The renal threshold varies with the substance involved. The renal threshold for glucose is approximately 180 mg/dL.

When the plasma glucose concentration exceeds 180 mg/dL, glucose appears in urine; this condition is called *glucosuria* (glū-kō-SYŪ-rē-uh) or *glycosuria*. After eating a meal rich in carbohydrates, the plasma glucose level may exceed the glucose T_m for a brief period. However, the liver quickly lowers the circulating glucose level, and very little glucose is lost in the urine. Chronically increased plasma and urinary glucose concentrations are abnormal. (Glycosuria is one of the key signs of diabetes mellitus.)

The renal threshold for amino acids is lower than that for glucose. Amino acids appear in urine when their plasma concentrations exceed 65 mg/dL. Plasma amino acid levels commonly exceed the renal threshold after eating a protein-rich meal, causing some amino acids to appear in the urine. This condition is termed *aminoaciduria* (am-ih-nō-as-ih-DYŪ-rē-uh).

The T_m values for water-soluble vitamins are relatively low. As a result, excess quantities of these vitamins are excreted in urine. (This is typically the fate of water-soluble vitamins in daily supplements.)

Measuring Osmotic Concentration

The osmotic concentration, or *osmolarity*, of a solution is the total number of solute particles in each liter. Osmolarity is usually expressed in **osmoles** per liter (Osm/L) or **milliosmoles** per liter (mOsm/L). If a liter of a fluid contains 1 mole of dissolved particles, the solute concentration is 1 Osm/L, or 1000 mOsm/L. Body fluids have an osmotic concentration of about 300 mOsm/L. For comparison, seawater is about 1000 mOsm/L and fresh water is about 5 mOsm/L. In a clinical setting, the osmolarity of urine is often reported as *osmolality*, expressed as milliosmoles per kilogram of water (mOsm/kg H₂O). When discussing osmotic concentrations in body fluids, these terms are often used interchangeably (1 liter of water has a mass of 1 kilogram).

Ion concentrations are often reported in *milliequivalents* per liter (mEq/L). Milliequivalents indicate the number of positive or negative charges in solution, rather than the number of solute particles. To convert mmol/L to mEq/L, multiply mmol/L by the number of charges on each ion. For example, each sodium ion has one charge only, so for Na⁺, 1 mmol/L = 1 mEq/L; for Ca²⁺, each ion has two charges, so 1 mmol/L = 2 mEq/L. The concentrations of large organic molecules are usually reported in grams, milligrams, or micrograms per unit volume of solution (typically, per deciliter, or dL).

An Overview of Reabsorbed and Secreted Substances

Table 26–3 lists some substances that are actively reabsorbed by the renal tubules. It also includes some of the substances secreted into tubular fluid by the proximal and distal convoluted tubules.

Table 26–3 Tubular Reabsorption and Secretion

Reabsorbed	Secreted	No Transport Mechanism
Ions Na^+ , Cl^- , K^+ , Ca_2^+ , Mg^{2+} , SO_4^{2-} , HCO_3^-	Ions K^+ , H^+ , Ca^{2+} , PO_4^{3-}	Urea Water Urobilinogen Bilirubin
Metabolites Glucose Amino acids Proteins Vitamins	Wastes Creatinine Ammonia Metabolic acids and bases	
	Miscellaneous Neurotransmitters (ACh, NE, E, dopamine) Histamine Drugs (penicillin, atropine, morphine, many others)	

Note that cells of the renal tubule ignore many substances in the tubular fluid, because there are no transport mechanisms for them. These substances tend to be metabolic wastes. As water and other substances are removed, the concentrations of these wastes in the tubular fluid gradually rise.

Reabsorption and Secretion along the Proximal Convoluted Tubule

The cells of the proximal convoluted tubule normally reabsorb 60–70% of the volume of the filtrate produced in the renal corpuscle. The tubular cells reabsorb organic nutrients, ions, water, and plasma proteins (if present) from the tubular fluid. The reabsorbed materials enter the peritubular fluid, diffuse into peritubular capillaries, and are quickly returned to the bloodstream. The epithelial cells can also secrete substances into the lumen of the renal tubule.

The proximal convoluted tubule (PCT) has the following major functions:

- **Reabsorption of Organic Nutrients.** Under normal circumstances, before the tubular fluid enters the nephron loop, the PCT reabsorbs more than 99% of the glucose, amino acids, and other organic nutrients in the fluid. This reabsorption involves a combination of facilitated diffusion and cotransport.
- **Active Reabsorption of Ions.** The PCT actively transports several ions, including sodium, potassium, and bicarbonate ions, plus magnesium, phosphate, and sulfate ions (**Figure 26–12**). Although the ion pumps involved are individually regulated, they may be influenced by circulating ion or hormone levels. For example, the hormone angiotensin II stimulates sodium ion (Na^+) reabsorption along the PCT. By absorbing carbon dioxide (CO_2), the PCT indirectly recaptures about 90% of the bicarbonate ions (HCO_3^-) from tubular fluid. Bicarbonate ions are important in stabilizing blood pH.

- **Reabsorption of Water.** Water reabsorption has a direct effect on the solute concentrations inside and outside the tubules. The filtrate entering the PCT has the same osmotic concentration as that of the surrounding peritubular fluid. As reabsorption proceeds, the solute concentration of tubular fluid decreases, and that of peritubular fluid and adjacent capillaries increases. Water then moves out of the tubular fluid and into the peritubular fluid by osmosis. Along the PCT, this mechanism results in the reabsorption of about 108 liters of water each day.
- **Passive Reabsorption of Ions.** As active reabsorption of ions takes place and water leaves the tubular fluid by osmosis, the concentration of other solutes in the tubular fluid increases above that in the peritubular fluid. If the tubular cells are permeable to them, those solutes move across the tubular cells and into the peritubular fluid by passive diffusion. Urea, chloride ions, and lipid-soluble materials may diffuse out of the PCT in this way. Such diffusion further decreases the solute concentration of the tubular fluid and promotes additional water reabsorption by osmosis.
- **Secretion.** Active secretion of hydrogen ions first takes place along the proximal convoluted tubule (**Table 26–4**). Because the proximal convoluted tubule and distal convoluted tubule secrete similar substances, and the distal convoluted tubule carries out comparatively little reabsorption, secretory mechanisms are considered with the discussion of the distal convoluted tubule.

Sodium ion reabsorption plays an important role in all these processes. Sodium ions may enter tubular cells by diffusion through sodium ion leak channels; by the sodium ion-linked cotransport of glucose, amino acids, or other organic solutes; or by countertransport for hydrogen ions (**Figure 26–12**). Once inside the tubular cells, sodium ions diffuse toward the basement membrane. The plasma membrane in this area contains sodium–potassium exchange pumps that eject sodium ions in exchange for extracellular potassium ions (K^+). The ejected sodium ions then diffuse through the peritubular fluid and into adjacent peritubular capillaries.

The reabsorption of ions and compounds along the PCT involves many different carrier proteins. Some people have an inherited inability to manufacture one or more of these carrier proteins. For this reason, these individuals are unable to recover specific solutes from tubular fluid. In *renal glucosuria*, for example, a defective glucose carrier protein makes it impossible for the PCT to reabsorb glucose from tubular fluid.

Reabsorption and Secretion along the Nephron Loop

Approximately 60–70% of filtrate volume produced by the glomerulus has been reabsorbed before the tubular fluid reaches the nephron loop. In the process, useful organic substrates and many mineral ions have been reclaimed. The

Table 26–4 Renal Structures and Their Functions

Segment	General Functions	Specific Functions	Mechanisms
Renal corpuscle	<i>Filtration</i> of plasma; generates approximately 180 L/day of filtrate similar in composition to blood plasma without plasma proteins	<i>Filtration</i> of water, inorganic and organic solutes from plasma; retention of plasma proteins and blood cells	Glomerular hydrostatic (blood) pressure working across capillary endothelium, dense layer, and filtration slits
Proximal convoluted tubule (PCT)	<i>Reabsorption</i> of 60%–70% of the water (108–116 L/day), 99–100% of the organic substrates, and 60–70% of the sodium and chloride ions in the original filtrate	<i>Active reabsorption</i> : Glucose, other simple sugars, amino acids, vitamins, ions (including sodium, potassium, calcium, magnesium, phosphate, and bicarbonate) <i>Passive reabsorption</i> : Urea, chloride ions, lipid-soluble materials, water <i>Secretion</i> : Hydrogen ions, ammonium ions, creatinine, drugs, and toxins (as at DCT)	Carrier-mediated transport, including facilitated diffusion (glucose, amino acids), cotransport (glucose, ions), and countertransport (with secretion of H ⁺) Diffusion (solute) or osmosis (water) Countertransport with sodium ions
Nephron loop	<i>Reabsorption</i> of 25% of the water (45 L/day) and 20–25% of the sodium and chloride ions present in the original filtrate; creation of the concentration gradient in the medulla	<i>Reabsorption</i> : Sodium and chloride ions Water	Active transport by Na ⁺ –K ⁺ /2 Cl [–] transporter Osmosis
Distal convoluted tubule (DCT)	<i>Reabsorption</i> of a variable amount of water (usually 5%, or 9 L/day), under ADH stimulation, and a variable amount of sodium ions, under aldosterone stimulation	<i>Reabsorption</i> : Sodium and chloride ions Sodium ions (variable) Calcium ions (variable) Water (variable) <i>Secretion</i> : Hydrogen ions, ammonium ions Creatinine, drugs, toxins	Cotransport Countertransport with potassium ions; aldosterone-regulated Carrier-mediated transport stimulated by parathyroid hormone and calcitriol Osmosis; ADH-regulated Countertransport with sodium ions Carrier-mediated transport
Collecting system	<i>Reabsorption</i> of a variable amount of water (usually 9.3%, or 16.8 L/day) under ADH stimulation, and a variable amount of sodium ions, under aldosterone stimulation	<i>Reabsorption</i> : Sodium ions (variable) Bicarbonate ions (variable) Water (variable) Urea (distal segments only) <i>Secretion</i> : Potassium and hydrogen ions (variable)	Countertransport with potassium or hydrogen ions; aldosterone-regulated Diffusion, generated within tubular cells Osmosis; ADH-regulated Diffusion Carrier-mediated transport
Peritubular capillaries	<i>Redistribution</i> of water and solutes reabsorbed in the cortex	Return of water and solutes to the general circulation	Osmosis and diffusion
Vasa recta	<i>Redistribution</i> of water and solutes reabsorbed in the medulla and stabilization of the concentration gradient of the medulla	Return of water and solutes to the general circulation	Osmosis and diffusion

nephron loop reabsorbs about half of the remaining water and two-thirds of the remaining sodium and chloride ions.

Recall that the nephron loop is made up of ascending and descending limbs, with thin and thick segments. The ascending limb is impermeable to water, but passively and actively removes sodium and chloride ions from the tubular fluid. Its ascending thin limb (ATL) is permeable to sodium ions, which diffuse into the surrounding peritubular fluid. The thick ascending limb (TAL) actively transports sodium and chloride ions out of the tubular fluid. The effect of this movement is most noticeable in the renal medulla, where the long ascending limbs of juxtamedullary nephrons create unusually high solute concentrations in the peritubular fluid.

The entire descending limb is freely permeable to water, but not to solutes, such as sodium and chloride ions. The

descending thin limb (DTL) has functions similar to those of the proximal convoluted tubule: It reabsorbs sodium and chloride ions out of the tubular fluid. Because of the ion concentration gradients created by the thick ascending limb, water moves out of the descending limb, helping to increase the solute concentration of the tubular fluid. This process, which allows the production of concentrated urine, will be discussed in detail in Section 26-6.

Tips

To remember the names and order of the limbs of the nephron loop, think “descending thin limb turns and sprouts up as the ascending thin limb and grows TAL (thick ascending limb).”

Figure 26–12 Transport Activities at the Proximal Convolved Tubule. Sodium ions may enter a tubular cell from the filtrate by diffusion, cotransport, or countertransport. The sodium ions are then pumped into the peritubular fluid by the sodium–potassium exchange pump. Other reabsorbed solutes may be ejected into the peritubular fluid by separate active transport mechanisms. The absorption of bicarbonate is indirectly associated with the reabsorption of sodium ions and the secretion of hydrogen ions.

Reabsorption and Secretion along the Distal Convolved Tubule

The composition and volume of tubular fluid change dramatically as it flows from the capsular space to the distal convoluted tubule. Only 15–20% of the initial filtrate volume reaches the distal convoluted tubule (DCT). The concentrations of electrolytes and metabolic wastes in the arriving tubular fluid no longer resemble the concentrations in blood plasma. Selective reabsorption or secretion, primarily along the DCT, makes the final adjustments in the solute composition and volume

of the tubular fluid. The DCT is an important site for three vital processes: (1) the active secretion of ions, acids, drugs, and toxins into the tubule; (2) the selective reabsorption of sodium ions and calcium ions from tubular fluid; and (3) the selective reabsorption of water, which assists in concentrating the tubular fluid.

Reabsorption at the Distal Convolved Tubule

Throughout most of the distal convoluted tubule, the tubular cells actively transport sodium ions (Na⁺) and chloride ions (Cl⁻)

Figure 26–13 Tubular Secretion and Solute Reabsorption by the Distal Convolved Tubule (DCT).

Aldosterone-sensitive portions of the distal convoluted tubule and collecting duct allow for the exchange of which ions?

out of the tubular fluid (**Figure 26–13a**). Tubular cells along the distal regions of the distal convoluted tubule (DCT) also contain ion pumps that reabsorb tubular sodium ions in exchange for another cation (usually potassium ions [K^+]) (**Figure 26–13b**). The hormone *aldosterone*, produced by the adrenal cortex, controls the sodium ion channels and the ion pump. This hormone

stimulates the synthesis and incorporation of sodium ion channels and sodium ion pumps in plasma membranes along the DCT and collecting duct. The net result is a reduction in the number of sodium ions lost in urine.

However, Na^+ conservation is associated with K^+ loss. Prolonged aldosterone stimulation can therefore produce

c Hydrogen ion secretion and urine acidification occur by two routes. The central theme is the exchange of hydrogen ions in the cytosol for sodium ions in the tubular fluid, and the reabsorption of the bicarbonate ions generated in the process.

hypokalemia, a dangerous reduction in the plasma potassium ion concentration. The secretion of aldosterone and its actions on the DCT and collecting system are opposed by the natriuretic peptide ANP.

The DCT is also the primary site of calcium ion (Ca^{2+}) reabsorption. The circulating level of parathyroid hormone (PTH) regulates this process.

Secretion at the Distal Convoluted Tubule

The blood entering the peritubular capillaries still contains several potentially undesirable substances that did not cross the filtration membrane at the glomerulus. In most cases, the

concentrations of these substances are too low to cause physiological problems. However, any ions or compounds in peritubular capillaries will diffuse into the peritubular fluid. If those concentrations become too high, the tubular cells may absorb these substances from the peritubular fluid and secrete them into the tubular fluid.

The rate of potassium and hydrogen ion secretion increases or decreases in direct response to changes in their concentrations in peritubular fluid. The higher their concentrations in the peritubular fluid, the higher the rate of secretion. Potassium and hydrogen ions merit special attention because their concentrations in body fluids must be maintained within narrow limits.

Potassium Ion Secretion. Figure 26-13a,b diagrams the mechanism of potassium ion (K^+) secretion. In effect, tubular cells trade sodium ions (Na^+) in the tubular fluid for excess potassium ions in body fluids. Potassium ions are removed from the peritubular fluid in exchange for sodium ions from the tubular fluid. These potassium ions diffuse into the lumen of the DCT through potassium ion leak channels in the apical surfaces of the tubular cells.

Hydrogen Ion Secretion. Hydrogen ion (H^+) secretion is also associated with the reabsorption of sodium ions (Na^+). Figure 26-13c shows two routes of secretion. Both involve the generation of carbonic acid (H_2CO_3) catalyzed by the enzyme *carbonic anhydrase*. Hydrogen ions generated by the dissociation of the carbonic acid are secreted by sodium ion-linked countertransport in exchange for sodium ions in the tubular fluid. The bicarbonate ions (HCO_3^-) diffuse into the peritubular fluid and then into the bloodstream, where they help prevent changes in plasma pH.

Hydrogen ion secretion acidifies the tubular fluid while increasing the pH of the blood.

Hydrogen ion secretion speeds up when the pH of the blood decreases. This can happen in metabolic acidosis (referred to as *lactic acidosis*), which can develop after exhaustive muscle activity, or *ketoacidosis*, which can develop in starvation or diabetes mellitus. The combination of hydrogen ion removal and bicarbonate ion production by the kidneys plays an important role in the control of blood pH. Because one of the secretory pathways is aldosterone sensitive, aldosterone stimulates hydrogen ion secretion. Prolonged aldosterone stimulation can cause *alkalosis*, or abnormally high blood pH.

Recall that the production of lactate and ketone bodies during the postabsorptive state is associated with or could cause acidosis, respectively. Under these conditions, the PCT

+ Clinical Note Diuretics

Diuresis (dī-yū-RE-sis; *dia*, through + *ouresis*, urination) is the elimination of urine. *Urination* is an equivalent term in a general sense, but *diuresis* typically indicates the production of a large volume of urine. **Diuretics** (dī-yū-RET-iks) are drugs that increase water loss through increased urination. The usual goal in diuretic therapy is to decrease blood volume, blood pressure, extracellular fluid volume, or all three. Controlling renal water losses with relatively safe and effective diuretics has saved the lives of many people, especially those with high blood pressure or congestive heart failure.

Diuretics are classified according to their mechanism of action or major site of action. However, all such drugs affect transport activities or water reabsorption along the nephron and collecting system. For example, consider the class of diuretics called *thiazides* (THĭ-uh-zĭdz). These drugs increase water loss by decreasing sodium and chloride ion transport in the proximal and distal convoluted tubules.

Diuretic use for nonclinical reasons also occurs. For example, some bodybuilders take large doses of diuretics to improve muscle definition temporarily. Some fashion models or horse jockeys do the same. Their goal is to reduce body weight for brief periods. This practice of “cosmetic dehydration” is extremely dangerous. It has caused several deaths due to electrolyte imbalance and consequent cardiac arrest.

and DCT deaminate amino acids in reactions that strip off the amino groups ($-\text{NH}_2$). The reaction sequence ties up hydrogen ions (H^+) and yields both **ammonium ions** (NH_4^+) and bicarbonate ions (HCO_3^-). As indicated in **Figure 26–13c**, the ammonium ions are then pumped into the tubular fluid by sodium ion–linked countertransport, and the bicarbonate ions enter the bloodstream by way of the peritubular fluid.

Tubular deamination thus has two major benefits. It provides carbon chains suitable for catabolism. It also generates bicarbonate ions that add to the buffering capacity of plasma.

Reabsorption and Secretion along the Collecting System

The collecting ducts receive tubular fluid from many nephrons and carry it toward the renal sinus. The normal amount of water and solute loss in the collecting system is hormonally regulated by aldosterone and antidiuretic hormone.

- Aldosterone controls sodium ion pumps along most of the DCT and the proximal portion of the collecting system. As previously noted, these actions are opposed by atrial natriuretic peptide (ANP).
- Antidiuretic hormone (ADH) controls the permeability of the DCT and collecting system to water. The secretion of ADH is suppressed by ANP, and this—combined with the

effects of atrial natriuretic peptide on aldosterone secretion and action—can dramatically increase urinary water losses.

The collecting system also has other reabsorption and secretory functions. Many of them are important to the control of body fluid pH. For example, Type A intercalated cells secrete hydrogen ions and reabsorb bicarbonate ions, while Type B intercalated cells secrete bicarbonate ions and reabsorb hydrogen ions. Principal cells reabsorb water and secrete potassium ions.

Reabsorption at the Collecting System

The collecting system reabsorbs sodium ions, bicarbonate ions, and urea as follows:

- **Sodium Ion Reabsorption.** The collecting system contains aldosterone-sensitive ion pumps that exchange sodium ions (Na^+) in tubular fluid for potassium ions (K^+) in peritubular fluid (**Figure 26–13b**).
- **Bicarbonate Ion Reabsorption.** Bicarbonate ions (HCO_3^-) are reabsorbed in exchange for chloride ions (Cl^-) in the peritubular fluid (**Figure 26–13c**).
- **Urea Reabsorption.** The concentration of urea in the tubular fluid entering the collecting duct is relatively high. The fluid entering the papillary duct generally has the same osmotic concentration as that of interstitial fluid of the renal medulla—about 1200 mOsm/L—but contains a much higher concentration of urea. As a result, urea tends to diffuse out of the tubular fluid and into the peritubular fluid in the deepest portion of the medulla.

Secretion at the Collecting System

The collecting system is important in controlling the pH of body fluids through the secretion of hydrogen or bicarbonate ions. If the pH of the peritubular fluid decreases, carrier proteins pump hydrogen ions into the tubular fluid and reabsorb bicarbonate ions that help restore normal pH. If the pH of the peritubular fluid rises (a much less common event), the collecting system secretes bicarbonate ions and pumps hydrogen ions into the peritubular fluid. The net result is that the body eliminates a buffer and gains hydrogen ions that lower the pH.

Checkpoint

11. What occurs when the plasma concentration of a substance exceeds its tubular maximum?
12. What effect would an increased amount of aldosterone have on the potassium ion concentration in urine?
13. What effect would a decrease in the sodium ion concentration in the filtrate have on the pH of tubular fluid?
14. Why does a decrease in the amount of sodium ions in the distal convoluted tubule lead to an increase in blood pressure?

See the blue Answers tab at the back of the book.

26-6 Countercurrent multiplication allows the kidneys to regulate the volume and concentration of urine

Learning Outcome Explain the role of countercurrent multiplication, describe hormonal influence on the volume and concentration of urine, and describe the characteristics of a normal urine sample.

The kidneys couple two countercurrent mechanisms to establish the conditions necessary to regulate the volume and concentration of urine. *Countercurrent* refers to the fact that the exchange takes place between fluids moving in opposite directions in two adjacent segments of the same tube. These two mechanisms are a *countercurrent multiplier* (filtrate flow in the nephron loop) and a *countercurrent exchanger* (blood flow in the vasa recta). These mechanisms establish and maintain an increasing osmotic gradient from the renal cortex through the medulla.

The Nephron Loop and Countercurrent Multiplication

The descending thin limb and the thick ascending limb of the nephron loop lie very close together. They are separated only by the peritubular fluid, which surrounds all the nephrons. The exchange of substances between these segments of a nephron is called **countercurrent multiplication**. Tubular fluid in the descending limb flows toward the renal pelvis, while tubular fluid in the ascending limb flows toward the cortex. *Multiplication* refers to the fact that the effect of the exchange increases as movement of the fluid continues.

Countercurrent multiplication performs two functions:

- It efficiently reabsorbs solutes and water before the tubular fluid reaches the DCT and collecting system.
- It establishes a concentration gradient in the peritubular fluid (called the *medullary osmotic gradient*) that permits the passive reabsorption of water from the tubular fluid in the collecting system. This allows the production of concentrated urine. The circulating level of antidiuretic hormone (ADH) regulates water reabsorption.

How does this occur? As we have indicated, the two parallel limbs of the nephron loop have very different permeability characteristics. The descending thin limb is permeable to water but relatively impermeable to solutes. The thick ascending limb is relatively impermeable to both water and solutes, but it contains active transport mechanisms that pump sodium and chloride ions from the tubular fluid into the peritubular fluid of the medulla.

Figure 26-14 shows an overview of countercurrent multiplication:

- Sodium ions (Na^+) and chloride ions (Cl^-) are pumped out of the thick ascending limb and into the peritubular fluid. This dilutes the tubular fluid.

- The pumping action increases the osmotic concentration in the peritubular fluid around the descending thin limb.
- This creates a small concentration difference between the tubular fluid and peritubular fluid in the renal medulla.
- The concentration difference results in an osmotic flow of water out of the descending thin limb and into the peritubular fluid. As a result, the solute concentration of the tubular fluid in the descending thin limb increases.
- The arrival of the highly concentrated tubular fluid in the thick ascending limb speeds up the transport of sodium and chloride ions into the peritubular fluid.

Solute pumping out of the tubular fluid in the thick ascending limb leads to higher solute concentrations in the tubular fluid in the descending thin limb, which then brings about increased solute pumping in the thick ascending limb. Notice that this process is a simple positive feedback loop that *multiplies* the concentration difference between the hypotonic tubular fluid in the thick ascending limb and the hypertonic peritubular fluid in the renal medulla.

Creation of the Medullary Osmotic Gradient

The concentration gradient created in the peritubular fluid of the medulla is called the **medullary osmotic gradient**. This section describes how the medullary osmotic gradient is produced. **Figure 26-14a** diagrams ion transport across the epithelium of the thick ascending limb (TAL). Active transport at the apical surface moves sodium, potassium, and chloride ions out of the tubular fluid. The carrier is called a $\text{Na}^+ - \text{K}^+ / 2 \text{Cl}^-$ **transporter** because each cycle of the pump carries a sodium ion, a potassium ion, and two chloride ions into the tubular cell. Then cotransport carriers pump potassium and chloride ions into the peritubular fluid. However, potassium ions are removed from the peritubular fluid as the sodium–potassium exchange pump moves sodium ions out of the tubular cell. The potassium ions then diffuse back into the lumen of the tubule through potassium ion leak channels. The net result is that sodium and chloride ions enter the peritubular fluid of the renal medulla.

The removal of sodium and chloride ions from the tubular fluid in the ascending limb raises the osmotic concentration of the peritubular fluid around the descending thin limb (**Figure 26-14b**). Recall that the descending thin limb is permeable to water but not to solutes. As tubular fluid travels deeper into the medulla within the descending thin limb, osmosis moves water into the peritubular fluid. Solutes remain behind. As a result, the tubular fluid at the turn of the nephron loop has a higher osmotic concentration than it did at the start.

The pumping mechanism of the TAL is highly effective. Almost two-thirds of the sodium and chloride ions that enter it are pumped out of the tubular fluid before that fluid reaches the DCT. In other tissues, differences in solute concentration are quickly resolved by osmosis. However, osmosis cannot take place

Figure 26–14 Countercurrent Multiplication and Urine Concentration.

across the wall of the thick ascending limb, because the epithelium there is impermeable to water. So, as sodium and chloride ions are removed, the solute concentration in the tubular fluid decreases. Tubular fluid arrives at the DCT with an osmotic concentration of only about 100 mOsm/L. This value is one-third the concentration of the peritubular fluid of the renal cortex.

The rate of ion transport across the thick ascending limb is proportional to an ion's concentration in the tubular fluid. As a result, more sodium and chloride ions are pumped into the medulla at the start of the thick ascending limb, where their ion concentrations are highest, than near the cortex. This regional difference in the rate of ion transport is the basis of the medullary osmotic gradient.

The Role of Urea

Normally, the maximum solute concentration of the peritubular fluid near the turn of the nephron loop is about 1200 mOsm/L. Sodium and chloride ions pumped out of the loop's thick ascending limb make up about two-thirds of that gradient (750 mOsm/L). The rest of the medullary osmotic gradient results from the presence of urea.

To understand how urea arrives in the medulla, let's look ahead to events in the last segments of the collecting system (**Figure 26-14c**). The thick ascending limb of the nephron loop, the DCT, and the collecting ducts are all impermeable to urea. As water is reabsorbed, the concentration of urea gradually increases in the tubular fluid. When the tubular fluid reaches the papillary duct, it typically contains urea at a concentration of about 450 mOsm/L. The papillary ducts are permeable to urea, so the urea concentration in the deepest parts of the medulla also averages 450 mOsm/L.

Summary of Countercurrent Multiplication

In summary, countercurrent multiplication is a way to either concentrate or dilute urine. The tubular fluid entering the descending limb of the nephron loop has an osmotic concentration of approximately 300 mOsm/L, due primarily to the presence of ions such as sodium and chloride. The concentration of organic wastes, such as urea, is low. About half of the tubular fluid entering the nephron loop is then reabsorbed along the descending thin limb. Two-thirds of the sodium and chloride ions are reabsorbed along the thick ascending limb. As a result, the DCT receives a reduced volume of tubular fluid with an osmotic concentration of about 100 mOsm/L. Urea and other organic wastes, which were not pumped out of the thick ascending limb, now represent a significant proportion of the dissolved solutes.

Regulation of Urine Volume and Osmotic Concentration: Production of Dilute and Concentrated Urine

Urine volume and osmotic concentration are regulated through the control of water reabsorption. Water is reabsorbed

by osmosis along the proximal convoluted tubule and the descending limb of the nephron loop. The water permeabilities of these regions cannot be adjusted. As a result, water reabsorption takes place wherever the osmotic concentration of the peritubular fluid is greater than that of the tubular fluid. The ascending limb of the nephron loop is impermeable to water. In the distal convoluted tubule and collecting system, 1–2% of the volume of water in the original filtrate is recovered during sodium ion reabsorption. All these water movements represent *obligatory water reabsorption* because they cannot be prevented. This reabsorption usually recovers 85% of the volume of filtrate.

The volume of water lost in urine depends on how much of the water remaining in the tubular fluid is reabsorbed along the DCT and collecting system. (This remaining water represents 15% of the filtrate volume, or approximately 27 liters per day.) The amount reabsorbed can be precisely controlled by a process called *facultative water reabsorption*. Precise control is possible because these segments are relatively impermeable to water except when ADH is present. This hormone causes special *water channels*, or *aquaporins*, to be inserted into the apical plasma membranes. These water channels dramatically enhance the rate of osmotic water movement. The higher the circulating level of ADH, the greater the number of water channels, and the greater the water permeability of these segments.

As noted earlier in this chapter, the tubular fluid arriving at the DCT has an osmotic concentration of only about 100 mOsm/L. In the presence of ADH, osmosis takes place. Water moves out of the DCT until the osmotic concentration of the tubular fluid equals that of the surrounding cortex (approximately 300 mOsm/L).

The tubular fluid then flows along the collecting duct, which passes through the concentration gradient of the medulla. Additional water is then reabsorbed. The urine reaching the minor calyx has an osmotic concentration closer to 1200 mOsm/L. How closely the osmotic concentration approaches 1200 mOsm/L depends on how much ADH is present.

Figure 26-15 diagrams the effects of ADH on the DCT and collecting system. Without ADH (**Figure 26-15a**), water is not reabsorbed in these segments, so all the fluid reaching the DCT is lost in the urine. The person then produces large amounts of very dilute urine. That is just what happens in cases of *diabetes insipidus*. With this condition, urinary water losses may reach 24 liters (6.3 gal) per day and the urine osmotic concentration range is 30–400 mOsm/L.

As the ADH level rises (**Figure 26-15b**), the DCT and collecting system become more permeable to water. As a result, the amount of water reabsorbed increases. At the same time, the osmotic concentration of the urine climbs. Under maximum ADH stimulation, the DCT and collecting system become so permeable to water that the osmotic concentration of the urine equals that of the deepest portion of the medulla.

Figure 26–15 The Effects of Antidiuretic Hormone (ADH) on the Distal Convolved Tubule (DCT) and Collecting Duct.

ADH creates a (small or large) volume of (dilute or concentrated) urine.

Note that the concentration of urine can never *exceed* that of the medulla, because the concentrating mechanism relies on osmosis.

The hypothalamus continuously secretes ADH at a low level. For this reason, the DCT and collecting system always have a significant degree of water permeability. At this low ADH level, the DCT reabsorbs approximately 9 liters of water per day, or about 5% of the original volume of filtrate produced by the glomeruli. At a normal ADH level, the collecting system reabsorbs about 16.8 liters per day, or about 9.3% of the original volume of filtrate. A healthy adult typically produces 1200 mL of urine per day (about 0.6% of the filtrate volume). Its osmotic concentration range is 855–1335 mOsm/L.

The effects of ADH are opposed by those of atrial natriuretic peptide (ANP). This hormone stimulates the production of a large volume of relatively dilute urine. This water loss reduces plasma volume to normal.

The Function of the Vasa Recta: Countercurrent Exchange

The solutes and water reabsorbed in the renal medulla must be returned to the bloodstream without disrupting the medullary osmotic gradient. This return is the function of the vasa recta, in a process called **countercurrent exchange**.

Recall that the vasa recta are long, straight capillaries that parallel the long nephron loops of juxtamedullary nephrons. Blood entering the vasa recta from the peritubular capillaries has an osmotic concentration of approximately 300 mOsm/L. As the blood descends into the medulla, it gradually increases in osmotic concentration as the solute concentration in the peritubular fluid increases. This increase in blood osmotic concentration involves both solute absorption and water loss. Solute absorption predominates, however, because the plasma proteins limit the osmotic flow of water out of the blood.

Blood ascending toward the cortex gradually decreases in osmotic concentration as the solute concentration of the peritubular fluid decreases. Again, this decrease involves both solute diffusion and osmosis. In this case osmosis predominates, because the presence of plasma proteins does not oppose the osmotic flow of water into the blood.

The net results are that (1) some of the solutes absorbed in the descending segment of the vasa recta do not diffuse out in the ascending segment and (2) more water moves into the ascending portion of the vasa recta than moves out in the descending segment. Thus, the vasa recta transport both water and solutes out of the medulla. Under normal conditions, the removal of solutes and water by the vasa recta precisely balances the rates of solute reabsorption and osmosis in the medulla.

Table 26–5 General Characteristics of Normal Urine

Characteristic	Normal Range
pH	4.5–8 (average: 6.0)
Specific gravity	1.003–1.030
Osmotic concentration (osmolality)	855–1335 mOsm/L
Water content	93–97%
Volume	700–2000 mL/day
Color	Pale yellow
Clarity	Clear
Odor	Varies with composition
Bacterial content	None (sterile)

Spotlight Figure 26–16 provides a summary of kidney function showing the major steps in the reabsorption of water and the production of concentrated urine. Please revisit **Table 26–4** for a detailed summary of the functions of the various renal structures.

Urine Composition and Analysis

Urine is the fluid and dissolved substances excreted by the kidney. The analysis of that urine by physical, chemical, and microscopic means is called *urinalysis*. This section considers urine analysis.

The Composition of Normal Urine

The general characteristics of normal urine are listed in **Table 26–5**. However, the composition of the urine produced each day varies with the metabolic and hormonal events under way.

The composition and concentration of urine are two related but distinct properties. The *composition* of urine reflects the filtration, reabsorption, and secretion activities of the nephrons. Some substances (such as urea) are neither actively excreted nor reabsorbed along the nephron. In contrast, organic nutrients are completely reabsorbed. Other substances, such as creatinine, are missed by filtration but are actively secreted into the tubular fluid.

Filtration, reabsorption, and secretion determine the kinds and amounts of substances excreted in urine. The *concentration* of these substances in any urine sample depends on the osmotic movement of water across the walls of the tubules and collecting ducts. Because the composition and concentration of urine vary independently, a person can produce a small volume of concentrated urine or a large volume of dilute urine and still excrete the same quantity of dissolved substances. For this reason, healthcare professionals who are interested in a detailed assessment of renal function commonly analyze the urine produced over a 24-hour period rather than a single urine sample.

1 The **renal corpuscle** produces filtrate that has the same osmotic concentration as plasma – about 300mOsm/L. It has the same composition as blood plasma but does not contain plasma proteins.

2 The active removal of ions and organic nutrients from the **proximal convoluted tubule** results in a continuous osmotic flow of water out of the tubular fluid. This decreases filtrate volume but keeps solutions inside and outside the tubule isotonic. About 60-70% of the filtrate volume is absorbed here.

3 In the thin **descending limb** of the nephron loop, water moves into the peritubular fluid. This reabsorption of water results in a small volume of highly concentrated tubular fluid.

KEY

= Water reabsorption

= Variable water reabsorption

= Na^+/Cl^- transport

= Aldosterone-regulated pump

= Urea transporter

300

= Fluid osmotic concentration (mOsm/L)

= Impermeable to solutes

= Impermeable to water

= Variable permeability to water

= Solutes

= Direction of blood flow

= Filtrate movement

4

The thick **ascending limb** is impermeable to water and solutes. Tubule cells actively transport Na^+ and Cl^- out of the tubule, thereby decreasing the solute concentration of the tubular fluid. Because only Na^+ and Cl^- are removed, urea makes up a greater proportion of the total solute concentration at the end of the nephron loop.

5

The **distal convoluted tubule** and collecting system further adjust the tubular fluid composition. The solute concentration of the tubular fluid is adjusted through active transport (reabsorption or secretion).

6

Final adjustments in tubular fluid volume and solute concentration are made by controlling the water permeability of the **collecting system**. ADH levels determine the final urine volume and concentration.

7

Vasa recta absorb water and solutes from the medullary nephrons and transport them into the bloodstream. This maintains the concentration gradient in the renal medulla.

8

The **papillary duct** is permeable to urea, so urea concentration is about 450 mOsm/L. This is the same value found in the deepest parts of the medulla.

Kidney Function Tests

Diagnostic tests used to evaluate kidney function include urinalysis, creatinine clearance, and blood urea nitrogen (BUN). Urinalysis is used to detect the presence of microorganisms, disease, drugs, or other substances. A creatinine clearance test helps determine how well the kidneys are functioning by estimating the glomerular filtration rate (GFR). The blood urea nitrogen (BUN) test also measures renal function.

Urinalysis. **Urinalysis** is the chemical and physical analysis of a urine sample. It is an important diagnostic tool, even in today's high-technology medicine. A standard urinalysis includes

an assessment of the color and appearance of urine. These two characteristics can be determined qualitatively without specialized equipment, but quantitative analytical tests are also used.

Normal urine is a clear, sterile liquid. Its yellow color comes from the pigment urobilin. The kidneys generate this pigment from the urobilinogens produced by intestinal bacteria and absorbed in the colon (look back at **Figure 19-5**). The characteristic odor of urine is due to the evaporation of small molecules, such as ammonia. Other substances not normally present, such as acetone or other ketone bodies, can also impart a distinctive smell. **Table 26-6** gives some typical values obtained from urinalysis.

Table 26-6 Typical Values Obtained from Standard Urinalysis

Compound	Primary Source	Daily Elimination*	Concentration	Remarks
NITROGENOUS WASTES				
Urea	Deamination of amino acids by liver and kidneys	21 g	1800 mg/dL	Increases if negative nitrogen balance exists
Creatinine	Breakdown of creatine phosphate in skeletal muscle	1.8 g	150 mg/dL	Proportional to muscle mass; decreases during atrophy or muscle disease
Ammonia	Deamination by liver and kidney, absorption from intestinal tract	0.68 g	60 mg/dL	
Uric acid	Breakdown of purines	0.53 g	40 mg/dL	Increases in gout, liver diseases
Hippuric acid	Breakdown of dietary toxins	4.2 mg	350 µg/dL	
Urobilin	Urobilinogens absorbed at colon	1.5 mg	125 µg/dL	Gives urine its yellow color
Bilirubin	Hemoglobin breakdown product	0.3 mg	20 µg/dL	Increase may indicate problem with liver elimination or excess production; causes yellowing of skin and mucous membranes in jaundice
NUTRIENTS AND METABOLITES				
Carbohydrates		0.11 g	9 µg/dL	Primarily glucose; glycosuria develops if T_m is exceeded
Ketone bodies		0.21 g	17 µg/dL	Ketonuria may occur during postabsorptive state
Lipids		0.02 g	0.002 mg/dL	May increase in some kidney diseases
Amino acids		2.25 g	188 µg/dL	Note relatively high loss compared with other metabolites due to low T_m ; excess (aminoaciduria) indicates T_m problem
IONS				
Sodium		4.0 g	40–220 mEq/L	Varies with diet, urine pH, hormones, etc.
Potassium		2.0 g	25–100 mEq/L	Varies with diet, urine pH, hormones, etc.
Chloride		6.4 g	110–250 mEq/L	
Calcium		0.2 g	17 mg/dL	Hormonally regulated (PTH/CT)
Magnesium		0.15 g	13 mg/dL	
BLOOD CELLS**				
RBCs		130,000/day	100/mL	Excess (hematuria) indicates vascular damage in urinary system
WBCs		650,000/day	500/mL	Excess (pyuria) indicates renal infection or inflammation

*Representative values for a 70-kg (154-lb) male.

**Usually estimated by counting the cells in a sample of sediment after urine centrifugation.

Creatinine Clearance. Creatinine clearance compares the creatinine level in urine with the creatinine level in blood by estimating the GFR. It is used as an index of overall kidney function. For example, a GFR around 100 means the kidneys are working at 100%. Creatinine results from the breakdown of creatine phosphate in muscle tissue and is normally eliminated in urine. Creatinine enters the filtrate at the glomerulus and is not reabsorbed in significant amounts.

Consider, for example, a person who eliminates 84 mg of creatinine each hour and has a plasma creatinine concentration of 1.4 mg/dL. The GFR is equal to the amount secreted divided by the plasma concentration, so this person's GFR is

$$\frac{84 \text{ mg/h}}{1.4 \text{ mg/dL}} = 60 \text{ dL/h} = 100 \text{ mL/min}$$

The GFR is usually reported in milliliters per minute.

The value 100 mL/min is only an approximation of the GFR. The reason is that up to 15% of creatinine in the urine enters by means of active tubular secretion. When necessary, a more accurate GFR can be obtained by using the complex carbohydrate *inulin*. This compound is not metabolized in the body and is neither reabsorbed nor secreted by the kidney tubules.

BUN. A **BUN (blood urea nitrogen)** test measures the amount of urea in blood. Urea is created in the liver from the breakdown of proteins. As previously discussed, a critical role of the kidneys is to excrete nitrogenous wastes—urea, uric acid, and creatinine. These wastes are expected to appear in urine, but high levels of nitrogenous wastes should not remain in the blood.

26-7 Urine is transported by the ureters, stored in the bladder, and eliminated through the urethra by urinary reflexes

Learning Outcome Describe the structures and functions of the ureters, urinary bladder, and urethra, discuss the voluntary and involuntary regulation of urination, and describe the urinary reflexes.

Filtrate modification and urine production end when the fluid enters the renal pelvis. The urinary tract (the ureters, urinary bladder, and urethra) transports, stores, and eliminates urine.

Figure 26-17 A Pyelogram. This anterior-posterior view of urinary system structures is color enhanced.

A **pyelogram** (PĪ-el-ō-gram) is an image of the urinary system (Figure 26-17). It is obtained by taking an x-ray of the kidneys after a radiopaque dye has been administered intravenously. Such an image provides an orientation to the relative sizes and positions of the main structures. Note that the sizes of the minor and major calyces, the renal pelvis, the ureters, the urinary bladder, and the proximal portion of the urethra are somewhat variable. These regions are lined by a *transitional epithelium* that can tolerate cycles of distension and relaxation without damage.

The Ureters

The ureters are a pair of muscular tubes about 20–30 cm (8–12 in.) long that extend between the kidneys and the urinary bladder. Each ureter begins at the funnel-shaped renal pelvis (Figure 26-4). The ureters extend inferiorly and medially, passing over the anterior surfaces of the *psoas major*

(Figure 26-3). The ureters are retroperitoneal and are firmly attached to the posterior abdominal wall. The paths taken by the ureters in males and females are different, due to variations in the nature, size, and position of the reproductive organs. In males, the base of the urinary bladder lies between the rectum and the pubic symphysis (Figure 26-18a). In females, the base of the urinary bladder sits inferior to the uterus and anterior to the vagina (Figure 26-18b).

The ureters penetrate the posterior wall of the urinary bladder without entering the peritoneal cavity. They pass through the bladder wall at an oblique angle. The **ureteric orifices** are slit-like rather than rounded (Figure 26-18c). This shape helps prevent the backflow of urine toward the ureter and kidneys when the urinary bladder contracts.

The wall of each ureter consists of three layers (Figure 26-19a): (1) an inner mucosa, made up of a transitional epithelium and the surrounding lamina propria, (2) a middle muscular layer made up of longitudinal and circular bands of smooth muscle, and (3) an outer connective tissue layer that is continuous with the fibrous capsule and peritoneum. About every 30 seconds, a peristaltic contraction begins at the renal pelvis. As it sweeps along the ureter, it forces urine toward the urinary bladder.

The Urinary Bladder

The urinary bladder is a hollow, muscular organ that serves as temporary storage for urine (Figure 26-18c). The dimensions of the urinary bladder vary with its state of distension. A full urinary bladder can contain as much as a liter of urine.

A layer of peritoneum covers the superior surfaces of the urinary bladder. Several peritoneal folds assist in stabilizing its position. The **median umbilical ligament** extends from the anterior, superior border toward the umbilicus (navel). The **lateral umbilical ligaments** pass along the sides of the bladder to the umbilicus. These fibrous cords are the vestiges of the two *umbilical arteries*, which supplied blood to the placenta during embryonic and fetal development. The urinary bladder's posterior, inferior, and anterior surfaces lie outside the peritoneal cavity. In these areas, tough ligamentous bands anchor the urinary bladder to the pelvic and pubic bones.

In sectional view, the mucosa lining the urinary bladder usually has folds called **rugae** that disappear as the bladder fills. The triangular smooth area bounded by the openings of the ureters and the entrance to the urethra makes up a region called the **trigone** (TRĭ-gōn) of the urinary bladder. There, the mucosa is smooth and very thick. The trigone acts as a funnel that channels urine into the urethra when the urinary bladder contracts.

The urethral entrance lies at the apex of the trigone, at the most inferior point in the urinary bladder. The region

Figure 26-18 Organs for Conducting and Storing Urine.

The (ureter or urethra) transports urine to the bladder.

Figure 26–19 The Histology of the Ureter, Urinary Bladder, and Urethra.

surrounding the urethral opening is known as the **neck** of the urinary bladder. It contains a muscular **internal urethral sphincter**. The smooth muscle fibers of this sphincter provide involuntary control over the discharge of urine from the bladder. The urinary bladder is innervated by postganglionic fibers from ganglia in the hypogastric plexus and by parasympathetic fibers from intramural ganglia that are controlled by branches of the pelvic nerves.

The wall of the urinary bladder contains mucosa, submucosa, and muscular layers (**Figure 26–19b**). The muscular layer consists of internal and external layers of longitudinal smooth muscle, with a circular layer between the two. Together, these layers form the powerful **detrusor** (de-TRŪ-sor), a muscle of the urinary bladder. When the

detrusor contracts, it compresses the urinary bladder and expels urine into the urethra.

The Urethra

The urethra extends from the neck of the urinary bladder and transports urine to the exterior of the body. The male urethra and the female urethra differ in length and in function. In males, the urethra extends from the neck of the urinary bladder to the tip of the penis (**Figure 26–18a,c**). This distance may be 18–20 cm (7–8 in.). The male urethra is subdivided into three segments: the prostatic urethra, the membranous urethra, and the spongy urethra. The **prostatic urethra** (*intermediate part of urethra*) passes through the center

of the prostate. The **membranous urethra** includes the short segment that penetrates the deep transverse perineal muscle of the pelvic floor. The **spongy urethra** extends from the distal border of the deep transverse perineal muscle to the external opening, or **external urethral orifice**, at the tip of the penis. In females, the urethra is very short. It extends 3–5 cm (1–2 in.) from the bladder to the vestibule (**Figure 26–18b**). The external urethral orifice is near the anterior wall of the vagina.

A skeletal muscular band, called the **external urethral sphincter**, acts as a valve. The external urethral sphincter is under voluntary control through the perineal branch of the pudendal nerve. This sphincter has a resting muscle tone and must be voluntarily relaxed to permit urination.

The urethral lining consists of a stratified epithelium that varies from transitional epithelium at the neck of the urinary bladder, to stratified columnar epithelium at the midpoint, to stratified squamous epithelium near the external urethral orifice. The lamina propria is thick and elastic. The mucosa is folded into longitudinal creases (**Figure 26–19c**). Mucus-secreting cells are found in the epithelial pockets. In males, the epithelial mucous glands may form tubules that extend into the lamina

propria. Connective tissues of the lamina propria anchor the urethra to surrounding structures. In females, the lamina propria contains an extensive network of veins. Concentric layers of smooth muscle surround the entire complex.

Urinary Reflexes: Urine Storage and Urine Voiding

Recall that urine reaches the urinary bladder by peristaltic contractions of the ureters. The urge to urinate generally appears when the urinary bladder contains about 200 mL of urine. Whether or not a person urinates depends on an interplay between spinal reflexes and higher centers in the brain that provide conscious control over urination. Two spinal reflexes control urination (micturition): the urine storage reflex and the urine voiding reflex. These must be considered together, because urine storage and release involve simultaneous, coordinated activities (**Figure 26–20**).

- **Urine Storage Reflex.** Urine storage occurs by spinal reflexes and the *pontine storage center*. When urine is being stored, afferent impulses from stretch receptors in the urinary

Figure 26–20 The Control of Urination.

bladder stimulate sympathetic outflow to the detrusor and internal urethral sphincter, inhibiting contraction of the detrusor and stimulating contraction of the internal urethral sphincter. The pontine storage center inhibits urination by decreasing parasympathetic activity and increasing somatic motor nerve activity at the external urethral sphincter. Urine storage (continence) occurs as urine is unable to pass through the urethra (**Figure 26–20a**).

- **Urine Voiding Reflex.** Urine voiding occurs by spinal reflexes and the *pontine micturition center*. The voiding reflex begins when afferent impulses from stretch receptors in the bladder stimulate interneurons that relay sensations to the pontine micturition center. This center initiates sacral spinal reflexes that (1) stimulate increased parasympathetic activity (detrusor contracts and internal urethral sphincter relaxes), (2) decrease sympathetic activity (detrusor contracts and internal urethral sphincter relaxes), and (3) decrease efferent somatic motor nerve activity (external urethral sphincter relaxes). Voiding (urination) occurs as urine passes through the urethra (**Figure 26–20b**).

At the end of urination, less than 10 mL of urine remains in the urinary bladder.

Infants lack voluntary control over urination because the necessary corticospinal connections have yet to be established.

Clinical Note Urinary Obstruction

Local blockages of the collecting ducts or ureters can result from casts—small blood clots, epithelial cells, lipids, or other materials—that form in the collecting ducts. Casts are commonly eliminated in urine. They are visible in microscopic analyses of urine samples. Renal calculi (KAL-kū-lī), or *kidney stones*, form within the urinary tract from calcium deposits, magnesium salts, or crystals of uric acid. The condition is called *nephrolithiasis* (nef-rō-lih-THĭ-uh-sis; *nephros*, kidney; *lithos*, stone). The blockage of the ureter by a stone or by other means (such as external compression) creates urinary obstruction. This problem is an emergency. In addition to causing extreme pain, it decreases or prevents filtration in the affected kidney by increasing the capsular hydrostatic pressure.

Calculi are generally visible on an x-ray. If urinary peristalsis and fluid pressures cannot dislodge them, they must be either surgically removed or destroyed. One nonsurgical procedure involves disintegrating the stones with a *lithotripter*, a device originally developed from machines used to de-ice airplane wings. Lithotripters focus sound waves on the stones, breaking them into smaller fragments that can be passed in the urine. Another nonsurgical approach is the insertion of a catheter with an attached laser that can shatter calculi with intense light beams.

Accordingly, “toilet training” before age 2 often involves training the parent to anticipate the timing of the reflex rather than training the child to exert conscious control.

Incontinence (in-KON-tih-nens) is the inability to control urination voluntarily. Trauma to the internal or external urethral sphincter can contribute to incontinence in otherwise healthy adults. For example, some people develop *stress urinary incontinence* (SUI) if childbirth overstretches and damages the sphincter muscles. In this condition, increased intra-abdominal pressures—caused, for example, by a cough or sneeze—can overwhelm the sphincter muscles, causing urine to leak out. Incontinence can also develop in older people due to a general loss of muscle tone.

Damage to the central nervous system, the spinal cord, or the nerve supply to the urinary bladder or external urethral sphincter can also produce incontinence. For example, incontinence commonly accompanies Alzheimer’s disease or spinal cord damage. In most cases, the affected individual develops an *automatic bladder*. The urinary reflexes remain intact, but voluntary control of the external urethral sphincter is lost, so the person cannot prevent the reflexive emptying of the urinary bladder. Damage to the pelvic nerves of the sacral spinal cord can destroy the urinary reflexes entirely because those nerves carry both afferent and efferent fibers of both reflex arcs. The urinary bladder then becomes greatly distended with urine. It remains filled to capacity while the excess urine flows into the urethra in an uncontrolled stream. The insertion of a catheter is often needed to facilitate the discharge of urine.

Checkpoint

17. **Obstruction of a ureter by a kidney stone would interfere with the flow of urine between which two points?**
18. **The ability to control the urinary reflexes depends on the ability to control which muscle?**

See the blue Answers tab at the back of the book.

26-8 Age-related changes affect kidney function and urination

Learning Outcome Describe the effects of aging on the urinary system.

In general, aging is associated with an increased incidence of kidney problems. One example—*nephrolithiasis*, the formation of calculi, or kidney stones—is described in the Urinary Obstruction Clinical Note. Other age-related changes in the urinary system include the following:

- **A Decrease in the Number of Functional Nephrons.** The total number of kidney nephrons decreases by 30–40% between ages 25 and 85.
- **A Reduction in the GFR.** This reduction results from fewer glomeruli, cumulative damage to the filtration apparatus in the remaining glomeruli and reduced renal blood flow.

Media resource available for this topic: Dissection Video: Sheep Kidney: Internal, Part 2: Detailed Overview

Clinical Note Renal Failure and Kidney Transplant

Renal failure occurs when the kidneys cannot filter wastes from the blood and can no longer maintain homeostasis. When kidney filtration slows for any reason, urine production decreases. As the person makes less and less urine, signs and symptoms of renal failure appear because water, ions, and metabolic wastes are retained. All body systems are affected. Blood pressure increases; anemia develops due to a decrease in erythropoietin production; and central nervous system problems can lead to sleeplessness, seizures, delirium, and even coma.

Acute renal failure occurs when filtration slows suddenly or stops due to renal ischemia, urinary obstruction, trauma, or nephrotoxic drugs. The reduction in kidney function takes place over a few days and may persist for weeks. Sensitized individuals can also develop acute renal failure after an allergic response to antibiotics or anesthetics.

In *chronic renal failure*, kidney function deteriorates gradually and problems accumulate over years. This condition generally cannot be reversed but can only be slowed. Eventually, symptoms of *end-stage renal failure* develop. *Hemodialysis* is a treatment that “cleanses” the blood by substituting for normal kidney functioning. It can relieve the symptoms of renal failure, but it is not a cure.

In terms of overall quality of life, the most satisfactory solution to end-stage renal failure is kidney transplant. This procedure involves implanting a new kidney from a living or deceased donor. The recipient’s nonfunctioning kidney(s) may be removed, especially if an infection is present. The transplanted kidney and ureter are usually placed extraperitoneally in the pelvic cavity (within the iliac fossa). The ureter is connected to the recipient’s urinary bladder. Patient survival is greater than 90% at 2 years after the transplant.

- **A Reduced Sensitivity to ADH.** With age, the distal segments of the nephron and collecting system become less responsive to ADH. Water and sodium ions are reabsorbed at a reduced rate, and more sodium ions are lost in urine.
- **Problems with the Urinary Reflexes.** Three factors are involved in such problems: (1) The external sphincter loses muscle tone and become less effective at voluntarily retaining urine. This leads to incontinence, often involving a slow leakage of urine. (2) The ability to control urination can be lost due to a stroke, Alzheimer’s disease, or other CNS problems affecting the cerebral cortex or hypothalamus. (3) In males, *urinary retention* may develop if the prostate enlarges and compresses the urethra, restricting the flow of urine.

Checkpoint

19. List four age-related changes in the urinary system.
20. Define nephrolithiasis.
21. Describe how incontinence may develop in an older person.

See the blue Answers tab at the back of the book.

26-9 The urinary system is one of several body systems involved in waste excretion

Learning Outcome Give examples of interactions between the urinary system and other organ systems studied so far.

The urinary system excretes wastes produced by other body systems, but it is not the only organ system involved in excretion. Together, the urinary, integumentary, respiratory, and digestive systems are regarded as an anatomically diverse **excretory system** whose components perform all the excretory functions that affect the composition of body fluids:

- **Integumentary System.** Water losses and electrolyte losses in sensible perspiration can affect the volume and composition of the plasma. The effects are most apparent when losses are extreme, such as during peak sweat production. Small amounts of metabolic wastes, including urea, also are eliminated in perspiration.
- **Respiratory System.** The lungs remove the carbon dioxide generated by cells. Small amounts of other compounds, such as acetone and water, evaporate into the alveoli and are eliminated through exhalation.
- **Digestive System.** The liver excretes small amounts of metabolic wastes in bile. A variable amount of water is lost in feces.

These excretory activities have an impact on the composition of body fluids. For example, the removal of carbon dioxide by the respiratory system also affects the pH of blood plasma. Note that the excretory functions of these systems are not regulated as closely as are those of the kidneys. Under normal circumstances, the effects of integumentary and digestive excretory activities are minor compared with those of the urinary system.

Build Your Knowledge **Figure 26-21** summarizes the functional relationships between the urinary system and other systems studied so far. Many of these relationships are explored further in Chapter 27, which describes major aspects of fluid, pH, and electrolyte balance.

Checkpoint

22. Identify the role the urinary system plays for all other body systems.
23. Name the body systems that make up the excretory system.

See the blue Answers tab at the back of the book.

Build Your Knowledge

Figure 26–21 Integration of the URINARY system with the other body systems presented so far.

26 Chapter Review

Study Outline

An Introduction to the Urinary System

1. The urinary system removes most physiological wastes and produces urine.

26-1 The organs of the urinary system function in excreting wastes and regulating body fluids

2. The urinary system includes two **kidneys**, two **ureters**, the **urinary bladder**, and the **urethra**. The kidneys produce **urine**, which is a fluid that contains water, ions, and soluble compounds. During **urination (micturition)**, urine is forced out of the body. (Figure 26-1)
3. The major functions of the **urinary system** are *excretion*, the removal of metabolic waste products from body fluids; *elimination*, the discharge of these waste products into the environment; and *homeostatic regulation* of the volume and solute concentration of blood plasma. Other homeostatic functions include regulating blood volume and pressure by adjusting the volume of water lost and releasing hormones; regulating plasma concentrations of ions; helping to stabilize blood pH; conserving nutrients; assisting the liver in detoxifying poisons; and, during starvation, deaminating amino acids so that they can be catabolized by other tissues.

26-2 Kidneys are highly vascular organs containing functional units called nephrons

4. The left kidney extends superiorly slightly more than the right kidney. Both kidneys and the adrenal gland superior to each kidney are retroperitoneal. (Figures 26-1, 26-2, 26-3)
5. The **hilum**, a medial indentation, provides entry for the **renal artery** and **renal nerves** and exit for the **renal vein** and the ureter. (Figures 26-3, 26-4)
6. The superficial region of the kidney, the **cortex**, surrounds the **medulla**. The ureter communicates with the **renal pelvis**, a chamber that branches into two **major calyces**. Each major calyx is connected to four or five **minor calyces**, which enclose the **renal papillae**. (Figure 26-4)
7. The blood supply to the kidneys includes the **renal, segmental, interlobar, arcuate**, and **cortical radiate arteries**. (Figure 26-5)
8. The **renal nerves**, which innervate the kidneys and ureters, are dominated by sympathetic postganglionic fibers.
9. The **nephron** is the basic functional unit in the kidney. It consists of the **renal corpuscle** and **renal tubule**. The renal tubule is long and narrow and divided into the *proximal convoluted tubule*, the *nephron loop*, and the *distal convoluted tubule*. **Filtrate** is produced at the renal corpuscle. The nephron empties **tubular fluid** into the **collecting system**, consisting of **collecting ducts** and **papillary ducts**. (Figures 26-6, 26-7)

- PhysioEx

10. The **proximal convoluted tubule (PCT)** actively reabsorbs nutrients, plasma proteins, and ions from the filtrate. These substances are released into the **peritubular fluid**, which surrounds the nephron. (Figure 26-6)
11. The **nephron loop**, also called the **loop of Henle**, includes a **descending limb** and an **ascending limb**. The *descending thin limb (DTL)* and the *ascending thin limb (ATL)* contain simple squamous epithelium, and the *thick ascending limb (TAL)* contains cuboidal epithelium. The ascending limb delivers fluid to the **distal convoluted tubule (DCT)**, which actively secretes ions, toxins, and drugs, and reabsorbs sodium ions from the tubular fluid. (Figures 26-6, 26-8)
12. The renal tubule begins at the renal corpuscle, which includes a knot of intertwined capillaries called the **glomerulus**, surrounded by the **glomerular capsule**. Blood arrives at the glomerulus by the **afferent arteriole** and departs in the **efferent arteriole**. (Figure 26-7)
13. At the glomerulus, a **visceral layer of podocytes** covers the **basement membrane** of the capillaries that project into the **capsular space**. The **foot processes**, or *pedicels*, of the podocytes are separated by narrow **filtration slits**. Together, the fenestrated endothelium, basement membrane, and foot processes form the **filtration membrane**. **Intraglomerular mesangial cells** lie between adjacent capillaries and control capillary luminal diameter. (Figure 26-7)
14. About 85% of nephrons are **cortical nephrons**, located in the renal cortex. **Juxtamedullary nephrons** are closer to the renal medulla, with their *nephron loops* extending deep into the **renal pyramids**. (Figure 26-8)
15. Blood travels from the efferent arteriole to the **peritubular capillaries** and the **vasa recta**. (Figure 26-8)
16. Nephrons produce filtrate; reabsorb organic nutrients, water, and ions; and secrete various waste products into the tubular fluid. (Table 26-1)

26-3 Different segments of the nephron form urine by filtration, reabsorption, and secretion

17. Urine production maintains homeostasis by regulating blood volume and composition. In the process, metabolic wastes—notably urea, creatinine, and uric acid—are excreted.

18. Urine formation involves **filtration, reabsorption, and secretion**.
19. Most regions of the nephron perform a combination of reabsorption and secretion. (*Figure 26-9; Table 26-2*)

26-4 The glomerulus filters blood through the filtration membrane to produce filtrate; several pressures determine the glomerular filtration rate

20. **Glomerular filtration** occurs as fluids and solutes move across the filtration membrane of the glomerulus into the capsular space in response to the **glomerular hydrostatic pressure (GHP)**—the hydrostatic (blood) pressure in the glomerular capillaries. This movement is opposed by the **capsular hydrostatic pressure (CsHP)** and by the **blood colloid osmotic pressure (BCOP)**. The **net filtration pressure (NFP)** at the glomerulus is the difference between the blood pressure and the opposing capsular and osmotic pressures. (*Figure 26-10*)
21. The **glomerular filtration rate (GFR)** is the amount of filtrate produced in the kidneys each minute. Any factor that alters the filtration pressure acting across the glomerular capillaries will change the GFR and affect kidney function.
22. A drop in filtration pressures stimulates the **juxtaglomerular complex (JGC)** to release renin and erythropoietin. (*Figure 26-11*)
23. Sympathetic activation (1) produces a powerful vasoconstriction of the afferent arterioles, decreasing the GFR and slowing the production of filtrate, (2) alters the GFR by changing the regional pattern of blood circulation, and (3) stimulates the release of renin by the juxtaglomerular complex. (*Figure 26-11*)
24. Glomerular filtration produces a filtrate with a composition similar to blood plasma, but with few, if any, plasma proteins.

26-5 The renal tubule reabsorbs nutrients, ions, and water and secretes ions and wastes; the collecting system reabsorbs ions and water

25. Four types of *carrier-mediated transport* (*facilitated diffusion, active transport, cotransport, and countertransport*) are involved in modifying filtrate. The saturation limit of a carrier protein is its **transport maximum (T_m)**, which determines the **renal threshold**—the plasma concentration at which various substances will appear in urine. (*Table 26-2*)
26. The transport maximum determines the renal threshold for the reabsorption of substances in tubular fluid. (*Table 26-3*)
27. The cells of the PCT normally reabsorb sodium and other ions, water, and almost all the organic nutrients that enter the filtrate. These cells also secrete various substances into the tubular fluid. (*Figure 26-12*)
28. Water and ions are reclaimed from tubular fluid by the nephron loop. The entire descending limb of the nephron loop is freely permeable to water, but not to solutes, such as sodium and chloride ions. The ascending limb of the nephron loop is impermeable to water, but passively and actively removes

sodium and chloride ions from the tubular fluid. Its ascending thin limb (ATL) is permeable to sodium ions. The thick ascending limb (TAL) actively transports sodium and chloride ions out of the tubular fluid.

29. The DCT performs final adjustments by actively secreting or absorbing materials. Sodium ions are actively absorbed, in exchange for potassium or hydrogen ions discharged into tubular fluid. Aldosterone secretion increases the rate of sodium reabsorption and potassium loss. (*Figure 26-13*)
30. The amount of water and solutes in the tubular fluid of the collecting ducts is further regulated by aldosterone and ADH secretions. (*Figure 26-13*)

26-6 Countercurrent multiplication allows the kidneys to regulate the volume and concentration of urine

31. The descending thin limb and the thick ascending limb of the nephron loop are close together and separated by peritubular fluid. The descending thin limb is permeable to water but relatively impermeable to solutes. The thick ascending limb is relatively impermeable to both water and solutes, but it contains active transport mechanisms that pump sodium and chloride ions from the tubular fluid into the peritubular fluid of the medulla.
32. The exchange of substances between the descending thin limb and the thick ascending limb of a nephron, called **countercurrent multiplication**, helps create the osmotic gradient in the medulla. The concentration gradient in the renal medulla encourages the osmotic flow of water out of the tubular fluid. As water is lost by osmosis and the volume of tubular fluid decreases, the urea concentration increases. (*Figure 26-14*)
33. Urine volume and osmotic concentration are regulated by controlling water reabsorption. Precise control over this occurs by *facultative water reabsorption*. (*Figure 26-15*)
34. Normally, the removal of solutes and water by the vasa recta precisely balances the rates of reabsorption and osmosis in the renal medulla.
35. More than 99% of the filtrate produced each day is reabsorbed before reaching the renal pelvis. (*Table 26-5*)
36. Each segment of the nephron and collecting system contributes to the production of concentrated urine. (*Spotlight Figure 26-16; Table 26-4*)
37. **Urinalysis** is the chemical and physical analysis of a urine sample. (*Table 26-6*)

26-7 Urine is transported by the ureters, stored in the bladder, and eliminated through the urethra by urinary reflexes

38. Urine production ends when tubular fluid enters the renal pelvis. The rest of the urinary system transports, stores, and eliminates urine. (*Figure 26-17*)
39. The ureters extend from the renal pelvis to the urinary bladder. Peristaltic contractions by smooth muscles move the urine along the tract. (*Figures 26-18, 26-19*)

40. The urinary bladder is stabilized by the **middle umbilical ligament** and the **lateral umbilical ligaments**. Internal features include the **trigone**, the **neck**, and the **internal urethral sphincter**. The mucosal lining contains prominent **rugae** (folds). Contraction of the **detrusor** compresses the urinary bladder and expels urine into the urethra. (Figures 26–18, 26–19)
41. A circular band of skeletal muscles forms the **external urethral sphincter**, which is under voluntary control. (Figure 26–18)
42. **Urination** is coordinated by the **urine storage reflex** and the **urine voiding reflex**, which are initiated by stretch receptors in the wall of the urinary bladder. Voluntary urination involves coupling these reflexes with the voluntary relaxation of the external urethral sphincter, which allows the relaxation of the **internal urethral sphincter**. (Figure 26–20)

26-8 Age-related changes affect kidney function and urination

43. Aging is generally associated with increased kidney problems. Age-related changes in the urinary system include (1) decreasing numbers of functional nephrons, (2) reduced GFR, (3) reduced sensitivity to ADH, and (4) problems with the urinary reflexes. (**Urinary retention** may develop in males whose prostate is enlarged.)

26-9 The urinary system is one of several body systems involved in waste excretion

44. The urinary system is the major component of an anatomically diverse **excretory system** that includes the integumentary system, the respiratory system, and the digestive system. (Figure 26–21)

Review Questions

See the blue Answers tab at the back of the book.

LEVEL 1 Reviewing Facts and Terms

1. Identify the structures of the kidney in the following diagram.

- | | |
|-----------|-----------|
| (a) _____ | (b) _____ |
| (c) _____ | (d) _____ |
| (e) _____ | (f) _____ |
| (g) _____ | (h) _____ |
| (i) _____ | (j) _____ |
| (k) _____ | (l) _____ |
| (m) _____ | |

- The kidneys are located (a) lateral to the spleen, (b) in a retroperitoneal position, (c) behind the vertebral column, (d) in the pelvic cavity, (e) ventral to the stomach.
- The process of urine formation involves all the following *except* (a) filtration of plasma, (b) reabsorption of water, (c) reabsorption of certain solutes, (d) secretion of wastes, (e) secretion of excess lipid-protein and glucose molecules.
- The glomerular filtration rate is regulated by all the following *except* (a) autoregulation, (b) sympathetic neural control, (c) cardiac output, (d) angiotensin II, (e) the hormone ADH.
- The descending limb of the nephron loop is an important site for (a) filtration of blood plasma, (b) reabsorption of water, (c) reabsorption of sodium ions and calcium ions, (d) secretion of drugs.
- Changing the luminal diameters of the afferent and efferent arterioles to alter the GFR can be an example of (a) hormonal regulation, (b) autonomic regulation, (c) autoregulation, (d) all of these.
- What are the primary functions of the urinary system?
- What organs make up the urinary system?
- Trace the pathway of the protein-free filtrate from where it is produced in the renal corpuscle until it drains into the renal pelvis in the form of urine. (Use arrows to indicate the direction of flow.)
- Name the segments of the nephron distal to the renal corpuscle and state the functions of each.
- What is the function of the juxtaglomerular complex?
- Trace the path of a drop of blood from its entry into the renal artery until its exit at a renal vein.
- Name and define the three distinct processes involved in the production of urine.
- What are the primary effects of angiotensin II on kidney function and regulation?
- Arrange the waste products ammonia, creatinine, urea, and uric acid according to their abundance in urine.

LEVEL 2 Reviewing Concepts

16. When the renal threshold for a substance exceeds its tubular maximum **(a)** more of the substance will be filtered, **(b)** more of the substance will be reabsorbed, **(c)** more of the substance will be secreted, **(d)** the amount of the substance that exceeds the tubular maximum will be found in the urine, **(e)** both a and d occur.
17. Glomerular filtration in the kidney nephrons is driven by various pressures acting around the glomerular filtration membrane. The highest of these is the **(a)** net filtration pressure (NFP), **(b)** glomerular hydrostatic pressure (GHP), **(c)** blood colloid osmotic pressure (BCOP), **(d)** capsular colloid osmotic pressure.
18. Thiazides are diuretics that increase water loss by decreasing **(a)** sodium and chloride ion transport, **(b)** urea and uric acid transport, **(c)** bicarbonate ion reabsorption, **(d)** secretion of hydrogen ions.
19. When ADH levels rise, **(a)** the amount of water reabsorbed increases, **(b)** the DCT becomes impermeable to water, **(c)** the amount of water reabsorbed decreases, **(d)** sodium ions are exchanged for potassium ions.
20. The control of blood pH by the kidneys during acidosis involves **(a)** the secretion of hydrogen ions and reabsorption of bicarbonate ions from the tubular fluid, **(b)** a decrease in the amount of water reabsorbed, **(c)** hydrogen ion reabsorption and bicarbonate ion loss, **(d)** potassium ion secretion.
21. What is meant by creatinine clearance? What is it used for?
22. What interacting controls stabilize the glomerular filtration rate (GFR)?
23. How are the glomerular hydrostatic pressure (GHP) and the capsular hydrostatic pressure (CsHP) related to each other?
24. Describe two functions of countercurrent multiplication in the kidney.
25. Describe the urine storage reflex.

LEVEL 3 Critical Thinking and Clinical Applications

26. In a normal kidney, which of the following conditions would cause an increase in the glomerular filtration rate (GFR)? **(a)** constriction of the afferent arteriole, **(b)** a decrease in the pressure of the glomerulus, **(c)** an increase in the capsular hydrostatic pressure, **(d)** a decrease in the concentration of plasma proteins in the blood, **(e)** a decrease in the net glomerular filtration process.
27. In response to *excess* water in the body, **(a)** antidiuretic hormone is secreted by the anterior lobe of the pituitary gland, **(b)** the active transport mechanisms in the ascending thick limb of the nephron loop cease functioning, **(c)** the permeability of the distal convoluted tubules and collecting ducts to water is decreased, **(d)** the permeability of the ascending limb of the nephron loop is increased, **(e)** the glomerular filtration rate is reduced.
28. Yasu was diagnosed with severe edema in her arms and legs. Her physician prescribes a diuretic (a substance that increases the volume of urine produced). Why might this help alleviate Yasu's problem?
29. Sione's grandfather has hypertension. His doctor tells him that part of his problem stems from renal arteriosclerosis. Why would this cause hypertension?
30. Bert is suffering from extreme pain in his flank, and his urine production has suddenly become very low. His doctor asks for an x-ray to determine the cause of the problem. What could it be?
31. The drug *Diamox* is sometimes used to treat mountain sickness. *Diamox* inhibits the action of carbonic anhydrase in the proximal convoluted tubule. Polyuria (excessive urine production resulting in frequent urination) is a side effect associated with the medication. Why does polyuria occur?

CLINICAL CASE Wrap-Up A Case of "Hidden" Bleeding

Normally, when a kidney is injured, the urine appears very bloody (*hematuria*). Waylen has made very little urine since his injury and massive blood loss, but the urine in his catheter is clear. This reduces the initial suspicion of a renal injury.

However, when the surgeon opens the left retroperitoneal space, he finds another large collection of free blood. When the surgeon clears this blood away, the source of Waylen's continued bleeding becomes apparent. His left renal artery, renal vein, and ureter have been completely torn away from the kidney at the hilum. The renal artery is briskly pumping what circulatory blood volume is left into the retroperitoneal space, where it is walled off from the abdominal space by the parietal peritoneum. Because the left ureter is completely torn

from the damaged kidney, there is no visible blood in the urine.

This kidney is too damaged to heal. The surgeon quickly performs a left *nephrectomy* (kidney removal). If Waylen survives this trauma, he will have to live with a solitary kidney. With the bleeding stopped, including the "hidden" bleeding, the trauma team is finally able to sustain an adequate circulating blood volume.

1. How could Waylen's abdominal x-rays show that his kidneys might be injured?
2. What will likely happen to the glomerular filtration rate (GFR) of Waylen's remaining right kidney if he survives this trauma?

See the blue Answers tab at the back of the book.

Related Clinical Terms

azotemia: The condition characterized by excessive urea or other nitrogen-containing compounds in the blood.

cystocele: Condition that occurs when the supportive tissue between a female's bladder and vaginal wall weakens, stretches, and allows the bladder to bulge into the vagina.

cystoscopy: Diagnostic procedure using an optical instrument called a cystoscope that is inserted through the urethra to visually examine the bladder and lower urinary tract, to collect urine samples, or to view the prostate.

enuresis: Involuntary urination, especially that of a child while asleep.

nephroptosis: Condition in which the kidney is displaced downward from its normal position; also called a *floating kidney*.

nephrotic syndrome: A kidney disorder that causes one to excrete excessive protein in the urine.

nephrotoxin: A toxin that has a specific harmful effect on the kidney.

polycystic kidney disease: An inherited condition that affects the development and structure of kidney tubules.

shock-wave lithotripsy: A noninvasive technique used to pulverize kidney stones by passing high-pressure shock waves through a water-filled tub in which the patient sits.

urologist: Physician who specializes in functions and disorders of the urinary system.

27

Fluid, Electrolyte, and Acid–Base Balance

Learning Outcomes

These Learning Outcomes correspond by number to this chapter's sections and indicate what you should be able to do after completing the chapter.

- 27-1 ■ Explain what is meant by fluid balance, electrolyte balance, and acid–base balance, and discuss their importance for homeostasis.
- 27-2 ■ Compare the composition of ECF and ICF, explain the basic concepts involved in the regulation of fluids and electrolytes, and identify the hormones that play important roles in fluid and electrolyte regulation.
- 27-3 ■ Describe the movement of fluid within the ECF, between the ECF and the ICF, and between the ECF and the environment.
- 27-4 ■ Discuss the mechanisms by which sodium, potassium, calcium, magnesium, phosphate, and chloride ion concentrations are regulated to maintain electrolyte balance.
- 27-5 ■ Explain the buffer systems that balance the pH of the ICF and ECF, and describe the compensatory mechanisms involved in maintaining acid–base balance.
- 27-6 ■ Identify the most frequent disturbances of acid–base balance and explain how the body responds when the pH of body fluids varies outside normal limits.
- 27-7 ■ Describe the effects of aging on fluid, electrolyte, and acid–base balance.

CLINICAL CASE

When Treatment Makes You Worse

Marquis is a 43-year-old office worker who is slightly overweight. At his annual checkup, his blood pressure measures 150/96 mm Hg, which is considered moderately high. Marquis feels fine, but his doctor tells him it is time to treat his hypertension. Marquis's doctor advises him to improve his diet and get more exercise. He also prescribes a new medication, hydrochlorothiazide, or HCTZ, which he instructs him to take every morning. HCTZ is a diuretic that is commonly used to lower blood pressure.

Marquis begins taking HCTZ and continues to feel well, although he notices the medication makes him urinate more

frequently. A few weeks later, he and a group of coworkers eat some bad potato salad at the office picnic and come down with food poisoning. After 3 days of diarrhea, Marquis feels horrible. He is so weak he can barely get out of bed. His muscles ache and his legs and feet cramp a lot. Worst of all, he feels as if there is a frog jumping around in his chest. He is often dizzy when this happens.

After a week in bed, Marquis feels even weaker. He visits his doctor, who sends him to the lab for some tests. "I know why you feel so terrible," says his doctor when he sees the lab results. **What is happening to Marquis? To find out, turn to the Clinical Case Wrap-Up at the end of the chapter.**

An Introduction to Fluid, Electrolyte, and Acid-Base Balance

For a moment, consider the fish living in a small pond. They live their entire lives totally dependent on the quality of that isolated environment. Severe water pollution will kill them, but even subtle changes can have equally grave effects. Changes in the volume of the pond, for example, can be quite important. If evaporation removes too much water, the fish become overcrowded. The oxygen and food supplies will run out, and the fish will suffocate or starve. The ionic concentration of the water is also crucial. Most of the fish in a freshwater pond will die if the water becomes too salty. Fish in a saltwater pond will die if rain dilutes the pond water. The pH of the pond water is also a vital factor. A change in pH is another reason that acid rain is such a problem.

Our cells too, live in a pond. Its shores are the exposed surfaces of the skin. Most body weight is water. Water makes up about 99% of the volume of the fluid outside cells, the *extracellular fluid* (ECF), and it is also an essential ingredient of the cytosol inside cells, the *intracellular fluid* (ICF). Cellular operations rely on water as a diffusion medium for the distribution of gases, nutrients, and wastes. If the water volume of the body changes, cellular activities are jeopardized. For example, if the water volume reaches a very low level, proteins denature, enzymes stop functioning, and cells die. Homeostatic mechanisms regulating fluid volume, ion concentrations, and pH are presented in this chapter.

27-1 Fluid balance, electrolyte balance, and acid-base balance are interrelated and essential to homeostasis

Learning Outcome Explain what is meant by fluid balance, electrolyte balance, and acid-base balance, and discuss their importance for homeostasis.

To survive, we must maintain a normal volume and composition of both the ECF and the ICF. The ionic concentrations and pH (hydrogen ion concentration) of these fluids are as important as their absolute quantities. If the concentration of calcium ions or potassium ions in the ECF becomes too high, cardiac arrhythmias develop and death can result. A pH outside the normal range can also lead to a variety of serious problems. Low pH—*acidity*—is especially dangerous because hydrogen ions break chemical bonds, change the shapes of complex molecules, disrupt plasma membranes, and impair tissue functions.

Tips

The "p" in pH refers to power. Hence, pH refers to the **p**ower of **H**ydrogen.

Three interrelated processes stabilize the volumes, solute concentrations, and pH of the ECF and the ICF:

- **Fluid Balance.** *Fluid balance* occurs when the amount of water gained each day is equal to the amount lost to the environment. Maintaining normal fluid balance involves regulating the content and distribution of body water in the ECF and the ICF. The digestive system is the main source of water gains. Metabolic activity generates a small amount of additional water. The urinary system is the main route for water loss under normal conditions, but as we saw in Chapter 25, sweating can become important when body temperature is elevated.
- **Electrolyte Balance.** **Electrolytes** are ions released when inorganic compounds dissociate. They are so named because they can conduct an electrical current in a solution. Each day, the body's fluids gain electrolytes from the foods and drinks ingested. One's body fluids also lose electrolytes in urine, sweat, and feces. For each ion, daily gains must balance

daily losses. For example, if a person loses 500 mg of Na^+ in urine and sweat, they need to gain 500 mg of Na^+ from food and drink to remain in sodium ion balance. If the gains and losses for every electrolyte are in balance, the person is in *electrolyte balance*. Electrolyte balance primarily involves balancing the rates of absorption across the digestive tract with rates of loss by the kidneys, although losses at sweat glands and other sites can play a secondary role.

- **Acid–Base Balance.** *Acid–base balance* occurs when the production of hydrogen ions (H^+) in the body is precisely offset by their loss. When acid–base balance exists, the pH of body fluids remains within normal limits. Preventing a decrease in pH is the primary problem, because the body generates a variety of acids during normal metabolic operations. The kidneys play a major role by secreting hydrogen ions into the urine and generating *buffers* (compounds that stabilize the pH of a solution) that enter the bloodstream. Such secretion takes place primarily in a nephron’s distal segments of the distal convoluted tubule (DCT) and along the collecting system. The lungs also play a key role by eliminating carbon dioxide.

In this chapter, we explore the dynamics of exchange among the various body fluids, and between the body and the external environment. Much of the information in this chapter should be familiar from discussions in earlier chapters about aspects of fluid, electrolyte, or acid–base balance that affect specific systems. Here we provide an overview that integrates those discussions to highlight important functional patterns.

The subjects discussed in this chapter have wide-ranging clinical importance: Steps to restore normal fluid, electrolyte, and acid–base balances must be part of the treatment of any serious illness affecting the nervous, cardiovascular, respiratory, urinary, or digestive system. Because this chapter builds on information in earlier chapters, we have included many references to relevant discussions and figures that can provide a quick review.

Checkpoint

1. Identify the three interrelated processes essential to stabilizing body fluid volumes, ion concentrations, and pH.

See the blue Answers tab at the back of the book.

27-2 Extracellular fluid (ECF) and intracellular fluid (ICF) are fluid compartments with differing solute concentrations that are closely regulated

Learning Outcome Compare the composition of ECF and ICF, explain the basic concepts involved in the regulation of fluids and electrolytes, and identify the hormones that play important roles in fluid and electrolyte regulation.

This section examines the composition of the ECF and ICF, how exchanges occur between them, and how these are regulated by hormones. But first let’s look at the big picture of how much total water is found in the body.

Body Water Content

Figure 27-1a presents an overview of the body makeup of a 70-kg (154-lb) person with a minimum of body fat. The distribution is based on overall average values for males and females ages 18–40 years. In humans, the ICF contains a greater proportion of total body water than does ECF. However, there are some differences between males and females in body water content (**Figure 27-1b**). Water makes up about 60% of the total body weight of an adult male, and 50% of that of an adult female. This difference between the sexes, which is mainly in the ICF, reflects the proportionately larger mass of adipose tissue in adult females, and the greater average muscle mass in adult males. (Adipose tissue is only 10% water, whereas skeletal muscle is 75% water.) Less striking differences occur in the ECF values, due to variations in the interstitial fluid volume of various tissues and the larger blood volume in males versus females.

The Fluid Compartments of the ECF and ICF

The **extracellular fluid**, or **ECF**, is made up mostly of the interstitial fluid of peripheral tissues and the plasma of circulating blood; the **intracellular fluid**, or **ICF**, consists of the cytosol inside cells. Minor components of the ECF include lymph, cerebrospinal fluid (CSF), synovial fluid, serous fluids (pleural, pericardial, and peritoneal fluids), aqueous humor, perilymph, and endolymph.

The ECF and ICF are called **fluid compartments** because they commonly behave as separate sections, maintaining different ionic compositions. The principal ions in the ECF are sodium, chloride, and bicarbonate (HCO_3^-). The ICF contains an abundance of potassium, magnesium, and phosphate ions (HPO_4^{2-}), plus large amounts of negatively charged proteins. **Figure 27-2** compares the concentrations of the cations and anions of the ICF with those of the two major subdivisions of the ECF (plasma and interstitial fluid) in terms of milliequivalents per liter (mEq/L). This figure reflects the total number of positive and negative electrical charges in solution. Specific ions and substances, such as proteins, contribute more since they have more than a single electric charge.

The osmotic concentration, or osmolarity, of a solution depends on solute concentration, or the total number of solute particles per liter. Despite the differences in the concentration of specific substances in **Figure 27-2**, the osmotic concentrations of the ICF and ECF are identical. This is because ions and proteins each count as one particle in solution, despite their number of electrical charges.

Figure 27–1 Composition of the Human Body.

a The body composition (by weight, averaged for both sexes) and major body fluid compartments of a 70-kg (154-lb) person. For technical reasons, it is extremely difficult to determine the precise size of any of these compartments; estimates of their relative sizes vary widely.

b A comparison of the body compositions of adult males and females, ages 18–40 years.

Osmosis eliminates minor differences in concentration almost at once because most plasma membranes are freely permeable to water. (The only noteworthy exceptions are the apical surfaces of epithelial cells along the ascending limb of the nephron loop, the distal convoluted tubule, and the collecting system.)

Solute Exchanges between the ECF and the ICF

If the plasma membranes of cells were freely permeable, diffusion would continue until the ions in the ECF and ICF were evenly distributed across all the membranes. But it does not,

because plasma membranes are selectively permeable: Ions can enter or leave the cells only by specific membrane channels. Also, carrier mechanisms move specific ions into or out of the cells. Therefore, the exchange of ions between the ICF and the ECF takes place across plasma membranes by osmosis, diffusion, and carrier-mediated transport. The presence of a plasma membrane and active transport at the membrane surface enable cells to maintain internal environments with a composition that differs from their surroundings.

In addition to solute exchanges between the ECF and ICF, exchanges also occur among the subdivisions of the ECF. These

Figure 27–2 Cations and Anions in Body Fluids. Notice that each fluid compartment is electrically neutral and the ionic composition is markedly different between the ICF and ECF (plasma and interstitial fluid).

Mg²⁺ and K⁺ are found in higher concentrations in the (*intracellular, extracellular*) fluid, whereas Na⁺ and Cl⁻ are found in higher concentrations in the (*intracellular, extracellular*) fluid.

exchanges occur primarily across the endothelial lining of capillaries. Fluid may also travel from the interstitial spaces to plasma through lymphatic vessels that drain into the venous system. Such exchanges mean that the kinds and quantities of dissolved electrolytes, proteins, nutrients, and wastes in the ECF vary regionally. Still, the variations among the compartments of the ECF seem minor compared with the major differences between the ECF and the ICF (**Figure 27–2**).

In clinical situations, we usually estimate that two-thirds of the total body water is in the ICF and one-third in the ECF. This ratio underestimates the real volume of the ECF, because portions of the ECF—including the water in bone, in many dense connective tissues, and in many of the minor ECF components—are relatively isolated. Exchange between these fluid volumes and the rest of the ECF takes place more slowly than does exchange between plasma and other interstitial fluids. For this reason, they can be safely ignored in many cases. Clinical attention usually focuses on the rapid fluid and solute movements that accompany the administration of blood, plasma, or saline solutions to counteract blood loss or dehydration. Physiologists and clinicians pay

particular attention to ionic distributions across membranes and to the electrolyte composition of body fluids. The Appendix (A) at the end of the book reports normal physiological values in the units most often used in clinical reports.

An Overview of the Regulation of Fluid and Electrolyte Balance

The regulation of fluid balance and of electrolyte balance is tightly intertwined because changes in solute concentrations lead to immediate changes in water distribution. The following basic principles are key to understanding fluid and electrolyte balance:

- *All the homeostatic mechanisms that monitor and adjust the composition of body fluids respond to changes in the ECF, not in the ICF.* Receptors monitoring the composition of two key components of the ECF—plasma and cerebrospinal fluid (CSF)—detect significant changes in their composition or volume and trigger appropriate nervous and endocrine responses. This arrangement makes functional sense,

because a change in one ECF component will spread rapidly throughout the entire ECF and affect all the body's cells. In contrast, the ICF is contained within trillions of individual cells that are physically and chemically isolated from one another by their plasma membranes. For this reason, changes in the ICF in one cell have no direct effect on the composition of the ICF in distant cells and tissues, unless those changes also affect the ECF.

- *No receptors directly monitor fluid or electrolyte balance.* In other words, receptors cannot detect how many liters of water, or grams of sodium, chloride, or potassium ions, the body contains. Nor can they count how many liters or grams we gain or lose throughout the day. But receptors can monitor *plasma volume* and *osmotic concentration*. The plasma volume and osmotic concentration are good indicators of the state of fluid balance and electrolyte balance for the body as a whole because fluid continuously circulates between interstitial fluid and plasma, and because exchange occurs between the ECF and the ICF.
- *Cells cannot move water molecules by active transport.* All movement of water across plasma membranes and epithelia takes place passively, in response to osmotic gradients established by the active transport of specific ions, such as sodium and chloride. It is useful to remember that “water follows salt.” As described in earlier chapters, when sodium and chloride ions (or other solutes) are actively transported across a membrane or epithelium, water follows by osmosis. This basic principle accounts for water absorption across the digestive epithelium, and for water conservation by the kidneys.
- *The body's content of water or electrolytes will increase if dietary gains exceed losses to the environment and will decrease if losses exceed gains.* This basic rule is important when considering the mechanics of fluid balance and electrolyte balance. Homeostatic adjustments affect the balance between urinary excretion and dietary absorption. As we saw in Chapter 26, circulating hormones regulate renal function. These hormones can also produce complementary changes in behavior, such as promoting thirst.

The Primary Hormones That Regulate Fluid and Electrolyte Balance

Three hormones mediate physiological adjustments to fluid balance and electrolyte balance: (1) *antidiuretic hormone* (ADH), (2) *aldosterone*, and (3) the *natriuretic peptides* (ANP and BNP).

Antidiuretic Hormone. Recall that **antidiuretic hormone (ADH)** is a pituitary hormone that promotes water retention by the kidneys. The hypothalamus contains specialized cells known as *osmoreceptors* that monitor the osmotic concentration of the ECF. These cells are very sensitive: A two percent

change in osmotic concentration (approximately 6 mOsm/L) is enough to alter osmoreceptor activity.

The population of osmoreceptors includes neurons that secrete ADH. These neurons are in the anterior hypothalamus. Their axons release ADH near fenestrated capillaries in the posterior lobe of the pituitary gland. The rate of ADH release varies directly with osmotic concentration: The higher the osmotic concentration, the more ADH is released.

Increased release of **ADH** has two important effects: (1) It stimulates water conservation by the kidneys, reducing urinary water losses and concentrating the urine; and (2) it stimulates the hypothalamic thirst center, promoting the intake of fluids. As described in Chapter 21, the combination of decreased water loss and increased water gain gradually restores the normal plasma osmotic concentration.

Aldosterone. Recall that **aldosterone** is a corticosteroid that stimulates sodium absorption by the kidneys and so regulates water and sodium balance. Aldosterone secretion plays a major role in determining the rate of Na^+ absorption and K^+ loss along the distal convoluted tubule and collecting system of the kidneys. The higher the plasma concentration of aldosterone, the more efficiently the kidneys conserve Na^+ . Because “water follows salt,” the conservation of Na^+ also increases water retention. As Na^+ is reabsorbed, Cl^- follows (look back at **Figure 26–13**), and water follows by osmosis as sodium and chloride ions move out of the tubular fluid.

Aldosterone is secreted in response to an increasing K^+ or decreasing Na^+ level in the blood reaching the adrenal cortex, or in response to *renin-angiotensin-aldosterone system* activation. As noted in earlier chapters, renin release occurs in response to any of three changes: (1) a decrease in plasma volume or blood pressure at the juxtaglomerular complex of the nephron, (2) a decrease in the osmotic concentration of tubular fluid at the DCT, or (3) a decreasing Na^+ or increasing K^+ concentration in the renal circulation.

Natriuretic Peptides. The **natriuretic** (*natrium*, sodium; *-uretic*, urine) **peptides**, *atrial natriuretic peptide* (ANP) and *B-type natriuretic peptide* (BNP), are released by cardiac muscle cells in response to abnormal stretching of the heart walls. Increased blood pressure or increased blood volume causes this stretching. Among their other effects, these peptides reduce thirst and block the release of ADH and aldosterone that might otherwise lead to water and salt conservation. The resulting *diuresis* (fluid loss by the kidneys) decreases both blood pressure and plasma volume, eliminating the stretching.

The Interplay between Fluid Balance and Electrolyte Balance

At first glance, it can be difficult to distinguish between water balance and electrolyte balance. For example, when the body loses water, plasma volume decreases and electrolyte concentrations

increase. Conversely, when the body gains or loses excess electrolytes, water is also gained or lost due to osmosis.

However, it is often useful to consider fluid balance and electrolyte balance separately because the regulatory mechanisms involved are quite different. This distinction is vital in a clinical setting, where problems with fluid balance and electrolyte balance must be identified and corrected promptly.

✓ Checkpoint

2. List the components of extracellular fluid (ECF) and intracellular fluid (ICF).
3. Name three hormones that play a major role in adjusting fluid and electrolyte balance in the body.
4. What effect might consuming a half-gallon of distilled water (water without minerals) have on a person's ADH level?

See the blue Answers tab at the back of the book.

27-3 Fluid balance involves the regulation and distribution of water gains and losses

Learning Outcome Describe the movement of fluid within the ECF, between the ECF and the ICF, and between the ECF and the environment.

As mentioned, **fluid balance** occurs when the amount of water gained each day is equal to the amount lost to the environment. We cannot easily determine the body's water content. However, the concentration of Na^+ , the most abundant ion in the ECF, provides useful clues to the state of fluid balance (**Figure 27-2**). When the body's water content increases, the Na^+ concentration of the ECF becomes abnormally low. And when the body's water content decreases, the Na^+ concentration becomes

Table 27-1 Daily Water Gains and Losses

Gains	Daily Input (mL)
Water content of food	1000
Water consumed as liquid	1200
Metabolic water produced during catabolism	300
Total	2500
Losses	Daily Output (mL)
Urination	1200
Evaporation at skin	750
Evaporation at lungs	400
Loss in feces	150
Total	2500

abnormally high. The body responds to such osmotic changes to ensure that fluid balance is maintained. Let's look at fluid gains and losses, and water movements.

Fluid Gains and Losses

Table 27-1 lists the major water gains and losses involved in daily fluid balance. **Figure 27-3** highlights the routes of fluid exchange between the fluid compartments and the environment.

Water Gains

A water gain of about 2500 mL/day is required to balance average water losses. This value amounts to about 40 mL/kg (about 1.35 fl oz/lb) of body weight per day. Water is gained through eating (1000 mL), drinking (1200 mL), and *metabolic generation* (300 mL).

Metabolic generation of water is the production of water within cells, primarily because of oxidative phosphorylation in mitochondria during aerobic metabolism. When cells

Figure 27-3 Exchanges between Fluid Compartments and the Environment. Fluid movements that maintain daily fluid balance in the body. The volumes are drawn to scale: The ICF is about twice as large as the ECF.

break down 1 g of lipid, 1.7 mL of water is generated. Breaking down proteins or carbohydrates yields much smaller amounts (0.41 mL/g and 0.55 mL/g, respectively).

A typical diet in the United States contains 46% carbohydrates, 40% lipids, and 14% protein. Such a diet produces approximately 300 mL of water per day, about 12% of the average daily requirement.

Water Losses

A person loses about 2500 mL of water each day through urine, feces, and *insensible perspiration*—the evaporation of water across the epithelia of the skin and lungs. The losses due to *sensible perspiration*—evaporation due to the secretory activities of the sweat glands—vary with physical activity. Sensible perspiration can cause significant water deficits, with maximum perspiration rates reaching 4 liters per hour. Fever can also increase water losses. For each degree that body temperature rises above normal, daily insensible water losses increase by 200 mL. The advice “Drink plenty of fluids” for anyone who is sick has a definite physiological basis.

Water Movement between Fluid Compartments

Recall that water movements occur between the ECF and ICF, and between the subdivisions of the ECF, but generally not within the ICF.

Water Movement between the ECF and ICF

Water can move between the ECF and the ICF. For example, a small amount of water moves from the ICF to the ECF each day, as the result of metabolic water generation (**Figure 27–3**). However, under normal circumstances the ECF and the ICF are in osmotic equilibrium. For this reason, no large-scale circulation occurs between the two compartments.

Water Movement within the ECF

Water circulates freely within the ECF compartment. Chapter 21 described the basic principles that determine fluid movement among the subdivisions of the ECF. Recall that the exchange between plasma and interstitial fluid, by far the largest components of the ECF, is due to the relationship between the net hydrostatic pressure, which tends to push water out of the plasma and into the interstitial fluid, and the net colloid osmotic pressure, which tends to draw water out of the interstitial fluid and into the plasma. The interaction between these opposing forces was diagrammed in **Figure 21–11**. It results in the continuous filtration of fluid from the capillaries into the interstitial fluid. Some of that water is then reabsorbed along the distal portion of the capillary bed, and the rest enters

lymphatic vessels for transport to the venous circulation. At any moment, interstitial fluid and minor fluid compartments contain about 80% of the ECF volume, and plasma contains the other 20%.

Any factor that affects the net hydrostatic pressure or the net colloid osmotic pressure will alter the distribution of fluid within the ECF. The movement of abnormal amounts of water from plasma into interstitial fluid results in *edema* (swelling). Pulmonary edema, for example, can result from an increase in the blood pressure in pulmonary capillaries. Generalized edema can result from a decrease in blood colloid osmotic pressure, as seen in advanced starvation, when plasma protein concentrations decrease. Localized edema can result from damage to capillary walls (as occurs in bruising), the constriction of regional venous circulation, or a blockage of the lymphatic drainage (as happens with *lymphedema*).

In addition to these water movements between major components of the ECF, water also moves continuously among the smaller ECF subdivisions. The volumes involved in these water movements are very small, and the volume and composition of the fluids are closely regulated.

Fluid Shifts between the ECF and ICF

A **fluid shift** is a rapid water movement between the ECF and the ICF in response to an osmotic gradient. Such a gradient is produced by changes in the osmotic concentration of the ECF (**Figure 27–4**). Fluid shifts occur rapidly, reaching equilibrium within minutes to hours. This process happens in the following two situations:

- *If the osmotic concentration of the ECF increases, that fluid will become hypertonic compared to the ICF.* The osmotic concentration of the ECF will increase if water is lost but electrolytes are retained. Water will then move from the cells into the ECF until osmotic equilibrium is restored.
- *If the osmotic concentration of the ECF decreases, that fluid will become hypotonic compared to the ICF.* The osmotic concentration of the ECF will decrease if a person gains water but does not gain electrolytes. Water will then move from the ECF into the cells, and the ICF volume will increase.

To summarize, if the osmotic concentration of the ECF changes, a fluid shift between the ICF and ECF will tend to oppose the change. The ICF acts as a water reserve because the volume of the ICF is much greater than that of the ECF. In effect, instead of a large change in the osmotic concentration of the ECF, smaller changes occur in both the ECF and ICF.

Figure 27–4 Fluid Shifts between the ICF and ECF.

Allocation of Water Losses and Dehydration

Dehydration, or *water depletion*, develops when water losses outpace water gains. When the body loses water but retains electrolytes, the osmotic concentration of the ECF increases. Water then moves out of the ICF and into the ECF by osmosis until the two solutions are again isotonic. At that point, both the ECF and ICF are somewhat more concentrated than normal, and both volumes are lower than they were before the fluid loss. Because the ICF has about twice the functional volume of the ECF, the net change in the ICF is small.

However, if the fluid imbalance continues unchecked, the loss of body water will produce severe thirst, dryness, and wrinkling of the skin. In the case of severe water losses such as excessive perspiration (from exercising in hot weather), inadequate water consumption, repeated vomiting, and diarrhea, more water than electrolytes is lost. Body fluids become increasingly concentrated, and the sodium ion concentration becomes abnormally high (a condition called *hypernatremia*). In addition, a significant decrease in plasma volume and blood pressure eventually occurs, and shock may develop.

Homeostatic responses to dehydration include physiological mechanisms (ADH and renin secretion) and behavioral

Clinical Note Water and Weight Loss

The safest way to lose weight is to reduce food intake while ensuring that all nutrient requirements are met. Water must be included on the list of nutrients, along with carbohydrates, fats, proteins, vitamins, and minerals. Nearly half of normal water intake comes from food. For this reason, when eating less, the body becomes more dependent on drinking fluids and on whatever water is generated metabolically.

At the start of a calorie-restricted diet, the body conserves water and catabolizes lipids. That is why the first week of dieting may seem rather unproductive. Over that week, the level of circulating ketone bodies gradually increases. In the weeks that follow, the rate of water loss by the kidneys increases to excrete wastes, such as the hydrogen ions released by ketone bodies and the urea and ammonia generated during protein catabolism. The rate of fluid intake must also increase, or else there is a risk of dehydration. While dieting, dehydration is especially serious, because as water is lost, the concentration of solutes in the ECF increases, further increasing the concentration of wastes and acids generated during the catabolism of energy reserves. This soon becomes a positive feedback loop: These wastes enter the filtrate at the kidneys, and their excretion draws additional water into the urine.

changes (increasing fluid intake, preferably as soon as possible). Clinical therapies for acute dehydration include administering hypotonic fluids by mouth or intravenous infusion. These procedures rapidly increase ECF volume and promote the shift of water back into the ICF.

Distribution of Water Gains and Hyperhydration

When drinking a glass of water, the body's water content increases without a corresponding increase in the concentrations of electrolytes. As a result, the ECF increases in volume but becomes hypotonic compared to the ICF. A fluid shift then occurs, and the volume of the ICF increases at the expense of the ECF. Once again, the larger volume of the ICF limits the relative amount of osmotic change. After the fluid shift, the ECF and ICF have slightly larger volumes and slightly lower osmotic concentrations than they did originally.

Normally, this situation will be promptly corrected. The decreased plasma osmotic concentration decreases ADH secretion, discouraging fluid intake and increasing water losses in urine. If the situation is *not* corrected, a variety of clinical problems will develop as water shifts into the ICF, distorting cells, changing the solute concentrations around enzymes and disrupting normal cell functions. This condition is called **hyperhydration**, or *water excess*. It can be caused by (1) drinking a

large volume of water or the infusion (injection into the bloodstream) of a hypotonic solution; (2) an inability to eliminate excess water in urine, due to chronic renal failure, heart failure, cirrhosis, or some other disorder; and (3) endocrine disorders, such as excessive ADH production.

The most obvious sign of hyperhydration is an abnormally low Na^+ concentration (*hyponatremia*). This reduction in Na^+ concentration in the ECF leads to a fluid shift into the ICF. The first signs are the effects on central nervous system (CNS) function. The individual initially acts drunk. This condition, called *water intoxication*, may sound odd, but is extremely dangerous. Untreated cases can rapidly progress from confusion to hallucinations, convulsions, coma, and then death. Treatment of severe hyperhydration generally involves administering diuretics and infusing a concentrated salt solution that promotes a fluid shift from the ICF to the ECF and returns the Na^+ concentration to a near-normal level.

Checkpoint

5. Define edema.
6. Describe a fluid shift.
7. Define dehydration.
8. If a person were in the desert for a day without water to drink, what effect would that have on the osmotic concentration of their blood plasma?

See the blue Answers tab at the back of the book.

27-4 In electrolyte balance, the concentrations of sodium, potassium, calcium, magnesium, phosphate, and chloride ions in body fluids are tightly regulated

Learning Outcome Discuss the mechanisms by which sodium, potassium, calcium, magnesium, phosphate, and chloride ion concentrations are regulated to maintain electrolyte balance.

Electrolyte balance occurs when gains and losses are equal for each electrolyte in the body. Electrolyte balance is important for these reasons:

- *Total electrolyte concentrations directly affect water balance*, as previously described.
- *The concentrations of individual electrolytes can affect cell functions*. We saw many examples in earlier chapters, including the effect of an abnormal Na^+ concentration on neuron activity and the effects of high or low Ca^{2+} and K^+ concentrations on cardiac muscle tissue.

This section pays particular attention to sodium and potassium ion balance because (1) they are major contributors to the osmotic concentrations of the ECF and the ICF, respectively, and (2) they directly affect the normal functioning of

all cells. Sodium is the main cation in the ECF. More than 90% of the osmotic concentration of the ECF results from sodium salts, mainly sodium chloride (NaCl) and sodium bicarbonate (NaHCO_3). Changes in the osmotic concentration of body fluids generally reflect changes in the Na^+ concentration.

Electrolytes in body fluids are measured in terms of *equivalents* (Eq). An **equivalent (Eq)** is the amount of a positive or negative ion that supplies 1 mole of electrical charge, and 1 equivalent = 1000 milliequivalents (mEq). For example, 1 mole of potassium ions (K^+) and 1 mole of chloride ions (Cl^-) are each 1 Eq (1000 mEq), but 1 mole of Ca^{2+} is 2 Eq (2000 mEq) because the calcium ion has a charge of +2.

The Na^+ concentration in the ECF averages about 140 mEq/L, versus 10 mEq/L or less in the ICF. Potassium is the main cation in the ICF, where its concentration reaches 160 mEq/L. The concentration of K^+ in the ECF is generally very low, from 3.5 to 5.5 mEq/L (look back at **Figure 27-2**).

Two general rules concerning Na^+ and K^+ balance are worth knowing:

- The most common problems with electrolyte balance are caused by an imbalance between gains and losses of Na^+ .
- Problems with K^+ balance are less common but significantly more dangerous than problems related to Na^+ balance.

Let's examine the contributions of these ions to electrolyte balance.

Sodium Balance

The total amount of sodium ions in the ECF represents a balance between two factors:

- *Sodium Ion Uptake across the Digestive Epithelium*. Sodium ions enter the ECF by crossing the digestive epithelium through diffusion and carrier-mediated transport. The rate of absorption varies directly with the amount of sodium in the diet.
- *Sodium Ion Excretion by the Kidneys and Other Sites*. Sodium ion losses take place primarily by excretion in urine and through perspiration. The kidneys are the most important sites of Na^+ regulation. We discussed the mechanisms for Na^+ reabsorption by the kidneys in Chapter 26.

A person in sodium balance typically gains and loses 48–144 mEq (1.1–3.3 g) of Na^+ each day. When Na^+ gains exceed Na^+ losses, the total Na^+ content of the ECF increases. When losses exceed gains, the Na^+ content decreases. However, a change in the Na^+ content of the ECF does not produce a change in the Na^+ concentration. When Na^+ intake or output changes, a corresponding gain or loss of water tends to keep the Na^+ concentration constant. For example, if a person eats a very salty meal, the osmotic concentration of the ECF will not increase. When Na^+ are pumped across the digestive

epithelium, the solute concentration in that portion of the ECF increases, and that of the intestinal contents decreases. Osmosis then occurs: Additional water enters the ECF from the digestive tract, increasing the blood volume and blood pressure. For this reason, people with high blood pressure or a renal salt sensitivity are advised to restrict the amount of salt in their diets.

Sodium Balance and ECF Volume

The sodium ion regulatory mechanism is diagrammed in **Figure 27–5**. It changes the ECF volume but keeps the Na^+ concentration stable. If a person consumes large amounts of salt *without* adequate fluid, as when eating salty potato chips without taking a drink, the plasma Na^+ concentration increases temporarily. A change in ECF volume soon follows, however. Fluid will exit the ICF in a fluid shift, increasing ECF volume and decreasing the Na^+ concentration somewhat. The secretion of ADH restricts water loss and stimulates thirst, promoting additional water consumption. Due to the inhibition of water receptors in the pharynx, ADH secretion begins even before Na^+ absorption occurs. The ADH secretion rate

increases more after Na^+ absorption, due to osmoreceptor stimulation.

When sodium ion losses exceed gains, the volume of the ECF decreases. This reduction occurs without a significant change in the osmotic concentration of the ECF. Thus, if a person perspires heavily but consumes only water, they will lose Na^+ , and the osmotic concentration of the ECF will decrease briefly. However, as soon as the osmotic concentration drops by 2% or more, ADH secretion decreases, so water losses by the kidneys increase. As water leaves the ECF in a fluid shift, the osmotic concentration returns to normal.

Minor changes in ECF volume do not matter, because they do not cause adverse physiological effects. If, however, regulation of the Na^+ concentration results in a large change in ECF volume, the situation will be corrected by the same homeostatic mechanisms responsible for regulating blood volume and blood pressure. This is the case because when ECF volume changes, so does plasma volume and, in turn, blood volume. If ECF volume increases, blood volume increases, and if ECF volume decreases, blood volume decreases. As described in Chapter 21, blood

Figure 27–5 Homeostatic Regulation of Sodium Ion Concentration in Body Fluids.

Figure 27-6 Integration of Fluid Volume Regulation and Sodium Ion Concentration in Body Fluids.

volume has a direct effect on blood pressure. An increase in blood volume increases blood pressure, and a decrease in blood volume decreases blood pressure.

The net result is that homeostatic mechanisms can monitor ECF volume indirectly by monitoring blood pressure. The receptors involved are baroreceptors at the carotid sinuses, the aortic arch, and the right atrium. The regulatory steps involved are reviewed in **Figure 27-6**.

Disorders of Sodium Balance

Sustained abnormalities in the Na⁺ concentration in the ECF occur only when there are severe problems with fluid balance, such as dehydration or hyperhydration. When the body's water content increases enough to decrease the

Na⁺ concentration of the ECF below 135 mEq/L, a state of **hyponatremia** (*natrium*, sodium) exists. When body water content decreases, the Na⁺ concentration increases. When that concentration exceeds 145 mEq/L, **hypernatremia** exists.

If the ECF volume is inadequate, both blood volume and blood pressure decrease, and the renin-angiotensin-aldosterone system is activated. In response, losses of water and Na⁺ are decreased, and gains of water and Na⁺ are increased. The net result is that ECF volume increases. Although the total amount of Na⁺ in the ECF is increasing (gains exceed losses), the Na⁺ concentration in the ECF remains unchanged, because osmotic water movement accompanies Na⁺ absorption.

If the plasma volume becomes abnormally large, venous return increases, stretching the atrial and ventricular walls and stimulating the release of natriuretic peptides (ANP and BNP). This in turn decreases thirst and blocks the secretion of ADH and aldosterone, which together promote water or salt conservation. As a result, salt and water loss by the kidneys increases and the volume of the ECF decreases.

Potassium Balance

About 98% of the body's potassium is in the ICF. Cells expend energy to recover K^+ as they diffuse across their plasma membranes and into the ECF. The K^+ concentration outside the cell is relatively low, and the concentration in the ECF at any moment represents a balance between (1) the rate of gain across the digestive epithelium and (2) the rate of loss into urine.

The K^+ concentration in the ECF is regulated by adjustments to K^+ losses in urine. This occurs by controlling the rate of active secretion by ion pumps along the distal convoluted tubule (DCT) of the nephron and the collecting system. Whenever a Na^+ is reabsorbed from the tubular fluid, it generally is exchanged for a cation (typically K^+) from the peritubular fluid. Urinary K^+ losses are usually limited to the amount gained by absorption across the digestive epithelium, typically 50–150 mEq (1.9–5.8 g) per day. (Potassium ion losses in feces and perspiration are negligible.)

The rate of tubular secretion of K^+ into urine varies in response to three factors:

- **Changes in the K^+ Concentration of the ECF.** In general, the higher the extracellular concentration of K^+ , the higher the rate of secretion.
- **Changes in pH.** When the pH of the ECF decreases, so does the pH of peritubular fluid. The rate of K^+ secretion then decreases, because H^+ , rather than K^+ , are secreted in exchange for Na^+ in tubular fluid. The mechanisms for H^+ secretion are summarized in **Figure 26–13c**.
- **The Level of Aldosterone.** The hormone aldosterone strongly affects the rate at which K^+ are lost in urine. The ion pumps that are sensitive to this hormone reabsorb Na^+ from tubular fluid in exchange for K^+ from peritubular fluid. Aldosterone secretion is stimulated by angiotensin II as part of the regulation of blood volume. A high plasma K^+ concentration also stimulates aldosterone secretion directly. Either way, under the influence of aldosterone, the amount of Na^+ conserved and the amount of K^+ excreted in urine are directly related.

Two disorders of K^+ imbalance are hypokalemia and hyperkalemia. **Hypokalemia** (*hypo-*, below + *kalium*, potassium) is a deficiency of K^+ in the bloodstream. **Hyperkalemia** (*hyper-*, above) is an elevated level of K^+ in the bloodstream (**Figure 27–7**).

Clinical Note Athletes and Salt Loss

Unfounded notions and rumors about water and salt requirements during exercise are common. Sweat is a hypotonic solution that contains Na^+ in lower concentration than the ECF. As a result, a person who is sweating profusely loses more water than salt. This loss leads to an increase in the Na^+ concentration of the ECF. The water content of the ECF decreases as the water loss occurs, so blood volume decreases. Clinically, this condition is called *volume depletion*. Because volume depletion takes place while blood is being shunted away from the kidneys, kidney function is impaired. As a result, wastes accumulate in the blood.

To prevent volume depletion, exercising athletes should drink liquids at regular intervals. The primary problem in volume depletion is water loss. Research has revealed no basis for the rumor that cramps will result if a person drinks while exercising. The best choice for rehydration is plain water. Body reserves of electrolytes are sufficient to tolerate extended periods of strenuous activity. Problems with Na^+ balance are extremely unlikely, except during marathons or other activities that involve maximal exertion for more than 6 hours. However, both volume depletion (causing acute renal failure) and water intoxication (causing fatal hyponatremia) have occurred in marathon runners.

Clinical Note Sports Drinks

Some sports drinks contain sugars and vitamins as well as electrolytes. During endurance events (marathons, ultramarathons, and distance cycling), solutions containing less than 10 g/dL of glucose may improve performance if consumed late in the event, when metabolic reserves are exhausted. However, high sugar concentrations (above 10 g/dL) can cause cramps, diarrhea, and other problems. The benefit of “glucose polymers” (often cornstarch) in sports drinks has yet to be proved. Drinking beverages fortified with vitamins is actively discouraged: Vitamins are not lost during exercise, and the consumption of these beverages in large volumes could, over time, cause hypervitaminosis.

Tips

The chemical symbols for sodium (Na) and potassium (K) are derived from their Latin names, **N**atrium and **K**alium.

Figure 27–7 Major Factors Involved in Disturbances of Potassium Ion Balance.

Balance of Other Electrolytes

The ECF concentrations of other electrolytes are also regulated. Here we consider the most important ions involved: calcium, magnesium, phosphate, and chloride.

Calcium Balance

Calcium is the most abundant mineral in the body. A person has 1–2 kg (2.2–4.4 lb) of this element, and 98% of it is in the skeleton. In addition to forming the crystalline component of bone, calcium ions play key roles in controlling muscular and neural activities, in blood clotting, as cofactors for enzymatic reactions, and as second messengers.

As noted in Chapters 6 and 18, calcium homeostasis primarily reflects an interplay between the reserves in bone, the rate of absorption across the digestive tract, and the rate of loss by the kidneys. The hormones parathyroid hormone (PTH), calcitriol, and (to a lesser degree) calcitonin maintain calcium homeostasis in the ECF. Parathyroid hormone and calcitriol increase the Ca^{2+} concentration. Their actions are opposed by calcitonin.

A small amount of Ca^{2+} is lost in the bile. Under normal circumstances, very few Ca^{2+} escape in urine or feces. To keep pace with these losses, an adult must absorb only 0.8–1.2 g/day of Ca^{2+} . That amount represents only about 0.03% of the calcium reserve in the skeleton. PTH from the parathyroid glands and calcitriol from the kidneys stimulate Ca^{2+} absorption by the digestive tract and Ca^{2+} reabsorption along the distal convoluted tubule (DCT) of the kidneys' nephrons.

Hypercalcemia exists when the Ca^{2+} concentration of the ECF exceeds 5.3 mEq/L. The primary cause of hypercalcemia in adults is *hyperparathyroidism*, a condition resulting from

excessive PTH secretion. Less common causes include malignant cancers of the breast, lung, kidney, and bone marrow, and excessive use of calcium or vitamin D supplements. Severe hypercalcemia (12–13 mEq/L) causes such signs and symptoms as fatigue, confusion, cardiac arrhythmias, and calcification of the kidneys and soft tissues throughout the body.

Hypocalcemia exists when the Ca^{2+} concentration is under 4.3 mEq/L. *Hypoparathyroidism* (inadequate PTH secretion), vitamin D deficiency, or chronic renal failure is typically responsible for hypocalcemia. Signs and symptoms include muscle spasms, sometimes with generalized convulsions, weak heartbeats, cardiac arrhythmias, and osteoporosis.

Magnesium Balance

The adult body contains about 29 g of magnesium. Almost 60% of it is in the skeleton. The magnesium ions (Mg^{2+}) in body fluids are found primarily in the ICF. The cytosolic concentration of Mg^{2+} averages about 26 mEq/L. Magnesium ions are required as a cofactor for several important enzymatic reactions, including the phosphorylation of glucose within cells and the use of ATP by contracting muscle fibers.

The typical range of Mg^{2+} concentration in the ECF is 1.4–2.0 mEq/L, considerably lower than the level in the ICF. The nephron proximal convoluted tubule (PCT) reabsorbs magnesium ions very effectively. Keeping pace with the daily urinary loss requires a minimum dietary intake of only 24–32 mEq (0.3–0.4 g) per day.

Phosphate Balance

Phosphate ions (PO_4^{3-}) are required for bone mineralization. About 740 g are bound up in the mineral salts of the skeleton.

Table 27–2 Electrolyte Balance for Average Adult

Ion and Normal ECF Range (mEq/L)	Disorder (mEq/L)	Signs and Symptoms	Causes	Treatments
Sodium (135–145)	Hypernatremia (>145)	Thirst, dryness and wrinkling of skin, reduced blood volume and pressure, eventual circulatory collapse	Dehydration; loss of hypotonic fluid	Ingestion of water or intravenous infusion of hypotonic solution
	Hyponatremia (<135)	Disturbed CNS function (water intoxication): confusion, hallucinations, convulsions, coma; death in severe cases	Infusion or ingestion of large volumes of hypotonic solution	Diuretic use and infusion of hypertonic salt solution
Potassium (3.5–5.0)	Hyperkalemia (>5.0)	Severe cardiac arrhythmias; muscle spasms	Renal failure; use of diuretics; chronic acidosis	Infusion of hypotonic solution; selection of different diuretics; infusion of buffers; dietary restrictions
	Hypokalemia (<3.5)	Muscular weakness and paralysis	Low-potassium diet; diuretics; hypersecretion of aldosterone; chronic alkalosis	Increase in dietary K^+ content; ingestion of K^+ tablets or solutions; infusion of potassium solution
Calcium (4.3–5.3)	Hypercalcemia (>5.3)	Confusion, muscle pain, cardiac arrhythmias, kidney stones, calcification of soft tissues	Hyperparathyroidism; cancer; vitamin D toxicity; calcium supplement overdose	Infusion of hypotonic fluid to lower Ca^{2+} levels; surgery to remove parathyroid gland; administration of calcitonin
	Hypocalcemia (<4.3)	Muscle spasms, convulsions, intestinal cramps, weak heartbeats, cardiac arrhythmias, osteoporosis	Poor diet; lack of vitamin D; renal failure; hypoparathyroidism; hypomagnesemia	Calcium supplements; administration of vitamin D
Magnesium (1.4–2.0)	Hypermagnesemia (>2.0)	Confusion, lethargy, respiratory depression, hypotension	Overdose of magnesium supplements or antacids (rare)	Infusion of hypotonic solution to lower plasma concentration
	Hypomagnesemia (<1.4)	Hypocalcemia, muscle weakness, cramps, cardiac arrhythmias, hypertension	Poor diet; alcoholism; severe diarrhea; kidney disease; malabsorption syndrome; ketoacidosis	Intravenous infusion of solution high in Mg^{2+}
Phosphate (1.8–3.0)	Hyperphosphatemia (>3.0)	No immediate symptoms; chronic elevation leads to calcification of soft tissues	High dietary phosphate intake; hypoparathyroidism	Dietary reduction; PTH supplementation
	Hypophosphatemia (<1.8)	Anorexia, dizziness, muscle weakness, cardiomyopathy, osteoporosis	Poor diet; kidney disease; malabsorption syndrome; hyperparathyroidism; vitamin D deficiency	Dietary improvement; vitamin D and/or calcitriol supplementation
Chloride (100–108)	Hyperchloremia (>108)	Acidosis, hyperkalemia	Dietary excess; increased chloride retention	Infusion of hypotonic solution to lower plasma concentration
	Hypocholema (<100)	Alkalosis, anorexia, muscle cramps, apathy	Vomiting; hypokalemia	Diuretic use and infusion of hypertonic salt solution

In body fluids, the most important functions of PO_4^{3-} involve the ICF. Inside cells these ions are required for the formation of high-energy compounds, the activation of enzymes, and the synthesis of nucleic acids.

The PO_4^{3-} concentration of the plasma is usually 1.8–3.0 mEq/L. Phosphate ions are reabsorbed from tubular fluid along the proximal convoluted tubule (PCT). Calcitriol stimulates PO_4^{3-} reabsorption along the PCT. Urinary and fecal losses of PO_4^{3-} amount to 30–45 mEq (0.8–1.2 g) per day.

Chloride Balance

Chloride ions are the most abundant anions in the ECF. The normal plasma concentration is 100–108 mEq/L. In the ICF, the Cl^- concentration is usually low (3 mEq/L). Chloride ions are absorbed across the digestive tract together with Na^+ . Several carrier proteins along the renal tubules

reabsorb Cl^- with Na^+ . The amount of Cl^- loss is small. A gain of 48–146 mEq (1.7–5.1 g) per day will keep pace with losses in urine and perspiration.

Additional information about sodium, potassium, and these other ions is listed in **Table 27–2**. This table also includes information about disorders that occur if there is too much or too little of them in the body.

✓ Checkpoint

- Identify four physiologically important cations and two important anions in the ECF.
- Why does prolonged sweating increase the plasma Na^+ level?
- Which is more dangerous, disturbances of Na^+ balance or disturbances of K^+ balance? Explain your answer.

See the blue Answers tab at the back of the book.

27-5 In acid–base balance, buffer systems as well as respiratory and renal compensation regulate pH changes in body fluids

Learning Outcome Explain the buffer systems that balance the pH of the ICF and ECF, and describe the compensatory mechanisms involved in maintaining acid–base balance.

The topic of **pH**—a measure of the acidity or alkalinity of a solution—and the chemical nature of acids, bases, and buffers was introduced in Chapter 2. **Table 27–3** reviews key terms important to the following discussion. For a more detailed review, refer to the appropriate sections of Chapter 2 before proceeding.

The pH of body fluids reflects interactions among all the acids, bases, and salts in solution in the body. Therefore, the pH of body fluids can be altered by adding either acids or bases. The pH of the ECF normally remains within narrow limits, usually 7.35–7.45. Any deviation from the normal range is extremely dangerous. Changes in the H^+ concentration disrupt the stability of plasma membranes, alter the structure of proteins, and change the activities of important enzymes. A person could not survive for long with an ECF pH below 6.8 or above 7.7.

When the pH of blood falls below 7.35, *acidemia* exists. The physiological state that results is called **acidosis**. When the pH of blood rises above 7.45, *alkalemia* exists. The physiological state that results is called **alkalosis**.

Acidosis and alkalosis affect virtually all body systems, but the nervous and cardiovascular systems are particularly sensitive to changes in pH. For example, severe acidosis (pH below 7.0) can be deadly, because (1) central nervous system function deteriorates, and the person may become comatose; (2) cardiac contractions grow weak and irregular, and signs

and symptoms of heart failure may develop; and (3) peripheral vasodilation produces a dramatic decrease in blood pressure, potentially producing circulatory collapse.

The control of pH, or **acid–base balance**, is a homeostatic process of great physiological and clinical significance. Several mechanisms contribute to this process, including *buffer systems* and compensation by the respiratory and urinary systems. The *combination* of buffer systems and respiratory and renal mechanisms maintains body pH within narrow limits. Both acidosis and alkalosis are dangerous, but in practice, problems with acidosis are much more common. This is so because normal cellular activities generate several types of acids.

Types of Acids in the Body

There are three general categories of acids in the body: (1) **fixed acids**, which do not leave solution; (2) **metabolic acids**, which take part in or are produced by cellular metabolism; and (3) **volatile acids**, which can leave the body and enter the atmosphere through the lungs. **Figure 27–8** gives examples of each. In general, fixed acids and metabolic acids do not greatly affect pH, so let's look at a volatile acid that might.

Carbonic acid (H_2CO_3) forms spontaneously from carbon dioxide (CO_2) and water in body fluids. This reaction proceeds much more rapidly in the presence of the enzyme *carbonic anhydrase*. This enzyme is found in the cytoplasm of red blood cells, liver and kidney cells, parietal cells of the stomach, and many other types of cells.

The partial pressure of carbon dioxide (P_{CO_2}) is the most important factor affecting the pH in blood. Most of the CO_2 in solution is converted to carbonic acid, and most of the carbonic acid dissociates into H^+ and **bicarbonate ions** (HCO_3^-). For this reason, the partial pressure of CO_2 and the pH are inversely related, as the seesaw illustrates in **Figure 27–9**. In other words, when the CO_2 level increases, additional H^+ and bicarbonate ions are released, so the pH decreases. (Recall that the pH is a *negative exponent*, so when the concentration of H^+ goes up, the pH value goes down.)

In contrast, as CO_2 leaves the bloodstream and diffuses into the alveoli, the number of H^+ and bicarbonate ions in the alveolar capillaries decreases, and blood pH increases.

Mechanisms of pH Control: Buffer Systems

To maintain acid–base balance over long periods of time, the body must balance gains and losses of H^+ . Hydrogen ions are gained at the digestive tract and through metabolic activities within cells. The kidneys eliminate H^+ by secreting them into urine. The lungs eliminate H^+ by forming water and CO_2 from H^+ and HCO_3^- . These sites of elimination are far removed from the sites of acid production. As the hydrogen ions travel through the body, they must be neutralized to avoid tissue damage.

Buffers in body fluids temporarily neutralize the acids produced by normal metabolic operations. To understand

Table 27–3 A Review of Important Terms Relating to Acid–Base Balance

pH	The negative exponent (negative logarithm) of the hydrogen ion concentration $[H^+]$
Neutral	A solution with a pH of 7; the solution contains equal numbers of hydrogen ions and hydroxide ions
Acidic	A solution with a pH below 7; in this solution, hydrogen ions (H^+) predominate
Basic, or alkaline	A solution with a pH above 7; in this solution, hydroxide ions (OH^-) predominate
Acid	A substance that dissociates to release hydrogen ions, decreasing pH
Base	A substance that dissociates to release hydroxide ions or accept hydrogen ions, increasing pH
Salt	An ionic compound consisting of a cation other than hydrogen and an anion other than a hydroxide ion
Buffer	A substance that tends to oppose changes in the pH of a solution by removing or replacing hydrogen ions; in body fluids, buffers maintain blood pH within normal limits (7.35–7.45)

Figure 27–8 Three Classes of Acids Found in the Body.

how buffers work, we need a bit of review of acids and bases. Recall from Chapter 2 that we can categorize **acids** and **bases** as either *strong* or *weak*:

- **Strong acids** and **strong bases** dissociate completely in solution. For example, hydrochloric acid (HCl), a strong acid, dissociates in solution by the reaction

- When **weak acids** or **weak bases** enter a solution, a significant number of molecules remain intact, so dissociation is not complete. For example, carbonic acid is a weak acid. At the normal pH of the ECF, an equilibrium exists, and the reaction can be diagrammed as follows:

**Figure 27–9** The Basic Relationship between P_{CO_2} and Blood pH. The P_{CO_2} is inversely related to the pH.

If the same concentration of a weak acid and a strong acid are placed in separate solutions, the weak acid will release fewer hydrogen ions and have less effect on the pH of the solution than will the strong acid.

Buffers are dissolved compounds that stabilize the pH of a solution by adding or removing H^+ . Buffers include weak acids that can donate H^+ , and weak bases that can absorb H^+ . A **buffer system** in body fluids generally consists of a combination of a weak acid and the anion released by its dissociation. The anion (here represented as Y) functions as a weak base. In solution, molecules of the weak acid exist in equilibrium with its dissociation products. In chemical notation, this relationship is represented as

Adding H^+ to the solution upsets the equilibrium. As a result, additional molecules of the weak acid (HY) form, removing some of the H^+ from the solution.

The body has three major buffer systems: the *phosphate buffer system*, the *protein buffer systems*, and the *carbonic acid–bicarbonate buffer system*. Each has slightly different characteristics and distributions (**Figure 27–10**).

As we look more closely at these buffer systems, remember that they provide only a temporary solution to an acid–base imbalance. To preserve homeostasis, the H^+ that these

systems capture must ultimately be either permanently tied up in water molecules, through the removal of CO_2 by the lungs, or removed from body fluids, through secretion by the kidneys. For that, respiratory and renal mechanisms are needed, as described later in this section.

The Phosphate Buffer System

The **phosphate buffer system** consists of the weak acid *dihydrogen phosphate* $H_2PO_4^-$ and the released anion *monohydrogen phosphate* (HPO_4^{2-}) (**Figure 27–10a**). The reversible reaction involved is

In addition, cells contain a *phosphate reserve* in the form of the weak base *sodium monohydrogen phosphate* (Na_2HPO_4). The dissociation of this weak base provides additional monohydrogen phosphate for use by this buffer system:

Figure 27–10 Buffer Systems in Body Fluids.

In which body fluid do the phosphate and protein buffer systems help regulate the pH?

The phosphate buffer system is quite important in buffering the pH of the ICF. This system is also important in stabilizing the pH of urine. In the ECF, the phosphate buffer system plays only a supporting role in the regulation of pH, primarily because the concentration of bicarbonate ions far exceeds that of dihydrogen phosphate.

Protein Buffer Systems

Protein buffer systems depend on the ability of amino acids to respond to pH changes by accepting or releasing H^+ , that is, by acting as a base or an acid (**Figure 27–10b**). Such molecules are said to be *amphoteric* (*ampho*, both).

The effects of protein buffer systems are very important in both the ECF and the ICF. In the ICF of active cells, structural and other proteins provide an extensive buffering capability. Their buffering prevents destructive changes in pH when cellular metabolism produces metabolic acids, such as lactic acid or pyruvic acid. Because exchange occurs between the ICF and the ECF, the protein buffer systems can also help stabilize the pH of the ECF. For example, when the pH of the ECF decreases, cells pump H^+ out of the ECF and into the ICF, where intracellular proteins can buffer them. When the pH of the ECF increases, pumps in plasma membranes move H^+ out of the ICF and into the ECF. These mechanisms can assist in buffering the pH of the ECF, but the process is slow. Hydrogen ions must be individually transported across the plasma membrane. For this reason, the protein buffer systems in most cells cannot make rapid, large-scale adjustments in the pH of the ECF.

All proteins function as *amino acid buffers*. In addition, there are two specialized protein buffer systems that help to maintain the pH of blood: *plasma protein buffers* (**Figure 27–10b**) and the *hemoglobin buffer system*.

Amino Acid Buffers. The underlying buffering mechanism of amino acids is shown in **Figure 27–11**:

- If pH increases (becomes more basic), the carboxyl group ($—COOH$) of the amino acid can dissociate, acting as a weak acid and releasing an H^+ . The carboxyl group then

becomes a carboxylate ion ($—COO^-$). At the normal pH of body fluids (7.35–7.45), the carboxyl groups of most amino acids have already given up a H^+ . (Proteins carry negative charges mainly for that reason.) However, some amino acids, notably histidine and cysteine, have R groups (side chains) that will donate H^+ if the pH increases outside the normal range.

- In a neutral solution, an amino acid carries both positive and negative charges. This state is called a *zwitterion* (the term is derived from German meaning *hybrid ion*).
- If pH decreases (becomes more acidic), the carboxylate ion and the amino group ($—NH_2$) can act as weak bases and accept additional H^+ , forming a carboxyl group ($—COOH$) and an amino ion ($—NH_3^+$), respectively. In free amino acids, both the main structural chain and the side chain can act as buffers. In a protein, most of the carboxyl and amino groups in the main chain are tied up in peptide bonds. Only the exposed amino group and carboxyl group at either end of a protein are available as buffers. As a result, most of the buffering capacity of proteins is provided by the R groups of amino acids.

The Hemoglobin Buffer System. The situation is somewhat different for red blood cells. These cells, which contain approximately 5.5% of the ICF, are normally suspended in the plasma. They are densely packed with hemoglobin, and their cytoplasm contains large amounts of carbonic anhydrase. Red blood cells (RBCs) have a significant effect on the pH of the ECF, because they absorb CO_2 from the plasma and convert it to carbonic acid. Carbon dioxide can diffuse across the RBC membrane very quickly, so no transport mechanism is needed. As the carbonic acid dissociates within an RBC, the bicarbonate ions diffuse into the plasma in exchange for chloride ions, a swap known as the *chloride shift*. Hemoglobin molecules buffer the hydrogen ions (look back at **Figure 23–22**). In the lungs, the entire reaction sequence diagrammed in **Figure 23–23** proceeds in reverse. This mechanism is known as the **hemoglobin buffer system**.

27

Figure 27–11 The Role of Amino Acid Buffers in Protein Buffer Systems. An amino acid in solution is a zwitterion and has both a negative and positive charge. Depending on the pH of their surroundings, amino acids either donate an H^+ (as at left) or accept an H^+ (as at right). Additionally, several different R groups may release or absorb H^+ .

The hemoglobin buffer system is the only intracellular buffer system that can have an immediate effect on the pH of the ECF. This buffer system helps prevent drastic changes in pH when the plasma P_{CO_2} is increasing or decreasing.

The Carbonic Acid–Bicarbonate Buffer System

Body cells generate CO_2 virtually 24 hours a day. (Exceptions are red blood cells, some cancer cells, and tissues temporarily deprived of oxygen.) As we have seen, most of the CO_2 is converted to carbonic acid, which then dissociates into a hydrogen ion and a bicarbonate ion (HCO_3^-). The carbonic acid and its dissociation products form the **carbonic acid–bicarbonate buffer system**. The primary role of this buffer system is to prevent changes in pH caused by metabolic acids and fixed acids in the ECF (**Figure 27–10c**).

The carbonic acid–bicarbonate buffer system consists of the reaction introduced in our discussion of volatile acids (**Figure 27–12a**):

Because the reaction is freely reversible, a change in the concentration of any one component affects the concentrations of all others. For example, if H^+ are added, most of them will be removed by interactions with HCO_3^- , forming H_2CO_3 . In the process, the HCO_3^- act as a weak base that buffers the excess H^+ . The H_2CO_3 formed in this way in turn

dissociates into CO_2 and H_2O (**Figure 27–12b**). The lungs can then excrete the extra CO_2 . In effect, this reaction takes the H^+ released by a strong metabolic or fixed acid and generates a volatile acid that can easily be eliminated.

The carbonic acid–bicarbonate buffer system can also protect against increases in pH, although such changes are rare. If H^+ are removed from the plasma, the reaction is driven to the right: The P_{CO_2} decreases, and H_2CO_3 dissociates to replace the missing H^+ .

The carbonic acid–bicarbonate buffer system has three important limitations:

- *It cannot protect the ECF from changes in pH that result from an increased or decreased level of CO_2 .* A buffer system cannot protect against changes in the concentration of its own weak acid. As **Figure 27–12a** indicates, an equilibrium exists among the components of this buffer system. Thus, in this system, the addition of excess H^+ from an outside source would drive the reaction to the left. But the addition of excess CO_2 would form H_2CO_3 and drive the reaction to the right. The dissociation of H_2CO_3 would release H^+ and HCO_3^- , decreasing the pH of the blood.
- *It can function only when the respiratory system and the respiratory control centers are working normally.* Normally, the increase in P_{CO_2} that occurs when fixed acids or metabolic acids are buffered stimulates an increase in the respiratory rate. This increase accelerates the removal of CO_2 by the lungs. The efficiency of the buffer system will be reduced

Figure 27–12 The Carbonic Acid–Bicarbonate Buffer System.

if the respiratory passageways are blocked, or blood flow to the lungs is impaired, or the respiratory centers do not respond normally. This buffer system cannot eliminate H^+ and remove the threat to homeostasis unless the respiratory system is functioning normally.

- *The ability to buffer acids is limited by the availability of bicarbonate ions.* Every time an H^+ is removed from the plasma, an HCO_3^- goes with it. When all the HCO_3^- have been tied up, buffering capabilities are lost.

Problems due to a lack of bicarbonate ions are rare, for several reasons. First, body fluids contain a large reserve of HCO_3^- , mostly in the form of dissolved molecules of the weak base *sodium bicarbonate* ($NaHCO_3$). This readily available supply of HCO_3^- is known as the **bicarbonate reserve**. The reaction involved (**Figure 27–12a**) is

When H^+ enter the ECF, the HCO_3^- tied up in H_2CO_3 molecules are replaced by HCO_3^- from the bicarbonate reserve (**Figure 27–12b**).

Second, additional HCO_3^- can be generated by the kidneys, through mechanisms described in Chapter 26 (look back at **Figure 26–13c**). In the distal convoluted tubule of the nephron and collecting system, carbonic anhydrase converts CO_2 within tubular cells into H_2CO_3 , which then dissociates. The H^+ is pumped into tubular fluid in exchange for a Na^+ , and the HCO_3^- is transported into peritubular fluid in exchange for a Cl^- . In effect, tubular cells remove HCl from peritubular fluid in exchange for $NaHCO_3$.

Regulation of Acid–Base Balance

Buffer systems can tie up excess H^+ , but they provide only a temporary solution to an acid–base imbalance. The H^+ are rendered harmless; they are not eliminated. To preserve homeostasis, the captured H^+ must ultimately be either permanently tied up in water molecules, through the removal of CO_2 by the lungs, or removed from body fluids, through secretion by the kidneys.

Suppose that a buffer molecule prevents a change in pH by binding an H^+ that enters the ECF. That buffer molecule is then tied up, reducing the capacity of the ECF to cope with any additional H^+ . Eventually, all the buffer molecules are bound to H^+ , and further pH control becomes impossible.

The situation can be resolved only by removing H^+ from the ECF (thereby freeing the buffer molecules) or by replacing the buffer molecules. Similarly, if a buffer provides an H^+ to maintain normal pH, homeostatic conditions will return only when either another H^+ has been obtained or the buffer has been replaced.

Regulating acid–base balance thus includes balancing H^+ gains and losses. This “balancing act” involves coordinating the actions of buffer systems with respiratory and renal compensation mechanisms. These mechanisms support the buffer systems by (1) secreting or absorbing H^+ , (2) controlling the excretion of acids and bases, and, when necessary, (3) generating additional buffers. It is the combination of buffer systems and these respiratory and renal mechanisms that maintains body pH within narrow limits.

Respiratory Compensation

Respiratory compensation is a change in the respiratory rate that helps stabilize the pH of the ECF. Respiratory compensation takes place whenever body pH strays outside normal limits. Such compensation works because respiratory activity has a direct effect on the carbonic acid–bicarbonate buffer system. Increasing or decreasing the rate of respiration alters pH by decreasing or increasing the P_{CO_2} . When the P_{CO_2} increases, the pH decreases, because the addition of CO_2 drives the carbonic acid–bicarbonate buffer system to the right. When the P_{CO_2} decreases, the pH increases because the removal of CO_2 drives that buffer system to the left.

We described the mechanisms responsible for the control of respiratory rate in Chapter 23. Here we present only a summary. (To review, look back at **Spotlight Figure 23–25** and **Figure 23–26**).

Chemoreceptors of the carotid and aortic bodies are sensitive to the P_{CO_2} of circulating blood. Other receptors, located on the ventrolateral surfaces of the medulla oblongata, monitor the P_{CO_2} of the CSF. A rise in P_{CO_2} stimulates the chemoreceptors, leading to an increase in the respiratory rate. As the rate of respiration increases, more CO_2 is lost at the lungs, so the P_{CO_2} returns to a normal level. Conversely, when the P_{CO_2} of the blood or CSF decreases, the chemoreceptors are inhibited. Respiratory activity becomes depressed and the breathing rate decreases, causing an elevation of the P_{CO_2} in the ECF.

Renal Compensation

Renal compensation is a change in the rates of H^+ and HCO_3^- secretion or reabsorption by the kidneys in response to changes in plasma pH. Under normal conditions, the body generates enough metabolic and fixed acids to add about 100 mEq of H^+ to the ECF each day. An equivalent number of H^+ must be excreted in urine to maintain acid–base balance. In addition, the kidneys assist the lungs by eliminating any CO_2 that either enters the renal tubules during filtration or diffuses into the tubular fluid as it travels toward the renal pelvis.

Hydrogen ions are secreted into the tubular fluid along the proximal convoluted tubule (PCT), the distal convoluted tubule (DCT), and the collecting system. (The basic mechanisms

involved are shown in **Figures 26-12 and 26-13c**.) The ability to eliminate many H^+ in a normal volume of urine depends on the presence of buffers in the urine. The secretion of H^+ can continue only until the pH of the tubular fluid reaches 4.0–4.5. (At that point, the H^+ concentration gradient is so great that H^+ leak out of the tubule as fast as they are pumped in.)

If the tubular fluid lacked buffers to absorb the H^+ , the kidneys could secrete less than 1% of the acid produced each day before the pH reached this limit. To maintain acid balance under these conditions, the kidneys would have to produce about 1000 liters of urine each day just to keep pace with the generation of H^+ in the body! Buffers in tubular fluid are extremely important because they keep the pH high enough for H^+ secretion to continue. Metabolic acids are being generated continuously. Without these buffering mechanisms, the kidneys could not maintain homeostasis.

The Process of pH Regulation by Kidney Tubule Cells. **Figure 27-13** diagrams the primary routes of H^+ secretion and the buffering mechanisms that stabilize the pH of tubular fluid. The three major buffers involved are the previously discussed carbonic acid–bicarbonate buffer system and phosphate buffer system, and the *ammonia buffer system* (**Figure 27-13a**). Glomerular filtration puts components of the carbonic acid–bicarbonate buffer system and the phosphate buffer system into the filtrate. Tubule cells (mainly those of the PCT) generate ammonia.

Figure 27-13a shows the secretion of H^+ , which relies on carbonic anhydrase activity within tubular cells. The H^+ generated may be pumped into the lumen in exchange for Na^+ , individually or together with Cl^- . The net result is the secretion of H^+ , accompanied by the removal of CO_2 (from the tubular fluid, the tubule cells, and the ECF), and the release of sodium bicarbonate into the ECF.

Figure 27-13b shows the generation of ammonia within the tubules. As tubule cells use the enzyme *glutaminase* to break down the amino acid *glutamine*, amino groups are released as either ammonium ions (NH_4^+) or ammonia (NH_3). The NH_4^+ are transported into the lumen in exchange for Na^+ in the tubular fluid. The NH_3 , which is highly volatile and toxic to cells, diffuses rapidly into the tubular fluid. There it reacts with an H^+ , forming NH_4^+ .

This reaction buffers the tubular fluid and removes a potentially dangerous compound from body fluids. The carbon chains of the glutamine molecules are ultimately converted to HCO_3^- , which is transported together with Na^+ into the ECF. The generation of ammonia by tubule cells ties up H^+ in the tubular fluid and releases sodium bicarbonate into the ECF, where it contributes to the bicarbonate reserve. These mechanisms of H^+ secretion and buffering are always functioning, but their levels of activity vary widely with the pH of the ECF.

Renal Responses to Acidosis and Alkalosis. Acidosis (low blood pH) develops when the normal plasma buffer mechanisms are stressed by excessive hydrogen ions. The kidney tubules do not distinguish among the various acids that may cause acidosis. Whether the decrease in pH results from the production of volatile, fixed, or metabolic acids, the renal contribution remains limited to (1) the secretion of H^+ , (2) the activity of buffers in the tubular fluid, (3) the removal of CO_2 , and (4) the reabsorption of sodium bicarbonate.

Tubule cells thus bolster the capabilities of the carbonic acid–bicarbonate ion buffer system. They do so by increasing the concentration of HCO_3^- in the ECF, replacing those already used to remove H^+ from solution. In a starving person, tubule cells break down amino acids, yielding ammonium ions that are pumped into the tubular fluid, bicarbonate ions to help buffer ketone bodies in the blood, and carbon chains for catabolism (**Figure 27-13b**).

When alkalosis (high blood pH) develops, (1) the rate of H^+ secretion by the kidneys decreases, (2) tubule cells do not reclaim the HCO_3^- in tubular fluid, and (3) the collecting system transports HCO_3^- into tubular fluid while releasing H^+ and Cl^- into the peritubular fluid (**Figure 27-13c**). The concentration of HCO_3^- in blood decreases, promoting the dissociation of H_2CO_3 and the release of H^+ . The additional H^+ generated by the kidneys help return the pH to a normal level.

Checkpoint

12. Identify the body's three major buffer systems.
13. What effect would a decrease in the pH of body fluids have on the respiratory rate?
14. Why must tubular fluid in nephrons be buffered?

See the blue Answers tab at the back of the book.

27-6 Disorders of acid–base balance can be classified as respiratory or metabolic

Learning Outcome Identify the most frequent disturbances of acid–base balance and explain how the body responds when the pH of body fluids varies outside normal limits.

For anyone considering a career in a health-related field, an understanding of acid–base dynamics is essential in both clinical diagnosis and patient management. Temporary shifts in the pH of body fluids occur frequently. For example, the *alkaline tide* following a meal causes a temporary increase in blood pH. Rapid and complete return to normal pH involves a combination of buffer system activity and the respiratory and renal compensatory mechanisms (**Figure 27-14**). Together these mechanisms can generally control pH very precisely, so the pH of the ECF seldom varies more than 0.1 pH unit, from 7.35 to 7.45.

Figure 27-13 pH Regulation of Tubular Fluid by Kidney Tubule Cells.

Figure 27–14 Interactions among the Carbonic Acid–Bicarbonate Buffer System and Respiratory and Renal Compensation Mechanisms in the Regulation of Plasma pH.

What is the kidney's response to alkalosis caused by the removal of H^+ ?

When buffering mechanisms are severely stressed, however, the pH drifts outside these limits, producing signs and symptoms of alkalosis or acidosis. More serious and prolonged disturbances of acid–base balance can result with the following conditions:

- **Disorders Affecting Circulating Buffers, Respiratory Performance, or Renal Function.** Several conditions, including *emphysema* and *renal failure*, are associated with dangerous changes in pH.
- **Cardiovascular Conditions.** Conditions such as *heart failure* or *hypotension* can affect the pH of internal fluids by causing fluid shifts and by changing the glomerular filtration rate and respiratory efficiency.
- **Conditions Affecting the Central Nervous System.** Neural damage or disease that affects the CNS can affect the respiratory and cardiovascular reflexes that are essential to normal pH regulation.

Serious abnormalities in acid–base balance generally have an initial *acute phase*, in which the pH moves rapidly out of the normal range. If the condition persists, physiological adjustments take place. The person then enters the *compensated phase*. However, unless the underlying problem is corrected, compensation typically cannot return the blood pH to the normal range. Even if the pH is returned to normal, the P_{CO_2} or HCO_3^- concentration can still be abnormal.

The name given to the resulting condition usually indicates the primary source of the problem:

- *Respiratory acid–base disorders* result from a mismatch between CO_2 generation in peripheral tissues and CO_2 excretion by the lungs. When a respiratory acid–base disorder is present, the CO_2 level of the ECF is abnormal.
- *Metabolic acid–base disorders* are caused by the generation of metabolic acids or fixed acids or by conditions affecting the concentration of HCO_3^- in the ECF.

Respiratory compensation alone may restore normal acid–base balance in persons with respiratory acid–base disorders. In contrast, compensation mechanisms for metabolic acid–base disorders may be able to stabilize pH, but other aspects of acid–base balance (buffer system function, bicarbonate ion and P_{CO_2} levels) remain abnormal until the underlying metabolic cause is corrected. Let's look further into both respiratory and metabolic acid–base disorders.

Respiratory Acid–Base Disorders

We can subdivide the respiratory acid–base disturbances into *respiratory acidosis* and *respiratory alkalosis*.

Respiratory Acidosis

Respiratory acidosis develops when the respiratory system cannot eliminate all the CO_2 generated by peripheral tissues. The primary sign is low blood pH due to **hypercapnia**, an increased blood P_{CO_2} . The usual cause is *hypoventilation*, an abnormally low respiratory rate. When the P_{CO_2} in the ECF rises, H^+ and HCO_3^- concentrations also begin rising as H_2CO_3 forms and dissociates. Other buffer systems can tie up some of the H^+ , but once the combined buffering capacity has been exceeded, the pH begins to fall rapidly. The effects are diagrammed in **Figure 27–15a**.

Respiratory acidosis is the most common challenge to acid–base equilibrium. Body tissues generate CO_2 rapidly. Even a few minutes of hypoventilation can cause acidosis, reducing the pH of the ECF to as low as 7.0. Under normal circumstances, the chemoreceptors that monitor the P_{CO_2} of blood and of CSF eliminate the problem by stimulating an increase in breathing rate.

If the chemoreceptors do not respond, if the breathing rate cannot be increased, or if the circulatory supply to the lungs is inadequate, the pH will continue to decrease. If the decrease is

severe, **acute respiratory acidosis** develops. Acute respiratory acidosis is an immediate, life-threatening condition. It is especially dangerous in people whose tissues are generating large amounts of CO_2 , or in those who are incapable of normal respiratory activity. For this reason, the reversal of acute respiratory acidosis is probably the major goal in the resuscitation of cardiac arrest or drowning victims. Thus, first-aid, CPR, and lifesaving courses always stress the “ABCs” of emergency care: Airway, Breathing, and Circulation.

Chronic respiratory acidosis develops when normal respiratory function has been compromised, but the compensatory mechanisms have not failed completely. For example, normal respiratory compensation may not occur in response to chemoreceptor stimulation in persons with CNS injuries and those whose respiratory centers have been desensitized by drugs such as alcohol or barbiturates. As a result, these people are prone to developing acidosis due to chronic hypoventilation.

Even when respiratory centers are intact and functional, damage to some parts of the respiratory system can prevent increased pulmonary exchange. Examples of conditions fostering chronic respiratory acidosis include emphysema, congestive heart failure, and pneumonia (which typically cause alveolar damage or blockage). Pneumothorax and respiratory muscle paralysis have a similar effect because they, too, limit adequate breathing rate.

When the pulmonary response is abnormal, the kidneys respond by increasing the rate of H^+ secretion into tubular fluid. This response slows the rate of pH change. However, renal mechanisms alone cannot return the pH to normal until the underlying respiratory or circulatory problems are corrected.

The primary problem in respiratory acidosis is that the rate of pulmonary exchange is inadequate to keep the arterial P_{CO_2} within normal limits. Breathing efficiency can typically be improved temporarily by inducing bronchodilation or by using mechanical aids that provide air under positive pressure. If breathing has stopped, artificial respiration or a mechanical ventilator is required. These measures may restore normal pH if the respiratory acidosis was not severe or prolonged. Treatment of acute respiratory acidosis is complicated by the fact that, as we will soon describe, it causes a complementary metabolic acidosis as oxygen-starved tissues generate lactate and H^+ .

Respiratory Alkalosis

Problems resulting from **respiratory alkalosis** are uncommon (**Figure 27–15b**). Respiratory alkalosis develops when respiratory activity lowers the blood P_{CO_2} to a below-normal level, a condition called **hypocapnia** (*-capnia*, presence of CO_2). A temporary hypocapnia can be produced by *hyperventilation* when increased respiratory activity leads to a reduction in the arterial P_{CO_2} . Continued hyperventilation can increase the pH to a level as high as 8.0. This condition generally corrects itself, because the reduction in P_{CO_2} halts the stimulation of the chemoreceptors,

Figure 27–15 Homeostatic Regulation of Acid–Base Balance.

so the urge to breathe fades until the CO_2 level has returned to normal. Respiratory alkalosis caused by hyperventilation seldom lasts long enough to cause a clinical emergency.

Common causes of hyperventilation include physical stresses such as pain, or psychological stresses such as extreme anxiety. Hyperventilation gradually increases the pH of the CSF, and CNS function is affected. The initial symptoms involve tingling sensations in the hands, feet, and lips. The person may also feel light-headed. If hyperventilation continues, the person may lose consciousness. Unconsciousness removes any contributing psychological stimuli, and the breathing rate decreases. The P_{CO_2} then increases until the pH returns to normal.

A simple treatment for respiratory alkalosis caused by hyperventilation is to have the person rebreathe air exhaled

into a small paper bag. As the P_{CO_2} in the bag increases, so do the person's alveolar and arterial CO_2 concentrations. This change eliminates the problem and restores the pH to a normal level. Other problems with respiratory alkalosis are rare and involve primarily (1) persons adapting to high altitudes, where the low P_{CO_2} promotes hyperventilation; (2) patients on mechanical respirators; or (3) persons whose brainstem injuries render them incapable of responding to shifts in the plasma CO_2 concentration.

Metabolic Acid–Base Disorders

We can divide the metabolic acid–base disturbances into *metabolic acidosis* and *metabolic alkalosis*.

Metabolic Acidosis

Metabolic acidosis is the second most common type of acid–base imbalance (after respiratory acidosis). It has the following three major causes:

- The most widespread cause of metabolic acidosis is the production of many fixed acids or metabolic acids. The H^+ released by these acids overload the carbonic acid–bicarbonate ion buffer system, so the pH begins to decrease (**Figure 27–16a**). We considered two examples of metabolic acidosis earlier:

- **Lactic acidosis** can develop after strenuous exercise or prolonged tissue *hypoxia* (oxygen starvation) as cells rely on anaerobic metabolism (look back at **Figure 10–20**).
- **Ketoacidosis** results from the generation of large quantities of ketone bodies during the postabsorptive state of metabolism. Ketoacidosis is a problem in starvation, and a potentially lethal complication of poorly controlled diabetes mellitus. In either case, peripheral tissues cannot obtain adequate glucose from the bloodstream, and they begin metabolizing lipids and ketone bodies.

Figure 27–16 Responses to Metabolic Acidosis.

How do the lungs respond to metabolic acidosis?

- A less common cause of metabolic acidosis is an impaired ability to excrete H^+ by the kidneys (**Figure 27-16a**). For example, conditions marked by severe kidney damage, such as *glomerulonephritis*, typically result in severe metabolic acidosis. Diuretics that “turn off” the sodium–hydrogen transport system in the kidney tubules also cause metabolic acidosis. The secretion of H^+ is linked to the reabsorption of Na^+ . When Na^+ reabsorption stops, so does H^+ secretion.
- Metabolic acidosis occurs after severe bicarbonate ion loss (**Figure 27-16b**). The carbonic acid–bicarbonate ion buffer system relies on bicarbonate ions to balance hydrogen ions that threaten pH balance. A decrease in the HCO_3^- concentration in the ECF makes this buffer system less effective, and acidosis soon develops. The most common cause of HCO_3^- depletion is chronic diarrhea. Under normal conditions, most of the HCO_3^- secreted into the digestive tract in pancreatic, hepatic, and mucous secretions are reabsorbed before the feces are eliminated. In diarrhea, these HCO_3^- are lost, so the HCO_3^- concentration in the ECF decreases.

The nature of the problem must be understood before treatment can begin. In some cases, the diagnosis is straightforward. For example, a patient with metabolic acidosis after a bicycle race probably has lactic acidosis. In other cases, potential causes are so varied that clinicians must piece together relevant clues to make a diagnosis.

Compensation for metabolic acidosis generally involves a combination of respiratory and renal mechanisms. Hydrogen ions interacting with bicarbonate ions form CO_2 molecules that are eliminated by the lungs. The kidneys excrete additional H^+ into the urine and generate HCO_3^- that are released into the ECF.

Metabolic Alkalosis

Metabolic alkalosis occurs when the HCO_3^- concentration is elevated (**Figure 27-17**). The HCO_3^- then interact with H^+ in solution, forming H_2CO_3 . The resulting decrease in H^+ concentration causes signs of alkalosis.

Metabolic alkalosis is rare, but we noted one interesting cause in Chapter 24. The phenomenon known as the *alkaline tide* is due to the influx into the ECF of large numbers of bicarbonate ions associated with the secretion of H^+ and Cl^- by the gastric mucosa. The alkaline tide temporarily increases the HCO_3^- concentration in the ECF during meals. But bouts of repeated vomiting may bring on serious metabolic alkalosis because the stomach continues to generate stomach acids to replace those that are lost. As a result, the HCO_3^- concentration of the ECF continues to increase.

Compensation for metabolic alkalosis involves a decrease in the breathing rate, coupled with an increased loss of HCO_3^- in urine. Treatment of mild cases typically addresses the primary cause—generally by controlling the vomiting—and may involve administering solutions that contain sodium chloride (NaCl) or potassium chloride (KCl).

Figure 27-17 Responses to Metabolic Alkalosis. Metabolic alkalosis most commonly results from the loss of acids, especially stomach acid lost through vomiting. As replacement gastric acid is produced, the alkaline tide introduces many bicarbonate ions into the bloodstream, so pH increases.

Table 27–4 Changes in Blood Chemistry Associated with the Major Classes of Acid–Base Disorders

Disorder	pH (normal 7.35–7.45)	HCO ₃ [−] (mEq/L) (normal = 21–28)	P _{CO₂} (mm Hg) (normal = 35–45)	Remarks	Treatments
Respiratory acidosis	Decreased (below 7.35)	Acute: normal Compensated: increased (above 28)	Increased (above 45)	Generally caused by hypoventilation and CO ₂ buildup in tissues and blood	Improve ventilation; in some cases, with bronchodilation and mechanical assistance
Metabolic acidosis	Decreased (below 7.35)	Decreased (below 24)	Acute: normal Compensated: decreased (below 35)	Caused by buildup of metabolic or fixed acid, impaired H ⁺ elimination at kidneys, or HCO ₃ [−] loss in urine or feces	Administration of bicarbonate (gradual), with other steps as needed to correct primary cause
Respiratory alkalosis	Increased (above 7.45)	Acute: normal Compensated: decreased (below 24)	Decreased (below 35)	Generally caused by hyperventilation and reduction in plasma CO ₂ levels	Reduce respiratory rate, allow rise in P _{CO₂}
Metabolic alkalosis	Increased (above 7.45)	Increased (above 28)	Increased (above 45)	Generally caused by prolonged vomiting and associated acid loss	pH below 7.55: no treatment; pH above 7.55: may require administration of NH ₄ Cl

Treating acute cases of metabolic alkalosis may involve administering ammonium chloride (NH₄Cl). Metabolism of the ammonium ion in the liver liberates an H⁺, so in effect the introduction of NH₄Cl leads to the internal generation of H⁺ and Cl[−]. As the H⁺ diffuses into the bloodstream, the pH falls toward a normal level.

For a summary of the patterns that characterize the four major categories of acid–base disorders, please see **Table 27–4**.

Combined Respiratory and Metabolic Acidosis

Respiratory acidosis and metabolic acidosis are typically linked, because oxygen-starved tissues generate large quantities of lactic acid (lactate and H⁺) and because sustained hypoventilation leads to decreased arterial P_{O₂}. The problem can be especially serious in cases of near drowning, in which body fluids have high P_{CO₂}, low P_{O₂}, and a large amount of lactic acid generated by the muscles of the struggling person. Prompt emergency treatment is essential. The usual procedure involves some form of artificial or mechanical respiratory assistance, coupled with intravenous infusion of an isotonic solution that contains sodium lactate, sodium gluconate, or sodium bicarbonate.

The Detection of Acidosis and Alkalosis

Spotlight Figure 27–18 shows the process of diagnosing acid–base disorders. Additional steps can help in identifying possible causes of the problem and in distinguishing compensated from uncompensated conditions. These steps may include determining the *anion gap* or using a diagnostic chart.

Checkpoint

15. How would a prolonged fast affect the body's pH?
16. Why can prolonged vomiting produce metabolic alkalosis?

See the blue Answers tab at the back of the book.

27-7 Aging affects fluid, electrolyte, and acid–base balance

Learning Outcome Describe the effects of aging on fluid, electrolyte, and acid–base balance.

Fetuses and infants have very different requirements for maintaining fluid, electrolyte, and acid–base balance than do adults. A fetus obtains the water, organic nutrients, and electrolytes it needs from the maternal bloodstream. Buffers in the fetal bloodstream provide short-term pH control, and the maternal kidneys eliminate the H⁺ generated. A newborn's body water content is high: At birth, water makes up about 75% of body weight, compared with 50–60% in adults. Basic aspects of electrolyte balance are the same in newborns as in adults, but the effects of fluctuations in the diet are much more immediate in newborns because their reserves of minerals and energy sources are much smaller.

The descriptions of fluid, electrolyte, and acid–base balance in this chapter were based on the responses of healthy adults under age 40. Aging affects many aspects of fluid, electrolyte, and acid–base balance, including the following:

- Total body water content gradually decreases with age. Between ages 40 and 60, average total body water content decreases slightly, from 60% to 55% for males and from 50% to 47% for females. After age 60, the values decrease further, to about 50% for males and 45% for females. Among other effects, each decrease reduces the dilution of wastes, toxins, and any drugs that have been administered.
- A decrease in the glomerular filtration rate and in the number of functional nephrons reduces the body's ability to regulate pH through renal compensation.
- The body's ability to concentrate urine decreases, so more water is lost in urine. In addition, the rate of insensible perspiration increases as the skin becomes thinner and more delicate. Maintaining fluid balance therefore requires a higher

ACID–BASE DISORDERS

Virtually anyone who has a problem that affects the cardiovascular, respiratory, urinary, digestive, or nervous system may develop potentially dangerous acid–base imbalances. For this reason, an arterial blood gas test is done to evaluate the body's acid–base balance. Standard tests measure arterial blood pH, partial pressure of carbon dioxide (P_{CO_2}), partial pressure of oxygen (P_{O_2}), and bicarbonate (HCO_3^-) levels. These measurements make diagnosing acid–base disorders relatively straightforward. The flowchart below shows the diagnostic steps used to determine whether a person has an acid–base disorder, and to further determine what type of acidosis or alkalosis exists.

daily water intake. A reduction in ADH and aldosterone sensitivity makes older people less able than younger people to conserve body water when losses exceed gains.

- Many people over age 60 experience a net loss in body mineral content as muscle mass and skeletal mass decrease. This loss can be prevented, at least in part, by a combination of exercise and an increased dietary mineral supply.
- The reduction in vital capacity that accompanies aging reduces the body's ability to perform respiratory compensation, increasing the risk of respiratory acidosis. This problem can be compounded by arthritis, which can reduce vital capacity by limiting rib cage movements, and by emphysema, another condition that, to some degree, develops with aging.

- Disorders affecting major systems become more common with increasing age. Most, if not all, of these disorders have some effect on fluid, electrolyte, and/or acid–base balance.

Checkpoint

17. As a person ages, the glomerular filtration rate and the number of functional nephrons decrease. What effect would these changes have on pH regulation?
18. After the age of 40, does the total body water content increase or decrease?

See the blue Answers tab at the back of the book.

27 Chapter Review

Study Outline

An Introduction to Fluid, Electrolyte, and Acid–base Balance

1. The distribution of gases, nutrients, and wastes in the body is dependent on the homeostatic mechanisms that regulate volume, ion concentrations, and pH of body fluids.

27-1 Fluid balance, electrolyte balance, and acid–base balance are interrelated and essential to homeostasis

2. Maintaining normal volume and composition of extracellular and intracellular fluids is vital to life. Three types of homeostasis are involved: **fluid balance**, **electrolyte balance**, and **acid–base balance**.

27-2 Extracellular fluid (ECF) and intracellular fluid (ICF) are fluid compartments with differing solute concentrations that are closely regulated

3. The **intracellular fluid (ICF)** contains nearly two-thirds of the total body water. The **extracellular fluid (ECF)** contains the rest. Exchange occurs between the ICF and the ECF, but the two **fluid compartments** retain their distinctive characteristics. (Figures 27–1, 27–2)
4. Homeostatic mechanisms that monitor and adjust the composition of body fluids respond to changes in the ECF.
5. No receptors directly monitor fluid or electrolyte balance. Receptors involved in fluid balance and in electrolyte balance respond to changes in plasma volume and osmotic concentration.
6. Body cells cannot move water molecules by active transport. All movements of water across plasma membranes and epithelia occur passively, in response to osmotic gradients.
7. The body's content of water or electrolytes will increase if intake exceeds outflow and will decrease if losses exceed gains.

8. ADH promotes water reabsorption by the kidneys and stimulates thirst. Aldosterone increases the rate of sodium reabsorption by the kidneys. Natriuretic peptides (ANP and BNP) oppose those actions and promote fluid and electrolyte losses in urine.
9. The regulatory mechanisms of fluid balance and electrolyte balance are quite different, and the distinction is clinically important.

27-3 Fluid balance involves the regulation and distribution of water gains and losses

10. Water circulates freely within the ECF compartment.
11. Water losses are normally balanced by gains through eating, drinking, and **metabolic generation**. (Figure 27–3; Table 27–1)
12. Water movement between the ECF and ICF is called a **fluid shift**. If the ECF becomes hypertonic relative to the ICF, water will move from the ICF into the ECF until osmotic equilibrium has been restored. If the ECF becomes hypotonic relative to the ICF, water will move from the ECF into the cells, and the volume of the ICF will increase. (Figure 27–4)

27-4 In electrolyte balance, the concentrations of sodium, potassium, calcium, magnesium, phosphate, and chloride ions in body fluids are tightly regulated

13. An **equivalent** (Eq) is the amount of a positive ion or negative ion that supplies 1 mole of electrical charge, and 1 equivalent = 1000 milliequivalents (mEq).

14. Problems with electrolyte balance generally result from a mismatch between gains and losses of sodium. Problems with potassium balance are less common, but more dangerous.
15. The rate of sodium uptake across the digestive epithelium is directly proportional to the amount of sodium in the diet. Sodium losses occur mainly in urine and through perspiration. (Figure 27-5)
16. Shifts in sodium balance result in expansion or contraction of the ECF. Large variations in ECF volume are corrected by homeostatic mechanisms triggered by changes in blood volume. If the volume becomes too low, ADH and aldosterone are secreted; if the volume becomes too high, natriuretic peptides (ANP and BNP) are secreted. (Figure 27-6)
17. Potassium ion concentrations in the ECF are very low and not as closely regulated as are sodium ion concentrations. Potassium excretion increases as ECF concentrations rise, under aldosterone stimulation, and when the pH increases. Potassium retention occurs when the pH decreases. (Figure 27-7)
18. ECF concentrations of other electrolytes, such as calcium, magnesium, phosphate, and chloride, are also regulated. (Table 27-2)

27-5 In acid-base balance, buffer systems as well as respiratory and renal compensation regulate pH changes in body fluids

19. Acids and bases are either **strong** or **weak**. (Table 27-3)
20. The pH of normal body fluids ranges from 7.35 to 7.45. Variations outside this relatively narrow range produce symptoms of **acidosis** or **alkalosis**.
21. **Volatile acids** can leave solution and enter the atmosphere. **Fixed acids** remain in body fluids until excreted by the kidneys. **Metabolic acids** are participants in, or are by-products of, cellular metabolism. (Figure 27-8)
22. Carbonic acid, a volatile acid, is the most important factor affecting the pH of the ECF. In solution, CO_2 reacts with water to form carbonic acid. An inverse relationship exists between pH and the partial pressure of CO_2 . (Figure 27-9)
23. Sulfuric acid and phosphoric acid, the most important fixed acids, are generated during the catabolism of amino acids and compounds containing phosphate groups.
24. Metabolic acids include metabolic products such as lactic acid and ketone bodies.
25. A **buffer system** typically consists of a weak acid and the anion released by its dissociation. The anion functions as a weak base that can absorb H^+ . The three major buffer systems are (1) the **phosphate buffer system** in the ICF and urine, (2) **protein buffer systems** in the ECF and ICF, and (3) the **carbonic acid-bicarbonate buffer system**, most important in the ECF. (Figure 27-10)
26. The phosphate buffer system plays a supporting role in regulating the pH of the ECF, but it is important in buffering the pH of the ICF and of urine.
27. In protein buffer systems, the initial, final, and R groups of component amino acids respond to changes in pH by

accepting or releasing hydrogen ions. The **hemoglobin buffer system** is a protein buffer system that helps prevent drastic changes in pH when the P_{CO_2} is increasing or decreasing. (Figure 27-11)

28. The carbonic acid-bicarbonate buffer system prevents pH changes caused by metabolic acids and fixed acids in the ECF. The readily available supply of bicarbonate ions is the **bicarbonate reserve**. (Figure 27-12)
29. The lungs help regulate pH by affecting the carbonic acid-bicarbonate buffer system. A change in respiratory rate can raise or lower the P_{CO_2} of body fluids, affecting the body's buffering capacity. This process is called **respiratory compensation**.
30. In **renal compensation**, the kidneys vary their rates of hydrogen ion secretion and bicarbonate ion reabsorption, depending on the pH of the ECF. (Figure 27-13)

27-6 Disorders of acid-base balance can be classified as respiratory or metabolic

31. Interactions among buffer systems, respiration, and renal function normally maintain tight control of the pH of the ECF, generally within a range of 7.35–7.45. (Figure 27-14)
32. *Respiratory acid-base disorders* result when abnormal respiratory function causes an extreme increase or decrease in CO_2 levels in the ECF. *Metabolic acid-base disorders* are caused by the generation of metabolic or fixed acids or by conditions affecting the concentration of bicarbonate ions in the ECF.
33. **Respiratory acidosis** results from excessive levels of CO_2 in body fluids. (Figure 27-15a)
34. **Respiratory alkalosis** is a relatively rare condition associated with hyperventilation. (Figure 27-15b)
35. **Metabolic acidosis** results from the depletion of the bicarbonate reserve, caused by an inability to excrete hydrogen ions by the kidneys, the production of large numbers of fixed and metabolic acids, or bicarbonate loss that accompanies chronic diarrhea. (Figure 27-16)
36. **Metabolic alkalosis** results when bicarbonate ion concentrations become elevated, as occurs during extended periods of vomiting. (Figure 27-17)
37. An arterial blood gas test evaluates blood pH, P_{CO_2} , P_{O_2} , and HCO_3^- levels to recognize and classify acidosis and alkalosis as either respiratory or metabolic in nature. (Spotlight Figure 27-18; Table 27-4)

27-7 Aging affects fluid, electrolyte, and acid-base balance

38. Age-related changes that affect fluid, electrolyte, and acid-base balance include (1) reduced total body water content, (2) impaired ability to perform renal compensation, (3) increased water demands due to decreased ability to concentrate urine and reduced sensitivity to ADH and aldosterone, (4) a net loss of minerals, (5) reductions in respiratory efficiency that affect respiratory compensation, and (6) increased incidence of conditions that secondarily affect fluid, electrolyte, or acid-base balance.

Review Questions

See the blue Answers tab at the back of the book.

LEVEL 1 Reviewing Facts and Terms

- The primary components of the ECF are (a) lymph and cerebrospinal fluid, (b) plasma and serous fluids, (c) interstitial fluid and plasma, (d) all of these.
- The body fluid that has the highest K^+ concentration is the (a) interstitial fluid, (b) plasma, (c) intracellular fluid, (d) lymph.
- Osmoreceptors in the hypothalamus monitor the osmotic concentration of the ECF and secrete _____ in response to higher osmotic concentrations. (a) BNP, (b) ANP, (c) aldosterone, (d) ADH.
- Write the missing names and molecular formulas for the following reactions between the carbonic acid–bicarbonate buffer system and the bicarbonate reserve.

- (a) _____
 (b) _____
 (c) _____
- Calcium homeostasis primarily reflects (a) a balance between absorption in the gut and excretion by the kidneys, (b) careful regulation of the blood calcium level by the kidneys, (c) an interplay between parathyroid hormone and aldosterone, (d) an interplay among reserves in the bones, the rate of absorption, and the rate of excretion, (e) hormonal control of calcium reserves in the bones.
 - The *most* important factor affecting the pH of body tissues is the concentration of (a) lactic acid, (b) ketone bodies, (c) metabolic acids, (d) carbon dioxide, (e) hydrochloric acid.
 - In buffering the pH of urine, the most important buffer system is the (a) carbonic acid–bicarbonate buffer system, (b) phosphate buffer system, (c) amino acid buffers, (d) plasma protein buffers, (e) hemoglobin buffer system.
 - Respiratory alkalosis is generally caused by (a) hypoventilation and CO_2 buildup in tissues and blood, (b) prolonged vomiting and associated acid loss, (c) impaired H^+ elimination at kidneys, (d) hyperventilation and reduction in plasma CO_2 levels.
 - Metabolic alkalosis occurs when (a) bicarbonate ion concentrations become elevated, (b) a severe bicarbonate loss occurs, (c) the kidneys fail to excrete hydrogen ions, (d) ketone bodies are generated in abnormally large quantities.
 - What is the primary role of the carbonic acid–bicarbonate buffer system? What are the three limitations of this system?

LEVEL 2 Reviewing Concepts

- Hyperkalemia is promoted by (a) excessive aldosterone secretion, (b) increased urine production, (c) diseases that hamper normal K^+ secretion, (d) chronically high blood pH.
- People consuming alcohol or taking barbiturates are in the danger of developing (a) acidosis due to chronic hyperventilation, (b) acidosis due to chronic hypoventilation, (c) alkalosis due to chronic hyperventilation, (d) alkalosis due to chronic hypoventilation.
- Diabetes mellitus can become lethal when there is (a) production of a large number of fixed acids, (b) influx into the ECF of large numbers of bicarbonate ions, (c) generation of large quantities of ketone bodies, (d) production of large amounts of lactic acid.
- In the capillaries of the peripheral tissues, a chloride shift is characterized by (a) Cl^- leaving the red blood cells, (b) Cl^- entering the red blood cells, (c) CO_2 leaving the red blood cells, (d) HCO_3^- entering the red blood cells.

- Differentiate among fluid balance, electrolyte balance, and acid–base balance, and explain why each is important to homeostasis.
- What are fluid shifts? What is their function, and what factors can cause them?
- What can an exercising athlete do to prevent blood volume depletion?
- Define and give an example of (a) a volatile acid, (b) a fixed acid, and (c) a metabolic acid. Which represents the greatest threat to acid–base balance? Why?
- What are the three major buffer systems in body fluids? How does each system work?
- How does hypocalcemia affect the skeleton and skeletal muscles?
- Differentiate between respiratory compensation and renal compensation.
- Distinguish between respiratory and metabolic disorders that disturb acid–base balance.
- What change can be noticed in the total body water content after the age of 60? How does this change affect body wastes?
- Why are sports drinks containing less than 10 g/dL of glucose considered beneficial for an athlete's performance? What can be the problems associated with drinking solutions with high sugar concentrations (above 10 g/dL) during an endurance event?
- Exercise physiologists recommend that adequate amounts of fluid be ingested before, during, and after exercise. Why is fluid replacement during extensive sweating important?

LEVEL 3 Critical Thinking and Clinical Applications

- After falling into an abandoned stone quarry filled with water and nearly drowning, a young boy is rescued. In assessing his condition, rescuers find that his body fluids have high P_{CO_2} and lactate levels, and low P_{O_2} levels. Identify the underlying problem and recommend the necessary treatment to restore homeostatic conditions.
- Shelly has started dieting as she wants to lose some weight. Which of the following changes are expected to occur in her body as a result of this? (a) a decrease in the concentration of circulating ketone bodies, (b) an increase in the rate of water loss by the kidneys, (c) a decrease in the concentration of wastes, (d) a decrease in the concentration of acids, (e) a decrease in the concentration of solutes in the ECF.
- Mikala, a nursing student, has been caring for burn patients. She notices that they consistently show elevated levels of potassium in their urine and wonders why. What should you tell her?
- While visiting a foreign country, Alma inadvertently drinks some water, even though she had been advised not to. She contracts an intestinal disease that causes severe diarrhea. How would this condition affect her blood pH, urine pH, and pattern of ventilation?
- Yuka is dehydrated, so her physician prescribes intravenous fluids. The attending nurse becomes distracted and erroneously gives Yuka a hypertonic glucose solution instead of normal saline. What effect will this mistake have on Yuka's plasma ADH levels and urine volume?
- Refer to the diagnostic flowchart in *Spotlight Figure 27–18*. Use information from the blood test results in the accompanying table to categorize the suspected acid–base disorders of the patients represented in the table.

Results	Patient 1	Patient 2	Patient 3	Patient 4
pH	7.5	7.2	7.0	7.7
P_{CO_2} (mm Hg)	32	45	60	50
Na^+ (mEq/L)	138	140	140	136
HCO_3^- (mEq/L)	22	20	28	34
Cl^- (mEq/L)	106	102	101	91
Anion gap* (mEq/L)	10	18	12	11

*Anion gap = Na^+ concentration – (HCO_3^- concentration + Cl^- concentration).

CLINICAL CASE Wrap-Up When Treatment Makes You Worse

"You're having trouble with your potassium," the doctor tells Marquis.

Marquis had been in a state of electrolyte balance, in which the rates of gain and loss for each electrolyte are equal every day, but he had high blood pressure before beginning treatment. The hydrochlorothiazide diuretic he is taking works by inhibiting reabsorption of Na^+ and K^+ in the distal convoluted tubules. Recall that "water follows salt." The increased excretion of Na^+ and K^+ causes increased excretion of water, which reduces blood volume and therefore decreases pressure on the arterial walls. About 98% of the body's K^+ is in the ICF, leaving only a small amount in the ECF that is critically controlled. The fecal loss of K^+ is usually negligible, but diarrhea causes significant K^+ loss. Three days of diarrhea, combined with the new "potassium-wasting" diuretic, have pushed Marquis into a state of hypokalemia. His blood K^+ measures only 2.5 mEq/L (normal 3.5–5.0 mEq/L).

Potassium ions are critical for a variety of cell functions, particularly in electrically active cells in the nervous system, skeletal muscle, and cardiac muscle. When the blood K^+ level is low, cells cannot repolarize and are unable to fire repeatedly. This causes muscle weakness, aching, and cramping. In cardiac muscle, hypokalemia increases the resting membrane potential and increases both the duration of the action poten-

tial and the duration of the refractory period, leading to cardiac arrhythmias.

1. How should Marquis's hypokalemia be treated?
2. What is happening when Marquis complains of a sensation of a "frog jumping around" in his chest that is accompanied by dizziness?

See the blue Answers tab at the back of the book.

Related Clinical Terms

antacid: A substance used to counteract or neutralize stomach acid.

bicarbonate loading: In sports, the act of ingesting bicarbonates prior to an athletic event to neutralize acidic by-products produced during strenuous physical activity involving anaerobic metabolism.

enema: A procedure in which a liquid or gas is injected into the rectum, usually with the intention of having the rectum dispel its contents, but sometimes used to introduce drugs or to permit x-ray imaging.

fluid replacement therapy: Procedure conducted with the intent to replace body fluids lost due to disease or restricted intake; or to maintain a higher-than-normal rate of fluid excretion to ensure the removal of toxins; or possibly to administer therapeutic or anesthetic agents slowly over time.

potassium adaptation: The tolerance to increasing amounts of potassium.

syndrome of inappropriate secretion of ADH (SIADH): A condition associated with excessive ADH secretion that results in the excretion of concentrated urine. It disturbs fluid and electrolyte balance, and causes nausea, vomiting, muscle cramps, confusion, and convulsions. This syndrome can occur with some forms of cancer, such as small cell lung cancer, pancreatic cancer, prostate cancer, and Hodgkin's disease, and possibly due to several other disorders.

total body water: The sum of fluids within all compartments.

The Reproductive System

Learning Outcomes

These Learning Outcomes correspond by number to this chapter's sections and indicate what you should be able to do after completing the chapter.

- 28-1 ■ List the basic structures of the human reproductive system and summarize the functions of each.
- 28-2 ■ Describe the structures of the male reproductive system and specify the composition of semen.
- 28-3 ■ Explain the differences between meiosis and mitosis, describe the process of spermatogenesis, and summarize the hormonal mechanisms that regulate male reproductive functions.
- 28-4 ■ Describe the anatomy and functions of the ovaries, the uterine tubes, the uterus, the vagina, and the structures of the female external genitalia.
- 28-5 ■ Describe the ovarian roles in oogenesis, explain the complete ovarian and uterine cycles, and summarize all aspects of the female reproductive cycle.
- 28-6 ■ Discuss the physiology of sexual intercourse in males and females.
- 28-7 ■ Describe the reproductive system changes that occur with development and aging.
- 28-8 ■ Give examples of interactions between the reproductive system and each of the other organ systems.

CLINICAL CASE

And Baby Makes Three?

The Garcias long to have a baby. They are both 30 years old, have been married for 5 years, and have been trying desperately to get pregnant.

Leticia waits and watches. Each time her period comes, her heart aches. Her period has never been like clockwork. Now she worries about the STI (sexually transmitted infection) she had in college. At that time, she was admitted to the hospital with a high fever and pelvic pain. A course of antibiotics finally turned things around.

Her husband, Carlos, rates his health as a “9” on a 10-point scale. He’s a distance runner and clocks an average of 40 miles per week. He says exercise helps him manage the stress of his sales job. Neither of them drinks alcohol or smokes cigarettes. **When should this couple seek help for infertility? To find out, turn to the Clinical Case Wrap-Up at the end of the chapter.**

An Introduction to the Reproductive System

Approximately 8 billion people currently live on Earth. This is an astonishing number given that the *reproductive system* is the only body system that is not essential to the life of an individual. Its activities do, however, affect other systems and ensure continuation of our species. This chapter focuses on how the male and female reproductive organs produce and store specialized reproductive cells called *gametes*. Sections describe how various reproductive organs secrete hormones that play major roles in maintaining normal sexual function, allowing those gametes to come together to form new individuals.

28-1 Male and female reproductive system structures produce gametes that combine to form a new individual

Learning Outcome List the basic structures of the human reproductive system and summarize the functions of each.

The human **reproductive system** ensures the continued existence of the human species—by producing, storing, nourishing, and transporting functional male and female reproductive cells. These cells are called **gametes** (GAM-ēts).

The reproductive system includes the following basic structures:

- **Gonads** (GŌ-nadz; *gone*, seed), reproductive organs that produce gametes and hormones
- Ducts that receive and transport the gametes
- Accessory glands and organs that secrete fluids into the reproductive system ducts or into other excretory ducts
- Perineal structures that are collectively known as the **external genitalia** (jen-ih-TĀ-lē-uh).

In humans, the ducts are connected to chambers and passageways that open to the outside. The structures involved make up the *reproductive tract*.

The male and female reproductive systems are functionally quite different. In individuals with **testes** (TES-tēz; singular, *testis*), or *testicles*, the gonads secrete sex hormones called *androgens*. The main androgen is *testosterone*. The testes also produce the male gametes, called *sperm*. Testes produce about one-half billion sperm each day. During *emission*, mature sperm travel along a lengthy duct system, where they are mixed with the secretions of accessory glands. The mixture created is known as *semen* (SĒ-men). During *ejaculation*, semen is expelled from the body.

Each month, individuals with **ovaries**, another form of gonads, release only one immature gamete, called an **oocyte** (Ō-ō-sīt). The ovaries also secrete sex hormones, including *estrogens*. The released oocyte travels along one of two short *uterine tubes*, which end in the muscular organ called the *uterus* (YŪ-ter-us). A short passageway, the *vagina* (va-JĪ-nuh), connects the uterus with the exterior.

During *sexual intercourse*, ejaculation introduces semen into the vagina, and the sperm then ascend the female reproductive tract. If a sperm reaches the oocyte and starts the process of *fertilization*, the oocyte matures into an *ovum* (plural, *ova*). The uterus will then enclose and support the developing *embryo* as it grows into a *fetus* and prepares for birth (a process covered in Chapter 29).

This chapter begins with the anatomy of the male and female reproductive systems. The physiological and hormonal mechanisms that regulate reproductive function are then considered. Earlier chapters introduced the anatomical reference points used in the discussions that follow. You may find it helpful to review the figures on the pelvic girdle (**Figures 8-7, 8-8**), perineal musculature (**Figure 11-13**), pelvic innervation

(Figure 13-12), and regional blood supply (Figures 21-24, 21-28).

Checkpoint

1. Define gamete.
2. List the basic structures of the reproductive system.
3. Define gonads.

See the blue Answers tab at the back of the book.

28-2 The structures of the male reproductive system consist of the testes, duct system, accessory glands, and penis

Learning Outcome Describe the structures of the male reproductive system and specify the composition of semen.

Figure 28-1 shows the main structures of the male reproductive system. Starting from a *testis*, the sperm travel within the male *reproductive duct system*, which consists of the *epididymis* (ep-ih-DID-ih-mus), the *ductus deferens* (DUK-tus DEF-eh-renz), and the *urethra* before leaving the body. Accessory glands—the

seminal (SEM-i-nal) *glands*, the *prostate* (PROS-tāt), and the *bulbo-urethral* (bul-bō-yū-RĒ-thral) *gland*—secrete various fluids into the duct system. The *external genitalia* consist of the *scrotum* (SKRŌ-tum), which encloses the testes, the urethra, and the *penis* (PĒ-nis), an erectile organ. The distal portion of the urethra passes through the penis. This section introduces the anatomy and basic functions of these structures.

The Testes and Associated Structures

Each testis is about 5 cm (2 in.) long, 3 cm (1.2 in.) wide, and 2.5 cm (1 in.) thick and weighs 10–15 g (0.35–0.53 oz). The testes hang within the **scrotum**, a fleshy pouch suspended inferior to the perineum. The scrotum is anterior to the anus, and posterior to the base of the penis (Figure 28-1).

The Spermatic Cords

The **spermatic cords** are paired structures extending between the abdominopelvic cavity and the testes (Figure 28-2). Each spermatic cord begins at the entrance to the *inguinal canal* (a passageway through the abdominal musculature). After passing through the inguinal canal, the spermatic cord descends into the scrotum.

Figure 28-1 Sagittal Section of the Male Reproductive System.

Figure 28–2 Anterior View of the Male Reproductive System. In the anatomical position, the penis is erect, and the dorsal surface is closest to the navel. When the penis is flaccid, its dorsal surface faces anteriorly.

Each spermatic cord consists of layers of fascia and muscle enclosing the ductus deferens and the blood vessels, nerves, and lymphatic vessels that supply the testes. The blood vessels include the *deferential artery*, a *testicular artery*, and the **pampiniform** (pam-PIN-ih-form) **plexus** of a *testicular vein*. Branches of the *genitofemoral nerve* from the lumbar plexus provide innervation.

The inguinal canals form during development as the testes descend into the scrotum. At that time, these canals link the scrotal cavities with the peritoneal cavity. In adult males, the inguinal canals are closed, but the spermatic cords create weak points in the abdominal wall that remain throughout life. As a result, *inguinal hernias*—protrusions of visceral tissues or organs into the inguinal canal—are common in males.

The Scrotum and the Position of the Testes

The scrotum is divided internally into two chambers. A raised thickening in the scrotal surface known as the **raphe** (RĀ-fē) **of scrotum** divides it in two (Figure 28–2). Each testis lies in a separate chamber, or **scrotal cavity**. Because the scrotal cavities are separated by a partition, infection or inflammation of one testis does not normally spread to the other.

A narrow space separates the inner surface of the scrotum from the outer surface of the testis. A serous membrane, the **tunica vaginalis** (TU-nih-ka vaj-ih-NAL-is), lines each scrotal cavity and reduces friction between the opposing parietal (outer) layer and visceral (inner) layer (Figure 28–3a).

The scrotum consists of a thin layer of skin and the underlying superficial fascia. The dermis contains a layer of smooth muscle, the **dartos** (DAR-tōs) **muscle**. Resting muscle tone in the dartos muscle elevates the testes and causes wrinkling of the scrotal surface.

A layer of skeletal muscle, the **cremaster** (krē-MAS-ter), lies deep to the dermis. When the cremaster contracts during sexual arousal or in response to decreased temperature, it tenses the scrotum and pulls the testes closer to the body. The *cremasteric reflex* can be initiated by stroking the skin on the upper thigh, causing the scrotum to move the testes closer to the body.

For sperm to develop normally in the testes, the temperature must be about 1.1°C (2°F) lower than elsewhere in the body. The cremaster and dartos muscle relax or contract to move the testes away from or toward the body as needed to maintain acceptable testicular temperatures. When air or body temperature increases, these muscles relax and the testes move away from the body. When the scrotum cools suddenly, as

Figure 28-3 Anatomy of the Scrotum and the Testes.

happens when entering a cold swimming pool, these muscles contract to pull the testes closer to the body and keep testicular temperatures from decreasing.

Gross Anatomy of the Testes

Deep to the tunica vaginalis covering the testis is the **tunica albuginea** (al-bū-JIN-ē-uh), a dense layer of connective tissue rich in collagen fibers (Figure 28-3a). These fibers are continuous with those surrounding the adjacent epididymis and extend into the testis. There they form fibrous partitions, or *septa testis*, that converge toward the region nearest the entrance to the epididymis. The connective tissues in this region support the blood vessels and lymphatic vessels that supply and drain the testis, and the *efferent ductules*, which transport sperm to the epididymis.

Histology of the Testes

The *septa testis* subdivides the testis into a series of **lobules** (Figure 28-3a). Distributed among the lobules are approximately 800 slender, tightly coiled **seminiferous** (sem-ih-NIF-er-us) **tubules** (Figure 28-3a,b). Each tubule averages about 80 cm (32 in.) in length. A typical testis contains nearly three-quarters km (one-half mile) of seminiferous tubules. Sperm production takes place within these tubules.

Each lobule contains several seminiferous tubules that merge into **straight tubules** that enter the mediastinum of the testis. Straight tubules are extensively interconnected, forming

a maze of passageways called the **rete** (RĒ-tē; *rete*, a net) **testis** (Figure 28-3a,b). Fifteen to 20 **efferent ductules** connect the rete testis to the epididymis.

Because the seminiferous tubules are tightly coiled, most tissue slides show them in transverse section (Figure 28-4a). A thin connective tissue capsule surrounds each tubule, and areolar tissue fills the spaces between the tubules (Figure 28-4b). Within those spaces are numerous blood vessels and large **interstitial endocrine cells** (*Leydig cells*). Interstitial endocrine cells produce androgens (androsterone and testosterone), the dominant sex hormones. Testosterone is the most important androgen.

Functional Anatomy of the Male Reproductive Duct System

The testes produce sperm that are immobile and not yet capable of successfully fertilizing an oocyte. The male reproductive duct system is responsible for the functional maturation, nourishment, storage, and transport of sperm.

The Epididymis

These immobile sperm are transported into the epididymis by fluid currents created by the cilia that line the efferent ductules. The **epididymis** (ep-ih-DID-ih-mis; *epi*, on + *didymos*, twin) is the start of the reproductive tract (Figure 28-5). It is a coiled tube bound to the posterior border of each testis.

Figure 28-4 Anatomy of the Seminiferous Tubules.

The epididymides (ep-ih-dih-DIM-ih-dēz) can be felt through the scrotal skin. Each epididymis is almost 7 m (23 ft) long, but it is coiled and twisted so it takes up very little space. It has a head, a body, and a tail (**Figure 28-5a,c**). The superior **head** is the largest part of the epididymis. The head receives sperm from the efferent ductules.

The **body** is the middle part that extends inferiorly from the head to the tail of the epididymis on the posterior surface of the testis. Near the inferior border of the testis, the number of coils decreases, marking the start of the **tail**. The tail re-curves, ascends, and connects to the ductus deferens. Sperm are stored primarily within the tail of the epididymis.

The epididymis has the following functions:

- *It monitors and adjusts the composition of the fluid produced by the seminiferous tubules.* The pseudostratified columnar epithelial lining of the epididymis has distinctive stereocilia (**Figure 28-5b**). These stereocilia increase the surface area available for absorption from, and secretion into, the fluid in the tubule.
- *It acts as a recycling center for damaged sperm.* Cellular debris and damaged sperm are absorbed in the epididymis. The

products of enzymatic breakdown are released into the surrounding interstitial fluids for pickup by the epididymal blood vessels.

- *It stores and protects sperm and facilitates their functional maturation.* It takes up to 3 weeks for a sperm to pass through the epididymis and complete its functional maturation. During this time, sperm exist in a sheltered environment that is regulated by the surrounding epithelial cells.

Transport along the epididymis involves a combination of fluid movement and peristaltic contractions of smooth muscle in the epididymis. After passing along the tail of the epididymis, the sperm enter the ductus deferens.

The Ductus Deferens

Each **ductus deferens** (plural, *ductus deferentia*), also called the *vas deferens*, is 40–45 cm (16–18 in.) long. It begins at the tail of the epididymis (**Figure 28-5a,c**). As part of the spermatic cord, it ascends through the inguinal canal (**Figure 28-2**). Inside the abdominal cavity, the ductus deferens passes posteriorly, curving inferiorly along the lateral surface of the urinary bladder toward the superior and posterior margin of the

Figure 28-5 Anatomy of the Epididymis.

prostate (**Figure 28-6a**). Just before the ductus deferens reaches the prostate and seminal glands, its lumen enlarges. This expanded portion is known as the **ampulla** (am-PUL-luh) of **ductus deferens**.

The wall of the ductus deferens contains a thick layer of smooth muscle (**Figure 28-6b**). Peristaltic contractions in this layer propel sperm and fluid along the duct, which is lined by a pseudostratified ciliated columnar epithelium. In addition to transporting sperm, the ductus deferens can store sperm in the ampulla for several months. During this time, the sperm remain in a state of inactivity with low metabolic rates.

The Male Urethra

In males, the **urethra** is a passageway that extends 18–20 cm (7–8 in.) from the urinary bladder to the tip of the penis. It is divided into *prostatic*, *membranous*, and *spongy* regions (**Figures 28-1, 28-7b**). The male urethra is used by both the urinary and reproductive systems. It conducts urine to the exterior and introduces semen into the female's vagina during sexual intercourse.

The Accessory Glands

The fluids secreted by the seminiferous tubules and the epididymis account for only about five percent of the volume of semen. The fluid component of semen is a mixture of secretions—each with distinctive biochemical characteristics—from many glands. Important glands of the male reproductive system include the *seminal glands*, the *prostate*, and the *bulbo-urethral glands*.

Among the major functions of these glands are (1) activating sperm; (2) providing the nutrients sperm need for motility; (3) propelling sperm and fluids along the reproductive tract, mainly by peristaltic contractions; and (4) producing buffers that counteract the acidity of the urethral and vaginal environments.

The Seminal Glands (Seminal Vesicles)

The ductus deferens on each side ends at the junction between the ampulla of ductus deferens and the duct that drains the seminal gland (**Figure 28-6a**). The **seminal glands**, also called the *seminal vesicles*, are tubular glands embedded in connective tissue on each side of the midline, sandwiched between

Figure 28–6 Anatomy of the Ductus Deferens and Accessory Glands.

the posterior wall of the urinary bladder and the rectum. Each tubular seminal gland is about 15 cm (6 in.) in length. The body of the gland has many short side branches. The entire assemblage is coiled and folded into a compact, tapered mass approximately 5 cm × 2.5 cm (2 in. × 1 in.).

Seminal glands have an epithelial lining that contains extensive folds (**Figure 28–6c**), reflecting that they are extremely active secretory glands. The seminal glands produce most of the volume of semen. The secretions of the seminal glands are discharged into the **ejaculatory duct**. The junction of the

duct of the seminal gland with the ampulla of ductus deferens marks the start of the ejaculatory duct. This short passageway is 2 cm (less than 1 in.). It penetrates the muscular wall of the prostate and empties into the prostatic urethra (**Figure 28-6a**).

The Prostate

The **prostate** is a small, muscular, rounded organ about 4 cm (1.6 in.) in diameter. The prostate encircles the proximal portion of the urethra as it leaves the urinary bladder (**Figures 28-1, 28-6a**). The glandular tissue of the prostate consists of a cluster of 30–50 compound tubulo-alveolar glands (**Figure 28-6d**). These glands are surrounded by a thick blanket of smooth muscle fibers.

The prostate produces **prostatic fluid**, a solution that makes up about a quarter of the volume of semen. This slightly acidic fluid is rich in enzymes, such as acid phosphatase and amylase, that prevent sperm coagulation in the vagina. Prostatic fluid is ejected into the prostatic urethra by peristaltic contractions of the muscular prostate wall.

Prostatic inflammation, or **prostatitis** (pros-ta-TĪ-tis), can occur in males at any age, but it most commonly affects older males. Prostatitis can result from bacterial infections but also occurs without pathogens. Signs and symptoms can resemble those of prostate cancer. Individuals with prostatitis may have pain in the lower back, perineum, or rectum. In some cases, the symptoms are accompanied by painful urination and mucus discharge from the external urethral orifice. Antibiotics are effective in treating most cases caused by bacterial infection.

The Bulbo-urethral Glands

The paired **bulbo-urethral glands**, or *Cowper's glands*, are compound tubular mucous glands located at the base of the penis (**Figure 28-7a**). These glands are round, with diameters nearly 10 mm (less than 0.5 in.). The duct of each gland travels alongside the spongy urethra for 3–4 cm (1.2–1.6 in.) before emptying into the urethral lumen.

The bulbo-urethral glands secrete thick, alkaline mucus (**Figure 28-6e**). The secretion helps neutralize any urinary acids that may remain in the urethra, and it lubricates the tip of the penis.

Semen

A typical ejaculation releases 2–5 mL of **semen** (*ejaculate*). When sampled for clinical analysis, semen is collected after a 36-hour period of sexual abstinence. Semen typically contains the following:

- **Sperm.** The normal sperm count ranges from 20 million to 100 million sperm per milliliter of semen. In addition, at least 60% of the sperm in the sample appear normal and will be actively swimming.
- **Seminal Fluid.** **Seminal fluid**, the liquid component of semen, is a mixture of glandular secretions with a distinct

ionic and nutrient composition. A typical sample of seminal fluid contains the combined secretions of the seminal glands (60%), the prostate (30%), the nurse cells and epididymis (5%), and the bulbo-urethral glands (less than 5%). An abnormally low volume may indicate problems with the prostate or seminal glands. In particular, the secretion of the seminal glands contains (1) a higher concentration of fructose, which is easily metabolized by sperm; (2) prostaglandins, which can stimulate smooth muscle contractions along the male and female reproductive tracts; and (3) fibrinogen, which forms a temporary semen clot within the vagina. The glandular fluid the seminal glands produce generally has the same osmotic concentration as that of blood plasma, but the compositions of the two fluids are quite different. The secretions of the seminal glands are slightly alkaline, helping to neutralize acids in the secretions of the prostate and within the vagina.

- **Enzymes.** Several important enzymes are in seminal fluid, including (1) a protease that may help dissolve mucus in the vagina; (2) **seminalplasmin** (sem-i-nal-PLAZ-min), a protein with antibiotic properties that may help prevent urinary tract infections in males; (3) a prostatic enzyme that converts fibrinogen to fibrin, coagulating the semen within a few minutes after ejaculation; and (4) *fibrinolysin*, which liquefies the clotted semen after 15–30 minutes.

A complete chemical analysis of semen appears in Appendix A, Table 1.

The Penis

The **penis** is a tubular organ for sexual intercourse and conducting urine to the exterior. Main structures include the root, body, and glans penis (**Figure 28-7a**). The **root of penis** is the fixed portion that attaches the penis to the body wall. It includes left crus of penis, right crus of penis, and the bulb of penis. This connection occurs immediately inferior to the pubic symphysis. The **body of penis** (*shaft*) is the tubular, movable portion of the organ. The **glans penis** (*head*) is the expanded distal end that surrounds the external urethral orifice. The *neck of glans* is the narrow portion of the penis between the body and the glans penis.

The skin overlying the penis resembles that of the scrotum. The dermis contains a layer of smooth muscle that is a continuation of the dartos muscle of the scrotum. The underlying areolar tissue allows the thin skin to move without distorting underlying structures. The subcutaneous layer also contains superficial arteries, veins, and lymphatic vessels.

A fold of skin called the **foreskin** or **prepuce** (PRĒ-pūs) surrounds the tip of the penis. (**Figure 28-7b**). The foreskin attaches to the relatively narrow neck of the penis and continues over the glans penis. **Modified sebaceous glands** in the skin of the neck and the inner surface of the foreskin secrete a whitish, oily

Figure 28–7 Anatomy of the Penis.

Which erectile tissue is split into two cylindrical masses that surround a central artery? Which erectile tissue surrounds the urethra?

substance, that along with dead skin cells is known as *smegma* (SMEG-ma). Smegma can be an excellent nutrient source for bacteria. As a result, mild inflammation and infections in this area are common, especially if the area is not washed thoroughly and frequently. One way to lessen the risk of such problems is **circumcision** (ser-kum-SIZH-un), the surgical removal of the foreskin. Circumcision lowers the risks of developing urinary tract infections, HIV infection, and penile cancer. Note that it is

a surgical procedure with risk of bleeding, infection, and other complications.

Deep to the areolar tissue, a dense network of elastic fibers encircles the internal structures of the penis. Most of the body of the penis consists of three cylindrical columns of **erectile tissue** (Figure 28–7b, c). Erectile tissue consists of a three-dimensional maze of vascular channels incompletely separated by partitions of elastic connective tissue and smooth muscle

Clinical Note Circumcision

Circumcision, or the removal of the foreskin of the penis, is an elective surgical procedure for a newborn. Certain religions conduct a ceremonial circumcision, as in the *bris* practiced in the Jewish faith when the infant is 8 days old. In the brief medical process of circumcision, the penis is anesthetized locally. A clamp or ring is applied to remove the prepuce. Circumcision in an adult may require a general anesthetic. A circumcised penis is easier to keep clean. The risk of developing a sexually transmitted disease, which can flourish under the foreskin, is decreased. However, these risks can also be managed by teaching good personal hygiene practices.

fibers. In the resting state, the arterial branches are constricted and the muscular partitions are tense. This combination restricts blood flow into the erectile tissue. During **erection** the penis stiffens and elevates to an upright position, but the flaccid (nonerect) penis hangs inferior to the pubic symphysis and anterior to the scrotum.

The anterior surface of the flaccid penis covers two cylindrical masses of erectile tissue: the **corpora cavernosa** (KOR-por-uh ka-ver-NŌ-suh; singular, *corpus cavernosum*). The two are separated by a thin septum and encircled by a dense collagenous sheath (**Figure 28-7c**). The corpora cavernosa separate at their bases, forming the **crus of penis** (**Figure 28-7a**). Each crus is bound to the ramus of the ischium and pubis by tough connective tissue ligaments. The corpora cavernosa extend along the length of the penis as far as its neck. The erectile tissue within each corpus cavernosum surrounds a central artery, or deep artery of the penis (**Figure 28-7c**).

The penis contains the distal portion of the urethra, which the relatively slender **corpus spongiosum** (spon-jē-Ō-sum) surrounds (**Figure 28-7a,b**). This erectile body extends to the tip of the penis, where it expands to form the glans penis. The sheath surrounding the corpus spongiosum contains more elastic fibers than does that of the corpora cavernosa, and the erectile tissue contains a pair of small arteries.

4. Name the male reproductive structures.
5. On a warm day, would the cremaster be contracted or relaxed? Why?
6. Trace the pathway that a sperm travels from the site of its production to outside the body.

See the blue Answers tab at the back of the book.

28-3 Spermatogenesis occurs in the testes, and hormones from the hypothalamus, pituitary gland, and testes control male reproductive functions

Learning Outcome Explain the differences between meiosis and mitosis, describe the process of spermatogenesis, and summarize the hormonal mechanisms that regulate male reproductive functions.

Overview of Mitosis and Meiosis

Mitosis, the production of genetically identical cells, and *meiosis*, the production of gametes, differ significantly in terms of the events that take place in the nucleus. Recall from Chapter 3 that human somatic cells contain 23 pairs of chromosomes, or 46 chromosomes altogether. Each pair consists of one chromosome provided by the male, and another provided by the female, at the time of fertilization. The two members of each of 22 pairs have similar sizes and genes and are known as **homologous** (huh-MOL-ō-gus) **chromosomes**. The 23rd pair, the sex chromosomes, are heterologous and have different sizes and genes.

Mitosis is part of the process of somatic cell division, producing two daughter cells each containing identical numbers and pairs of chromosomes. Because of this equality, mitosis is described as an *equational division*. The pattern is illustrated in **Figure 28-8a**. Because daughter cells contain both members of each chromosome pair, they are called **diploid** (DIP-loyd; *diplo*, double) ($2n = 46$) cells. (You can review the description of mitosis and cell division in Chapter 3.)

Meiosis is a specialized form of cell division that produces only gametes. In contrast to mitosis, meiosis follows the pattern in **Figure 28-8b**. It involves two cycles of cell division (*meiosis I* and *meiosis II*) resulting in four cells, each containing 23 *individual* chromosomes capable of transcribing proteins. These cells are called **haploid** (HAP-loyd; *haplo*, single) ($n = 23$) cells and contain only one member of each homologous pair of chromosomes and one sex chromosome. Because gametes contain half the number of chromosomes found in somatic cells, the fusion of the nuclei of a sperm and oocyte produces a cell that has the normal number of chromosomes, rather than twice that number. The events in the nucleus shown in **Figure 28-8b** are the same for the formation of sperm or oocytes.

As a cell prepares to begin meiosis, DNA replication occurs within the nucleus just as it does in a cell preparing for mitosis. The duplicated chromosomes condense and become visible with a light microscope. As in mitosis, each chromosome now consists of two duplicate *chromatids* (KRŌ-mah-tidz).

At this point, the close similarities between meiosis and mitosis end. In meiosis, the corresponding maternal (inherited from the biological mother) and paternal (inherited from the

Figure 28–8 A Comparison of Chromosome Fates in Mitosis and Meiosis.

biological father) chromosomes now come together in a pairing event known as **synapsis** (sih-NAP-sis). Synapsis involves 23 pairs of chromosomes, and each member of each pair consists of two chromatids. A matched set of four chromatids is called a **tetrad** (TET-rad; *tetras*, four) (**Figure 28–8b**). Some genetic material can be exchanged between the biological parental chromatids of a chromosome pair at this stage of meiosis. Such an exchange, called *crossing over*, increases genetic variation among potential offspring. We discuss genetics in Chapter 29.

Meiosis includes two division cycles, referred to as **meiosis I** and **meiosis II**. We identify the stages within each cycle with I or II, for example as prophase I or metaphase II.

Meiosis I

Meiosis I begins with prophase I; the nuclear envelope disappears at the end of prophase I. As metaphase I begins, the tetrads line up along the metaphase plate. As anaphase I begins, the tetrads break up—the biological maternal and biological paternal chromosomes separate. This is a major difference between

mitosis and meiosis: In mitosis, each daughter cell receives a copy of every chromosome, biological maternal and biological paternal, but in meiosis I, each daughter cell receives two copies of *either* the biological maternal chromosome *or* the biological paternal chromosome. (Compare the two parts of **Figure 28–8**.)

As anaphase I proceeds, the biological maternal and biological paternal components are randomly and independently distributed. That is, as each tetrad splits, we cannot predict which daughter cell will receive copies of the biological maternal chromosome, and which will receive copies of the biological paternal chromosome. As a result, telophase I ends with the formation of two daughter cells containing unique combinations of biological maternal and biological paternal chromosomes. Both cells contain 23 chromosomes.

This first meiotic division is called a **reductional division** because it reduces the number of chromosomes from the diploid number ($2n = 46$) to the haploid number ($n = 23$). Each of these chromosomes still consists of two chromatids. The two chromatids are temporary structures and will separate during meiosis II.

Meiosis II

The interphase between meiosis I and meiosis II is brief. No DNA is replicated during that period. Each cell then proceeds through prophase II, metaphase II, and anaphase II. During anaphase II, the chromatids separate. Telophase II yields four haploid cells, each containing 23 chromosomes. Because the number of chromosomes remains equal (haploid), meiosis II is an **equational division**.

The chromosomes are evenly distributed among the four cells, but the cytoplasm may not be. In the process of *spermatogenesis*, meiosis produces four immature gametes that are identical in size. Each will develop into a functional sperm. Within ovaries, meiosis produces one relatively huge oocyte and three

tiny, nonfunctional polar bodies. (If fertilization takes place, the oocyte completes meiosis II, yielding an ovum.) We examine the details of spermatogenesis next. We consider the production of female oocytes, *oogenesis*, in Section 28-5.

Spermatogenesis

As we have indicated, **spermatogenesis** (sper-ma-tō-JEN-eh-sis) is the process of sperm formation (**Figure 28-9**). Spermatogenesis begins at *puberty* (sexual maturation) and continues until relatively late in life (past age 70).

The complete process of spermatogenesis takes about 64 days. It involves three steps:

Figure 28-9 The Process of Spermatogenesis. The fates of three representative chromosome pairs are shown; for clarity, biological maternal and biological paternal chromatids are not identified.

What is the name of the cell at each stage of sperm development, from mitosis to spermiogenesis?

1. **Mitosis. Spermatogonia** (sper-ma-tō-GŌ-nē-uh) are stem cells in the seminiferous tubules that undergo cell divisions throughout adult life. Some of these cells differentiate into **primary spermatocytes** (sper-MA-tō-sīts), which prepare to begin meiosis.
2. **Meiosis.** Primary spermatocytes then undergo meiotic divisions that produce **spermatids** (SPER-ma-tidz), undifferentiated male gametes.
3. **Spermiogenesis.** In *spermiogenesis*, spermatids differentiate into physically mature **sperm**.

Spermatogenesis is a continuous process, so all stages of meiosis occur within the seminiferous tubules. Each seminiferous tubule contains spermatogonia, spermatocytes at various stages of meiosis, spermatids, and sperm. They also contain large *nurse cells*, which provide a microenvironment that supports spermatogenesis. The sperm eventually lose contact with the nurse cells of the seminiferous tubule and enter the fluid in the lumen.

Mitosis and Meiosis during Spermatogenesis

Spermatogenesis begins at the outermost layer of cells in the seminiferous tubules and proceeds toward the lumen (Figure 28–10a,b). At each step in this process, the daughter cells move closer to the lumen.

First, spermatogonia divide by mitosis to produce two daughter cells. One daughter cell from each division remains at that location as a spermatogonium, while the other is pushed toward the lumen (space) of the tubule. The displaced cell differentiates into a primary spermatocyte. Primary spermatocytes then begin meiosis, giving rise to *secondary spermatocytes* that divide and differentiate into immature spermatids.

Spermiogenesis

The four spermatids initially remain interconnected by bridges of cytoplasm because *cytokinesis* (cytoplasmic division) is not completed in meiosis I or meiosis II. These cytoplasmic connections assist in transferring nutrients and hormones between the cells, helping ensure that the cells develop together. The bridges are not broken until the last stages of physical maturation.

In **spermiogenesis**, the last step of spermatogenesis, the spermatids gradually develop into mature sperm (Figures 28–9, 28–11). At *spermiation*, a sperm loses its attachment to the nurse cell and enters the lumen of the seminiferous tubule.

The Role of Nurse Cells

Developing spermatocytes undergoing meiosis, and spermatids undergoing spermiogenesis, are not free in the seminiferous tubules. Instead, they are surrounded by the cytoplasm of adjacent *nurse cells*. **Nurse cells**, which are also known as *Sertoli cells*, play a critical supportive role in spermatogenesis.

These cells have five important functions that directly or indirectly affect mitosis, meiosis, and spermiogenesis within the seminiferous tubules:

- **Maintenance of the Blood-Testis Barrier.** A **blood-testis barrier** isolates the seminiferous tubules from the general circulation. This barrier is comparable in function to the blood-brain barrier. Nurse cells are joined by tight junctions between basal cytoplasmic processes. They form a layer that divides the seminiferous tubule into an outer basal compartment and an inner luminal compartment. The *basal compartment* contains the spermatogonia. Meiosis and spermiogenesis occur in the *luminal compartment* (Figure 28–10a,b).

Figure 28–10 Spermatogenesis in a Seminiferous Tubule.

a Nurse cells surround the stem cells of the tubule and support the developing spermatocytes and spermatids.

b Stages in spermatogenesis in the wall of a seminiferous tubule.

Figure 28–11 The Process of Spermiogenesis and Anatomy of a Sperm.

Spermiogenesis. The differentiation of a spermatid into a sperm. This process is completed in approximately 24 days.

In which of the four parts of a sperm are the centrioles found?

- Transport across the nurse cells is tightly regulated, so conditions in the luminal compartment remain very stable.
- The nurse cells produce the fluid in the lumen of a seminiferous tubule. They also regulate the fluid's composition. This luminal fluid is very different from the surrounding interstitial fluid. It is high in androgens, estrogens, potassium ions, and amino acids. The blood-testis barrier is essential to preserving the differences between the luminal fluid and the interstitial fluid.
- In addition, this barrier prevents immune system cells from detecting and attacking the developing sperm. The plasma membranes of sperm contain sperm-specific antigens not found in somatic cell membranes, so they might be identified as "foreign."
- Support of Mitosis and Meiosis.** Circulating follicle-stimulating hormone (FSH) and testosterone stimulate nurse cells. These stimulated nurse cells then promote the division of spermatogonia and the meiotic divisions of spermatocytes.
- Support of Spermiogenesis.** Spermiogenesis requires nurse cells. These cells surround and enfold the spermatids, providing nutrients and chemical stimuli that promote their development. Nurse cells also phagocytize cytoplasm that is shed by spermatids as they develop into sperm.
- Secretion of Inhibin.** Nurse cells secrete the peptide hormone *inhibin* (in-HIB-in) in response to factors released by developing sperm. Inhibin depresses the pituitary production of FSH and perhaps the hypothalamic secretion of gonadotropin-releasing hormone (GnRH). The faster the rate of sperm production, the more inhibin is secreted. By regulating FSH and GnRH secretion, nurse cells provide negative feedback control of spermatogenesis.
- Secretion of Androgen-Binding Protein.** *Androgen-binding protein* (ABP) binds androgens (primarily testosterone) in the luminal fluid of the seminiferous tubules. This protein is likely important for increasing androgen concentration and stimulating spermiogenesis. FSH stimulates the production of ABP.

Maturation of Sperm

The sperm that lie within the lumen of the seminiferous tubule have most of the physical characteristics of mature sperm but are functionally immature and incapable of coordinated movement or fertilization. It takes up to 2 weeks for a sperm to pass through the epididymis and complete its functional maturation. During this time, sperm exist in a sheltered environment that is precisely regulated by the surrounding epithelial cells.

Sperm leaving the epididymis are mature but immobile. To become *motile* (actively swimming) and fully functional, they must undergo a process called **capacitation**. When mixed with the secretions of the seminal glands, sperm undergo the first step in capacitation and begin beating their flagella. Capacitation normally takes place in two steps: (1) Sperm become motile when they are mixed with secretions of the seminal glands, and (2) they become capable of successful fertilization when exposed to conditions in the female reproductive tract.

The Anatomy of a Sperm

Sperm are among the most highly specialized cells in the body. Each sperm has four distinct regions: head, neck, middle piece, and tail (**Figure 28–11**). The **head** is a flattened ellipse containing a nucleus with densely packed chromosomes. At the tip of the head is the **acrosome** (AK-rō-sōm), a membranous compartment containing enzymes essential to fertilization. During spermiogenesis, saccules of the spermatid's Golgi apparatus fuse and flatten into an *acrosomal vesicle*, which ultimately forms the acrosome.

A short **neck** attaches the head to the **middle piece**. The neck contains both centrioles of the original spermatid. The microtubules of the distal centriole are continuous with those of the middle piece and tail. Mitochondria in the middle piece are arranged in a spiral around the microtubules. Mitochondria provide the ATP required to move the tail.

The **tail** is the only flagellum in the human body. A *flagellum* is a whiplike organelle that moves a cell from one place to another. Cilia beat in a predictable, wavelike fashion, but the tail of a sperm has a corkscrew motion.

Unlike other, less specialized cells, a mature sperm lacks an endoplasmic reticulum, a Golgi apparatus, lysosomes, peroxisomes, inclusions, and many other organelles. The loss of these organelles reduces the cell's size and mass. A sperm is essentially a mobile carrier for chromosomes, and extra weight would slow it down. Because a sperm lacks glycogen or other energy reserves, it must absorb nutrients (primarily fructose) from the surrounding fluid.

Hormonal Regulation of Male Reproductive Function

The hormonal interactions that regulate male reproductive function are diagrammed in **Spotlight Figure 28–12**. We introduced major reproductive hormones in Chapter 18. The anterior lobe of the pituitary gland releases *follicle-stimulating hormone* (FSH) and *luteinizing hormone* (LH). The pituitary releases these hormones in response to *gonadotropin-releasing hormone* (GnRH). This peptide is synthesized in the hypothalamus and carried to the anterior lobe by the hypophyseal portal system.

The hormone GnRH is secreted in pulses rather than continuously. In adult males, small pulses occur at 60- to 90-minute intervals. As levels of GnRH change, so do the rates of secretion of FSH and LH (and testosterone, which is released in response to LH). The GnRH pulse frequency remains relatively steady from hour to hour, day to day, and year to year, unlike the situation in females, as described later in the chapter. As a result, plasma levels of FSH, LH, and testosterone remain within a relatively narrow range until relatively late in a male's life.

Testosterone plays a major role in maintaining male sexual function (**Spotlight Figure 28–12**). Testosterone functions like other steroid hormones, circulating in the bloodstream while bound to one of two types of transport proteins. These proteins are (1) *gonadal steroid-binding globulin* (GBG), which carries about two-thirds of the circulating testosterone, and (2) the albumins, which bind the remaining one-third. Testosterone diffuses across the plasma membrane of target cells and binds to an intracellular receptor. The hormone–receptor complex then binds to the DNA in the nucleus.

Clinical Note Dehydroepiandrosterone (DHEA)

Dehydroepiandrosterone, or DHEA, is the primary androgen secreted by the zona reticularis of the adrenal cortex. Androgens, which are secreted in small amounts, are converted to testosterone (or estrogens) by other tissues. The significance of this adrenal androgen secretion remains unclear, but DHEA is being promoted as a wonder drug for increasing vitality, strength, and muscle mass. The effects of long-term high doses of DHEA remain largely unknown. However, high levels of DHEA in females have been linked to an increased risk of ovarian cancer. The International Olympic Committee and many other sports organizations have banned the use of DHEA.

Male reproductive function is regulated by the complex interaction of hormones from the hypothalamus, anterior lobe of the pituitary gland, and the testes. Negative feedback systems keep testosterone levels within a relatively narrow range until late in life.

In many target tissues, some of the arriving testosterone is converted to **dihydrotestosterone (DHT)**. A small amount of DHT diffuses back out of the cell and into the bloodstream, and DHT levels are usually about 10% of circulating testosterone levels. Dihydrotestosterone can also enter peripheral cells and bind to the same hormone receptors targeted by testosterone. In addition, some tissues (notably those of the external genitalia) respond to DHT rather than to testosterone. Other tissues (including the prostate) are more sensitive to DHT than to testosterone.

In adult males, negative feedback controls the level of testosterone production. Above-normal testosterone levels inhibit the release of GnRH by the hypothalamus, causing a reduction in LH secretion and lowering testosterone levels (**Spotlight Figure 28–12**).

The plasma of adult males also contains relatively small amounts of the estrogenic hormone *estradiol* (2 ng/dL versus 525 ng/dL of testosterone). Seventy percent of the estradiol is formed from circulating testosterone. Interstitial endocrine cells and nurse cells of the testes secrete the rest. An enzyme called aromatase converts testosterone to estradiol. For unknown reasons, estradiol production increases in older males.

✓ Checkpoint

7. What effect would a low FSH level have on sperm production?

See the blue Answers tab at the back of the book.

+ Clinical Note Enlarged Prostate

Enlargement of the prostate, or **benign prostatic hyperplasia**, is so common in males over age 50 that it is considered an aspect of aging. The increase in size happens as testosterone production by the interstitial endocrine cells decreases. For unknown reasons, small masses called *prostatic concretions* may form within the gland. At the same time, the interstitial endocrine cells begin releasing small quantities of estrogens into the bloodstream. The combination of a lower testosterone level and the presence of estrogens probably stimulates prostatic growth. In severe cases, prostatic swelling constricts and blocks the urethra and constricts the rectum. If not corrected, the urinary obstruction can cause permanent kidney damage. Partial surgical removal is the most effective treatment. In the procedure known as a **TURP** (*transurethral prostatectomy*), an instrument pushed along the urethra cuts away the swollen prostatic tissue. Most of the prostate remains in place, and normal function returns.

+ Clinical Note Prostate Cancer

Prostate cancer occurs when malignant cells invade prostatic tissue. Prostate cancer is rare in males younger than 50 years, but cancer risk increases with age. Family history seems to play a role in prostate cancer development, and males whose biological father or biological brother has had prostate cancer have a higher-than-average risk of developing the disease. It appears that higher-than-normal levels of dihydrotestosterone (DHT) may lead to the development of prostate cancer. Two drugs, finasteride and dutasteride, which block the enzyme that converts testosterone into DHT, lower the risk for prostate cancer. Aggressive treatment of localized prostate cancer in older patients is controversial because many of these males have nonmetastatic tumors (tumors that have not spread). In addition, even if their cancer is left untreated, these males are more likely to die of some other disease.

+ Clinical Note Prostate-Specific Antigen (PSA) Testing

Blood tests are used to screen for prostate cancer and to monitor the success of treatment. The most sensitive is a blood test called **prostate-specific antigen (PSA)**. An elevated level of this antigen, which is normally present in a low concentration, may indicate the presence of prostate cancer. Screening with periodic PSA tests is now being recommended for some males over age 50. If prostate cancer is detected, treatment decisions vary depending on how rapidly the PSA level is rising.

28-4 The structures of the female reproductive system consist of the ovaries, uterine tubes, uterus, vagina, and external genitalia

Learning Outcome Describe the anatomy and functions of the ovaries, the uterine tubes, the uterus, the vagina, and the structures of the female external genitalia.

The female reproductive system produces sex hormones and functional gametes. It must also be able to protect and support a developing embryo and nourish a newborn infant. The main organs of the female reproductive system are the *ovaries*, the *uterine tubes*, the *uterus*, the *vagina*, and the components of the external genitalia (vulva)—the *clitoris* and the *labia majora* and *labia minora* (**Figure 28–13**). Accessory glands—the *urethral glands* and the *greater vestibular glands*—release secretions into the reproductive tract.

The ovaries, uterine tubes, and uterus are enclosed within an extensive mesentery known as the **broad ligament**

Figure 28–13 Sagittal Section of the Female Reproductive System.

(Figure 28–14a). The uterine tubes run along the superior border of the broad ligament and open into the pelvic cavity lateral to the ovaries. The broad ligament attaches to the sides and floor of the pelvic cavity, where it becomes continuous with the parietal peritoneum. The broad ligament subdivides this part of the peritoneal cavity.

The pocket formed between the posterior wall of the uterus and the anterior surface of the colon is the **recto-uterine** (rek-tō-YŪ-ter-in) **pouch**. The pocket formed between the uterus and the posterior wall of the bladder is the **vesico-uterine** (ves-ih-kō-YŪ-ter-in) **pouch**. These subdivisions are easily recognized in sagittal section (Figure 28–13).

Several other ligaments assist the broad ligament in supporting and stabilizing the uterus and associated reproductive organs. These ligaments lie within the mesentery sheet of the broad ligament and are connected to the ovaries or uterus. The

broad ligament limits side-to-side movement and rotation, and the other ligaments (described in the upcoming discussion of the ovaries and uterus) prevent superior–inferior movement.

Let’s look further at the structures and basic functions of the female reproductive system.

The Ovaries

The paired ovaries are small, lumpy, almond-shaped organs near the lateral walls of the pelvic cavity (Figure 28–14b). The ovaries perform three main functions. They (1) produce immature gametes, or oocytes; (2) secrete sex hormones, including *estrogens* and *progesterone*; and (3) secrete *inhibin*, involved in the feedback control of pituitary FSH production.

The **mesovarium** (mez-ō-VĀ-rē-um), a thickened fold of mesentery, supports and stabilizes the position of each

Figure 28–14 Relationships between the Ovaries, Uterine Tubes, and Uterus.

ovary (**Figure 28–14a**). Each ovary is also stabilized by a pair of supporting ligaments: the ovarian ligament and the suspensory (*infundibulopelvic*) ligament. The **ovarian ligament** extends from the uterus, near the attachment of the uterine tube, to the medial surface of the ovary. The **suspensory ligament** extends from the lateral surface of the ovary past the open end of the uterine tube to the pelvic wall. The suspensory ligament contains the major blood vessels of the ovary: the **ovarian artery** and **ovarian vein**. These vessels are connected to the ovary at the **ovarian hilum**, where the ovary attaches to the mesovarium (**Figure 28–14b**).

A typical ovary is about 5 cm long, 2.5 cm wide, and 8 mm thick (2 in. × 1 in. × 0.33 in.). It weighs 6–8g (about 0.25 oz). An ovary is pink or yellowish and has a nodular consistency. The visceral peritoneum, or *germinal epithelium*, covers the surface of each ovary and consists of a layer of columnar

epithelial cells that overlies a dense connective tissue layer called the **tunica albuginea** (al-bū-JIN-ē-ah) (**Figure 28–14b**). We divide the interior tissues, or **stroma**, of the ovary into a superficial **cortex** and a deeper **medulla**. Gametes are produced in the cortex.

The Uterine Tubes

Each **uterine tube** (*fallopian tube* or *oviduct*) is a hollow, muscular cylinder measuring about 13 cm (5.2 in.) in length (**Figure 28–14a**).

Regions of the Uterine Tubes

Each uterine tube is divided into three regions, from lateral to medial (**Figure 28–15a**):

1. *The Infundibulum.* The end closest to the ovary forms an expanded funnel, or **infundibulum**, with numerous finger-like projections that extend into the pelvic cavity. The projections are called **fimbriae** (FIM-brē-ē) (**Figure 28-16a**). Fimbriae drape over the surface of the ovary, but there is no physical connection between the two structures. The inner surfaces of the infundibulum are lined with cilia that beat toward the middle region of the uterine tube.
2. *The Ampulla.* The middle region is called the **ampulla**. The thickness of its smooth muscle layers gradually increases as the tube approaches the uterus.
3. *The Isthmus.* The ampulla leads to the **isthmus** (IS-mus), a short region connected to the uterine wall.

Clinical Note Ovarian Cancer

Ovarian cancer is cancer that develops in ovarian cells. It goes undetected in its early stages because there typically are no signs or symptoms. When symptoms are present, they are generally attributed to some other condition. Common later-stage symptoms include pelvic area discomfort, constipation, abdominal swelling, back pain, and fatigue. A female in the United States has a 1 in 70 chance of developing ovarian cancer in her lifetime. The prognosis is relatively good for cancers that originate in the general ovarian tissues or from abnormal oocytes. These cancers generally respond well to some combination of chemotherapy, radiation, and surgery. However, 85% of ovarian cancers develop from epithelial cells, and sustained remission occurs in only about one-third of these cases.

Functional Anatomy of the Uterine Tube

The epithelium lining the uterine tube is composed of ciliated columnar epithelial cells with scattered mucin-secreting cells. Concentric layers of smooth muscle surround the mucosa (**Figure 28-15b**). A combination of ciliary movement and peristaltic contractions in the walls of the uterine tube transports oocytes toward the uterus (**Figure 28-15c**). In addition, the uterine tube provides a nutrient-rich environment that contains lipids and glycogen for both oocytes and sperm. If fertilization occurs, it typically takes place near the boundary between the ampulla and isthmus of the uterine tube.

In addition to ciliated cells, the epithelium lining the uterine tubes contains *peg cells*. The peg cells project into the lumen of the uterine tube. They secrete a fluid that both completes the capacitation of sperm and supplies nutrients to sperm and the pre-embryo.

The Uterus

The **uterus** protects, nourishes, and removes wastes for the developing *embryo* (weeks 1–8) and *fetus* (week 9 through delivery). In addition, contractions of the muscular uterus are important in expelling the fetus at birth.

The uterus is a small, pear-shaped organ (**Figure 28-16**). It is about 7.5 cm (3 in.) long with a maximum diameter of 5 cm (2 in.). It weighs 50–100g (1.75–3.5 oz). In its normal position, the uterus bends anteriorly near its base, a condition known as *anteflexion* (an-tē-FLEK-shun) (**Figure 28-13**). In this position, the uterus covers the superior and posterior surfaces of the urinary bladder. If the uterus bends backward toward the sacrum, the condition is termed *retroflexion* (re-trō-FLEK-shun). Retroflexion occurs in about 20% of

Figure 28-15 Anatomy of the Uterine Tubes.

Figure 28–16 Gross Anatomy of the Uterus.

adult females and has no clinical significance. (A retroflexed uterus generally becomes anteflexed spontaneously during the third month of pregnancy.)

Suspensory Ligaments of the Uterus

In addition to the broad ligament, three pairs of suspensory ligaments stabilize the uterus and limit its range of movement (**Figure 28–16b**). The **uterosacral** (yū-te-rō-SĀ-krul) **ligaments** extend from the lateral surfaces of the uterus to the anterior face of the sacrum, keeping the body of the uterus from moving inferiorly and anteriorly. The **round ligaments** arise on the lateral margins of the uterus just posterior and inferior to the attachments of the uterine tubes. These ligaments extend through the inguinal canal and end in the connective tissues of the external genitalia. (Unlike the inguinal canals in males, these canals in females are very small, containing only the round ligaments and the *ilioinguinal nerves*; this makes inguinal hernias in females very rare.) The round ligaments restrict posterior movement of the uterus. The **cardinal ligaments** extend from the base of the uterus and vagina to the lateral walls of the pelvis. These ligaments tend to prevent inferior movement of the uterus. The muscles and fascia of the pelvic floor provide additional mechanical support.

Gross Anatomy of the Uterus

We divide the uterus into four main anatomical regions (**Figure 28–16a**). The uterine **body** is the largest portion of the uterus. The **fundus** is the rounded portion of the body superior to the attachment of the uterine tubes. The body ends at a constriction known as the **isthmus** of the uterus. The **cervix** (SER-viks) is the inferior portion of the uterus that extends from the isthmus to the vagina.

Clinical Note Pap Smear

For many young females, the **Pap smear** is the reason for a regular visit to the healthcare professional. This important screening test evaluates the health of the *cervix*, the inferior portion of the uterus that projects into the vaginal canal. Early detection of cervical cancer is the main goal of the test. Developed by Dr. Georgios Papanikolaou (hence the name of the test), the simple and quick Pap smear is a form of *exfoliative cytology*. The practitioner opens the patient's vagina with a speculum, and gently scrapes the cervix with a swab to collect epithelial cells. These cells are then studied in the pathology lab for any evidence of cancerous changes. Pap smear screening coupled with a human papilloma virus (HPV) vaccine can prevent cervical cancers. HPV vaccines are available for children starting at age 9; everyone through age 26 should get an HPV vaccine if they were not fully vaccinated.

The tubular cervix projects about 1.25 cm (0.5 in.) into the vagina. Within the vagina, the distal end of the cervix forms a curving surface that surrounds the **external os** (*os*, an opening or mouth) of the uterus. The external os leads into the **cervical canal**, a constricted passageway that opens into the **uterine cavity** of the body at the **internal os**.

The uterus receives blood from branches of the **uterine arteries**. These vessels arise from branches of the *internal iliac arteries*, and from the *ovarian arteries*, which arise from the abdominal aorta inferior to the renal arteries. The arteries to the uterus are extensively interconnected, ensuring a reliable flow of blood to the organ despite changes in its position and shape during pregnancy. Numerous veins and lymphatic vessels also drain each portion of the uterus.

The organ is innervated by autonomic fibers from the hypogastric plexus (sympathetic) and from sacral segments S₃ and S₄ (parasympathetic). Sensory information reaches the central nervous system (CNS) within the posterior roots of spinal nerves T₁₁ and T₁₂. The most delicate anesthetic procedures used during labor and delivery, known as *segmental blocks*, target only spinal nerves T₁₀–L₁.

The Uterine Wall

The dimensions of the uterus are highly variable. In females of reproductive age who have not given birth, the uterine wall is about 1.5 cm (0.6 in.) thick.

Layers of the Uterine Wall. The uterine wall is made up of three main layers. The fundus and the posterior surface of the uterine body and isthmus are covered by an outer serous membrane that is continuous with the peritoneal lining. This incomplete serosa is called the **perimetrium**. The wall has a thick, middle, muscular **myometrium** (mĭ-ō-MĒ-trē-um; *myo-*, muscle + *metra*, uterus) and a thin, inner, glandular **endometrium** (en-dō-MĒ-trē-um) (**Figure 28–17a**).

The myometrium is the thickest portion of the uterine wall. It makes up almost 90% of the mass of the uterus. Smooth muscle in the myometrium is arranged into longitudinal, circular, and oblique layers. The smooth muscle tissue of the myometrium provides much of the force needed to move a fetus out of the uterus and into the vagina.

The endometrium makes up about 10% of the mass of the uterus. The glandular and vascular tissues of the endometrium support the physiological demands of the growing fetus. Vast numbers of *uterine glands* open onto the endometrial surface and extend deep into the lamina propria, almost to the myometrium. Under the influence of estrogens, the uterine glands, blood vessels, and epithelium change with the phases of the monthly *uterine cycle*.

Histology of the Uterine Wall. The endometrium is divided into a **functional layer**—the layer closest to the uterine

Figure 28–17 Histology of the Uterine Wall.

cavity—and a **basal layer**, adjacent to the myometrium (**Figure 28–17b**). The functional layer contains most of the **uterine glands** and contributes most of the endometrial thickness. This layer undergoes dramatic changes in thickness and structure during the uterine cycle. The basal layer attaches the endometrium to the myometrium and contains the terminal branches of the tubular uterine glands. The structure of the basal layer remains fairly constant over time, but the functional layer undergoes cyclical changes in response to sex hormone levels.

Within the myometrium, branches of the uterine arteries form **arcuate arteries**, which encircle the endometrium (**Figure 28–17a**). **Radial arteries** supply **straight arteries**, which deliver blood to the basal layer of the endometrium, and **spiral arteries**, which supply the functional layer.

The Vagina

The **vagina** is an elastic, muscular tube that has three major functions. It (1) is a passageway for the elimination of menstrual fluids; (2) receives the penis during sexual intercourse and holds sperm prior to their passage into the uterus; and (3) forms the inferior portion of the *birth canal*, through which the fetus passes during delivery.

Gross Anatomy of the Vagina

The vagina extends between the cervix and the body exterior (**Figure 28–18a**). At the proximal end of the vagina, the cervix projects into the **vaginal canal**. The shallow recess surrounding the cervical protrusion is known as the **vaginal fornix** (FOR-niks). The vagina is typically 7.5–9 cm (3–3.6 in.) long. Its diameter varies because it is highly distensible.

The two *bulbospongiosus* muscles extend along either side of the vaginal entrance. Contractions of the bulbospongiosus muscles constrict the vagina. These muscles cover the **vestibular bulb**, a mass of erectile tissue on each side of the vagina (**Figure 28–19**). The vestibular bulbs have the same embryonic origins as the corpus spongiosum of the penis in males.

The vagina opens into the *vestibule*, a space bordered by the female external genitalia (**Figure 28–18a**). The **hymen** (HĪ-men) is an elastic epithelial fold of variable size that partially blocks the entrance to the vagina. An intact hymen is typically stretched or torn during first sexual intercourse, tampon use, pelvic examination, or physical activity.

The vagina lies parallel to the rectum, and the two are in close contact posteriorly. Anteriorly, the urethra extends along

Figure 28–18 Anatomy of the Vagina.**Figure 28–19** Anatomy of the Female External Genitalia.

the superior wall of the vagina from the urinary bladder to the external urethral orifice, which opens into the vestibule.

The primary blood supply of the vagina is by the **vaginal branches** of the internal iliac (or uterine) arteries and veins. Innervation is from the hypogastric plexus, sacral nerves S_2 – S_4 , and branches of the pudendal nerve.

Histology of the Vagina

In sectional view, the lumen of the vagina appears constricted, forming a rough H-shape. The vaginal walls contain a network of blood vessels and layers of smooth muscle (**Figure 28–18b**). The lining is moistened by secretions of the cervical glands and by the movement of water across the permeable epithelium.

The vaginal lumen is lined by a nonkeratinized stratified squamous epithelium (**Figure 28–18b**). In the relaxed state, this epithelium forms folds called *rugae* (RŪ-gē). The underlying lamina propria is thick and elastic, and it contains small blood vessels, nerves, and lymph nodes. The vaginal mucosa is surrounded by an elastic *muscular* layer consisting of layers of smooth muscle fibers arranged in circular and longitudinal bundles continuous with the uterine myometrium. The portion of the vagina adjacent to the uterus has a serosal covering that is continuous with the pelvic peritoneum. Along the rest of the vagina, the muscular layer is surrounded by an *adventitial layer* of fibrous connective tissue.

The vagina contains a population of resident bacteria, usually harmless, supported by nutrients in the cervical mucus. The metabolic activity of these bacteria creates an acidic environment, which restricts the growth of many pathogens. However, this acidic environment also inhibits the motility of sperm.

Vaginitis (vaj-ih-NĪ-tis), an inflammation of the vagina, is caused by fungal, bacterial, or parasitic infections. In addition to any discomfort that may result, the condition may affect the survival of sperm and thereby reduce fertility.

The hormonal changes associated with the *ovarian cycle*, the monthly cycle that produces an oocyte, also affect the vaginal epithelium. By examining a *vaginal smear*—a sample of epithelial cells shed at the surface of the vagina—a clinician can estimate the corresponding stages in the ovarian and uterine cycles. This diagnostic procedure is an example of *exfoliative cytology*.

The Female External Genitalia

The area containing the external genitalia is the **vulva** (VUL-vuh), or *pudendum* (pū-DEN-dum; **Figure 28–19**). The vagina opens into the **vestibule**, a central space surrounded by small folds known as the **labia minora** (LĀ-bē-uh mi-NOR-uh; singular, *labium minus*). The labia minora are covered with smooth, hairless skin. The urethra opens into the vestibule just anterior to the vaginal entrance. The **urethral glands** discharge into the urethra near the external urethral opening.

Anterior to this opening, the **clitoris** (KLIT-ō-ris) projects into the vestibule. A small, rounded tissue projection, the clitoris is derived from the same embryonic structures as the penis in males and has a major role in female sexual response. Internally, it contains erectile tissue called **corpus cavernosum of clitoris** (comparable to those structures of the penis) that form its **body**. A small erectile **glans** sits atop the body. The vestibular bulbs, located along each side of the vestibule, are comparable to the male corpus spongiosum. These erectile tissues engorge with blood during sexual arousal. Extensions of the labia minora encircle the body of the clitoris, forming its **prepuce**.

A variable number of small **lesser vestibular glands** discharge their secretions onto the exposed surface of the vestibule between the orifices of the vagina and urethra. During sexual arousal, the **greater vestibular glands**, located on each side of the distal portion of the vagina, secrete into the vestibule. These mucous glands keep the area moist and lubricated. The vestibular glands have the same embryonic origins as the bulbo-urethral glands in males.

The outer margins of the vulva are formed by the mons pubis and the labia majora. The **mons pubis** is a pad of adipose tissue covering the pubic symphysis. Adipose tissue also accumulates within the **labia majora** (singular, *labium majus*), prominent folds of skin that encircle and partially conceal the

labia minora and adjacent structures. The outer margins of the labia majora and the mons pubis are covered with coarse hair, but the inner surfaces of the labia majora are hairless. Sebaceous glands and scattered apocrine sweat glands secrete onto the inner surface of the labia majora, moistening and lubricating them.

The Breasts

Female **breasts** are two projections anterior to the pectoral muscles that include a mammary gland, a variable amount of fat, a nipple, and an areola. Breasts are rudimentary in the male. A newborn infant cannot fend for itself, and several of its key systems have yet to complete development. Over the initial period of adjustment to an independent existence, the infant is nourished from the milk secreted by the **mammary glands**. Milk production, or **lactation** (lak-TĀ-shun), takes place in these glands. Mammary glands are specialized organs of the integumentary system that are controlled mainly by hormones of the reproductive system and by the *placenta*, a temporary structure that provides the embryo and fetus with nutrients.

On each side, a mammary gland lies in the subcutaneous tissue of the pectoral **adipose tissue** deep to the skin of the chest (**Figure 28–20a**). Each breast has a **nipple**, a small conical projection where the ducts of the underlying mammary gland open onto the body surface. The reddish-brown skin around each nipple is the **areola** (a-RĒ-ō-luh). Large sebaceous glands deep to the areolar surface give it a grainy texture.

The glandular tissue of a mammary gland consists of separate lobes, each containing several secretory lobules. Ducts leaving the lobules converge, giving rise to a single **lactiferous** (lak-TIF-er-us) **duct** in each lobe. Near the nipple, that lactiferous duct enlarges, forming an expanded chamber called a **lactiferous sinus**. Typically, 15–20 lactiferous sinuses open onto the surface of each nipple. Dense connective tissue surrounds the duct system and forms partitions that extend between the lobes and the lobules. These bands of connective tissue, the *suspensory ligaments of the breast*, originate in the dermis of the overlying skin. A layer of areolar tissue separates the mammary gland complex from the underlying pectoralis muscles. Branches of the *internal thoracic artery* supply blood to each mammary gland (look back at **Figure 21–20**).

Figure 28–20b,c compares the histology of inactive and active mammary glands. An inactive, or *resting*, mammary gland is dominated by a duct system rather than by active glandular cells. The size of the mammary glands in a nonpregnant female reflects primarily the amount of adipose tissue present, not the amount of glandular tissue. The secretory apparatus normally does not complete its development unless pregnancy occurs. An active mammary gland is a tubulo-alveolar gland, consisting of multiple glandular tubes that end in secretory alveoli. We discuss the hormonal mechanisms involved in lactation in Chapter 29.

Figure 28–20 Anatomy of the Breast.

Clinical Note Fibrocystic Disease and Breast Cancer

The uterine cycle also influences cyclical changes in the mammary glands. Occasional discomfort or even inflammation of mammary gland tissues can occur late in the cycle. If inflamed lobules become walled off by scar tissue, **cysts** are created. Clusters of cysts can be felt in the breast as discrete masses, a condition known as **fibrocystic disease**. Because its symptoms are similar to those of breast cancer, biopsies may be needed to distinguish between this benign condition and breast cancer.

Breast cancer is a malignant, metastasizing tumor of the mammary gland. Notable risk factors include (1) a family history of breast cancer, (2) a first pregnancy after age 30, and (3) early menarche (first menstruation) or late menopause (end of menstruation).

Despite repeated studies, no links have been proven between breast cancer and birth control pills, fat consumption, or alcohol use. It appears likely that multiple factors are involved. In some families an inherited genetic variation has been linked to higher-than-normal risk of developing the disease. However, most females never develop breast cancer—even females in families with a history of the disease. Females who breastfed (nursed) infants have a 20% lower incidence of breast cancer after menopause than do females who did not breastfeed. The reason is not known. Furthermore, nursing does not appear to affect the incidence of premenopausal breast cancer.

+ Clinical Note Laparoscopy

Laparoscopy is a minimally invasive procedure that allows a direct view into the abdominopelvic cavity. The technique is often used to assess the health of female pelvic structures when another diagnostic test, such as an x-ray, is inconclusive. The surgeon makes a tiny incision through the abdominal wall while the patient is under general anesthesia. Through this opening, carbon dioxide gas is injected into the abdomen to spread out the organs and increase visibility. Then the laparoscope is inserted. The scope is a flexible tube with a tiny light and an equally tiny camera. The surgeon can look around, take photos, and collect biopsies. Laparoscopy can determine, for example, the presence of a blocked uterine tube or a cyst on an ovary.

+ Clinical Note Mammoplasty

Mammoplasty includes three types of surgical breast alteration. *Breast augmentation* involves increasing breast size. In this procedure, the size or contour of the breast is modified by the placement of fluid-filled implants under the skin, and either superficial or deep to the pectoral muscles. The surgeon may be able to insert the implant through an incision along the margin of the areola of the nipple. A second approach is to enter from the axilla. A third option is to make a small incision directly underneath each breast. *Breast reduction* involves decreasing breast size. Some females choose breast reduction because they experience neck or back pain due to excessive breast size. Finally, females who have undergone surgery for breast cancer in which breast tissue has been removed may seek *breast reconstruction*.

28-5 Oogenesis occurs in the ovaries, and hormones from the hypothalamus, pituitary gland, and ovaries control female reproductive functions

Learning Outcome Describe the ovarian roles in oogenesis, explain the complete ovarian and uterine cycles, and summarize all aspects of the female reproductive cycle.

Three interrelated processes help to ensure the continuation of our species from the female perspective: oogenesis, the ovarian cycle, and the uterine cycle. *Oogenesis* is the production of gametes called oocytes. Oogenesis takes place in the ovaries within structures called *follicles*. The *ovarian cycle* is the monthly series of events associated with the maturation of an oocyte. The *uterine cycle* involves a series of events that prepares the uterus for implantation of a fertilized oocyte. This section describes these events and how they are influenced by hormones.

Oogenesis

Ovum production, or **oogenesis** (ō-ō-JEN-eh-sis; oo-, of an egg), begins before a female's birth, accelerates at puberty, and ends at *menopause* (end of menstruation). Between puberty and menopause, oogenesis occurs monthly as part of the ovarian cycle.

Oogenesis is summarized in **Figure 28-21**. This process begins during fetal development, when female reproductive stem cells called **oogonia** (ō-ō-GŌ-nē-uh; singular, *oogonium*) undergo mitosis, producing diploid **primary oocytes** ($2n$). After 5 months of development, fetal ovaries contain an estimated 7 million primary oocytes. Not all survive. At birth the ovaries have approximately 2 million primary oocytes. However, most of these primary oocytes do not survive until puberty, degenerating in a process called *atresia* (ah-TRĒ-zē-uh). By puberty, their number has decreased to about 400,000.

The remaining primary oocytes begin meiosis I, proceed as far as prophase I, and then remain in that state until the female reaches puberty. At that point, some are stimulated to finish meiosis I, producing haploid **secondary oocytes** (n). Note that the cytoplasm of the primary oocyte is unevenly distributed during the two meiotic divisions (**Figure 28-21**). Oogenesis produces one secondary oocyte, which contains most of the original cytoplasm, and two or three **polar bodies**, nonfunctional cells that later disintegrate.

The secondary oocyte then begins meiosis II, but it is suspended at metaphase II. In the process of *ovulation*, the ovary releases such a secondary oocyte. This secondary oocyte will not complete meiosis II and become a mature ovum unless fertilization occurs.

✓ Checkpoint

8. Name the structures of the female reproductive system.
9. What effect would blockage of both uterine tubes by scar tissue (resulting from an infection such as gonorrhea) have on a female's ability to conceive?
10. What benefit does the acidic pH of the vagina provide?
11. Would the blockage of a single lactiferous sinus interfere with the delivery of milk to the nipple? Explain.

See the blue Answers tab at the back of the book.

Figure 28–21 The Process of Oogenesis. For clarity, biological maternal and biological paternal chromatids are not identified.

Follicle Development

Specialized structures in the cortex of the ovaries called **ovarian follicles** (ō-VAR-ē-an FOL-i-klz) are the sites of both oocyte growth and meiosis I of oogenesis. Follicle development and the ovarian cycle are shown in **Figure 28–22**.

1 Primordial Ovarian Follicles in Egg Nest. Primary oocytes are in the outer portion of the ovarian cortex, near the tunica albuginea, in clusters called *egg nests*. A single squamous layer of *follicle cells* surrounds each primary oocyte within an egg nest. The primary oocyte and its follicle cells form a **primordial ovarian follicle**. At puberty, each ovary contains about 200,000 primordial follicles. Forty years later, few if any primary ovarian follicles remain, although only about 500 secondary oocytes will have been ovulated.

Beginning at puberty, primordial ovarian follicles are continuously activated to join other follicles already in development. The activating mechanism is unknown, but local hormones or growth factors within the ovary may be involved. The activated primordial ovarian follicle will either eventually mature and release a secondary oocyte or degenerate through follicular atresia.

2 Formation of Primary Ovarian Follicle. The preliminary steps in follicle development vary in length but may take almost a year to complete. Follicle development begins with the activation of primordial ovarian follicles into **primary ovarian follicles**. The follicular cells enlarge, divide, and form several layers of cells around the growing primary oocyte. The cells begin to produce sex hormones called estrogens. Microvilli from the surrounding follicle cells intermingle with microvilli originating at the surface of the oocyte. This region is called the **zona pellucida** (ZŌ-na pe-LŪ-sid-uh; *pellucidus*, translucent). The microvilli

increase the surface area available for the transfer of materials from the follicular cells to the growing oocyte.

3 Formation of Secondary Ovarian Follicle. Many primordial ovarian follicles develop into primary ovarian follicles, but only a few mature further in the next 4 months or so.

Figure 28–22 Follicle Development and the Ovarian Cycle. The photomicrographs show the changes in an ovarian follicle as it develops. It enters the 28-day ovarian cycle as a tertiary ovarian follicle. The drawing of the ovary illustrates the sequence and relative sizes of the various stages in the development, ovulation, and degeneration of an ovarian follicle. Follicles do not physically move around the periphery of the ovary.

This process is apparently under the control of a growth factor produced by the oocyte. The transformation begins as the wall of the follicle thickens. At this stage, the complex is known as a **secondary ovarian follicle**. The primary oocyte continues to grow slowly.

4 Formation of Tertiary Ovarian Follicle. During the next 2 to 3 months, the follicle wall continues to grow and the deeper follicular cells begin secreting *follicular fluid*. This fluid accumulates in small pockets that gradually expand between the inner and outer cellular layers of the follicle. The secondary ovarian follicle as a whole has doubled in size, and is now called a *tertiary ovarian follicle*. Tertiary ovarian follicles, also called *vesicular follicles*, continue to grow and accumulate follicular fluid.

The Ovarian Cycle

The tertiary follicles are then ready to complete their maturation as part of the 28-day ovarian cycle. The monthly process of the maturation, ovulation, and degeneration of a tertiary ovarian follicle is known as the **ovarian cycle** (Figure 28–22). We can divide the ovarian cycle into a *follicular phase* (folliculogenesis) and a *luteal phase* (luteogenesis), each lasting about 14 days. The luteal phase involves the follicle after ovulation, when it becomes an endocrine structure called a *corpus luteum* (LŪ-tē-um) that secretes a sex hormone.

The Follicular Phase

In the **follicular phase**, or *preovulatory phase*, a tertiary ovarian follicle is ready to complete its maturation. Ovulation marks the end of this phase.

At the start of each ovarian cycle, an ovary contains only a few tertiary follicles destined for further development. Stimulated by FSH, one of these follicles becomes dominant by day 5 of the cycle and it rapidly increases in size. This remaining **tertiary ovarian follicle**, also called a *mature graafian* (GRAF-ē-an) *follicle*, is about 15–20 mm (0.6–0.8 in.) in diameter. It is formed by days 10–14 of the ovarian cycle. Its large size creates a prominent bulge in the surface of the ovary. The oocyte and its covering of follicular cells projects into the expanded central chamber of the follicle, the **antrum** (AN-trum). The antrum is surrounded by a mass of **granulosa cells**. As the granulosa cells enlarge and multiply, adjacent cells in the ovarian stroma form a layer of **thecal endocrine cells** (*theca*, a box) around the follicle. Thecal endocrine cells and granulosa cells work together to produce the sex hormones called **estrogens**.

Until this time, the primary oocyte has been suspended in prophase of meiosis I. As the development of the remaining tertiary ovarian follicle ends, rising LH levels prompt the primary oocyte to complete meiosis I. The completion of the first meiotic division produces a secondary oocyte and a small, nonfunctional polar body (Figure 28–21). The secondary

oocyte begins meiosis II but stops short of dividing. Meiosis II will not be completed unless fertilization occurs.

Generally, on day 14 of a 28-day ovarian cycle, the secondary oocyte and its surrounding follicular cells lose their connections with the follicular wall and drift free within the antrum. The granulosa cells still associated with the secondary oocyte form a protective layer known as the **corona radiata** (kō-RŌ-nuh rā-dē-AH-tuh).

5 Ovulation. At **ovulation** (ōv-ū-LĀ-shun), the tertiary follicle releases the secondary oocyte. The distended follicular wall then ruptures, releasing the follicular contents, including the secondary oocyte, into the pelvic cavity. The sticky follicular fluid keeps the corona radiata attached to the surface of the ovary near the ruptured wall of the follicle. The oocyte is then moved into the uterine tube by contact with the fimbriae that extend from the tube's funnel-like opening (Figure 28–14a), and/or by fluid currents produced by the cilia that line the tube.

Usually only a single oocyte is released into the pelvic cavity at ovulation, although many primordial ovarian follicles may have developed into primary ovarian follicles, and several primary ovarian follicles may have been converted to secondary ovarian follicles. These follicles undergo follicular atresia.

The Luteal Phase

After ovulation occurs, the **luteal phase**, or *postovulatory phase*, begins. This phase ends with the degeneration of the corpus luteum.

6 Formation of Corpus Luteum. The empty tertiary ovarian follicle initially collapses, and ruptured vessels bleed into the antrum. Under the stimulation of LH, the remaining granulosa cells then invade the area and proliferate to create the **corpus luteum**.

The corpus luteum is so named (*lutea*, yellow) because this is the color of the cholesterol it contains. This cholesterol is used to manufacture the steroid hormone **progesterone** (prō-JES-ter-ōn). Progesterone is the main hormone during the luteal phase. Progesterone's primary function is to prepare the uterus for pregnancy by stimulating the maturation of the uterine lining and the secretions of uterine glands. The corpus luteum also secretes moderate amounts of estrogens, but levels are not as high as they were at ovulation.

7 Formation of Corpus Albicans. The corpus luteum begins to degenerate about 12 days after ovulation (unless fertilization takes place). Progesterone and estrogen levels then decrease significantly. Fibroblasts invade the nonfunctional corpus luteum, producing a knot of pale scar tissue called a **corpus albicans** (AL-bi-kanz).

The disintegration of the corpus luteum marks the end of the ovarian cycle. A new ovarian cycle then begins with another group of tertiary ovarian follicles.

The Uterine (Menstrual) Cycle

The **uterine cycle**, or *menstrual* (MEN-strū-ul) *cycle*, is a repeating series of changes in the structure of the endometrium (**Figure 28–23**). The uterine cycle averages 28 days in length, but it can range from 21 to 35 days in healthy females of reproductive age.

The uterine cycle begins at puberty. The first cycle, known as *menarche* (me-NAR-kē; *men*, month + *arche*, beginning), typically occurs at age 11–12. The cycles continue until *menopause* (MEN-ō-pawz), the termination of the uterine cycle, at

age 45–55. Over the interim, the regular appearance of uterine cycles is interrupted only by circumstances such as illness, stress, starvation, or pregnancy.

The uterine cycle is divided into three phases: (1) the *menstrual phase*, (2) the *proliferative phase*, and (3) the *secretory phase*. The phases take place in response to hormones associated with the regulation of the ovarian cycle. The menstrual and proliferative phases occur during the follicular phase of the ovarian cycle. The secretory phase corresponds to the luteal phase of the ovarian cycle.

Figure 28–23 A Comparison of the Structure of the Endometrium during the Phases of the Uterine Cycle.

Which layer of the endometrium is affected most during the uterine cycle?

Tips

Progesterone literally means a steroid (**-one**) that favors (**pro-**) gestation (**-gest**).

Menstrual Phase

The uterine cycle begins with the **menstrual phase**. This phase is marked by the degeneration and sloughing (shedding) of the endometrial functional layer, leading to **menstruation** (men-strū-Ā-shun), also called **menses** (MEN-sēz) (Figure 28-23a). Endometrial degeneration occurs in patches. It is caused by constriction of the spiral arteries, which reduces blood flow to areas of the endometrium. Deprived of oxygen and nutrients, the secretory glands and other tissues in the functional layer begin to deteriorate. Eventually, the weakened arterial walls rupture, and blood pours into the connective tissues of the functional layer. Blood cells and degenerating tissues then break away and enter the uterine cavity, to be shed as they pass through the external os and into the vagina. Only the functional layer is affected, because the deeper, basal layer receives blood from the straight arteries, which remain uncontracted.

The sloughing of tissue is gradual, and repairs begin almost immediately at each site. Nevertheless, before menstruation has ended, the entire functional layer has been lost. The menstrual phase generally lasts from 1 to 7 days. During this time about 35–50 mL (1.2–1.7 oz) of blood are lost.

The process can be relatively painless. However, painful menstruation, or **dysmenorrhea**, can result from myometrial contractions (“cramps”), uterine inflammation, or conditions involving adjacent pelvic structures.

The Proliferative Phase

The basal layer, including the basal parts of the uterine glands, survives menstruation intact. In the days after menstruation, the epithelial cells of the uterine glands multiply and spread across the endometrial surface, restoring the uterine epithelium (Figure 28-23b). Further growth and vascularization completely restore the functional layer.

During this reorganization, the endometrium is in the **proliferative phase**. Restoration takes place at the same time as the tertiary ovarian follicles enlarge in the ovary. Estrogens secreted by the developing ovarian follicles stimulate and sustain the proliferative phase.

By the time ovulation occurs, the functional layer is several millimeters thick. Prominent mucous glands extend to its border with the basal layer. At this time, the uterine glands are manufacturing mucus that is rich in glycogen. This specialized mucus appears to be essential for the survival of the fertilized ovum through its earliest developmental stages. (These stages are described in Chapter 29.) The entire functional layer is highly vascularized, with small arteries spiraling toward the endometrial surface from larger arteries in the myometrium.

The Secretory Phase

During the **secretory phase** of the uterine cycle, the uterine glands enlarge, accelerating their rates of secretion. The arteries that supply the uterine wall elongate and spiral through the tissues of the functional layer (Figure 28-23c). This activity occurs under the combined stimulatory effects of progesterone and estrogens from the corpus luteum. The secretory phase begins at the time of ovulation and persists if the corpus luteum remains intact.

Secretory activities peak about 12 days after ovulation. Over the next day or two, the glands become less active. The uterine cycle ends as the corpus luteum stops producing stimulatory hormones. A new uterine cycle then begins with the onset of menstruation and the disintegration of the functional layer.

The secretory phase generally lasts 14 days. For this reason, the date of ovulation can be identified by counting backward 14 days from the first day of menstruation.

Hormonal Coordination of the Ovarian and Uterine Cycles

The female reproductive tract is under hormonal control that involves interplay between secretions of both the pituitary gland and the gonads. Circulating hormones control the **female reproductive cycle**, coordinating the ovarian and uterine cycles for proper reproductive function. If the two cycles are not properly coordinated, *infertility*, the inability to conceive or carry a pregnancy to term, results.

As in males, GnRH from the hypothalamus regulates reproductive function in females. However, in females, the GnRH pulse frequency and amplitude (amount secreted per pulse) change throughout the ovarian cycle. If the hypothalamus were a radio station, the pulse frequency would correspond to the radio frequency it is transmitting on, and the amplitude would be the volume. We discuss changes in pulse frequency because their effects are both dramatic and reasonably well understood. Circulating levels of estrogens and progesterone primarily control changes in GnRH pulse frequency. Estrogens increase the GnRH pulse frequency, and progesterone decreases it.

The endocrine cells of the anterior lobe of the pituitary gland respond as if each group of endocrine cells is monitoring different frequencies. As a result, each group of cells is sensitive to some GnRH pulse frequencies and insensitive to others. For example, consider the *gonadotropes*, the cells that produce FSH and LH. At one pulse frequency, the gonadotropes secrete FSH, but at another frequency, these cells primarily release LH. FSH and LH production also occurs in pulses that follow the rhythm of GnRH pulses. If GnRH is absent or is supplied at a constant rate (without pulses), FSH and LH secretion stops in a matter of hours.

Spotlight Figure 28-24 shows the changes in circulating hormone levels that accompany the ovarian and uterine cycles.

The ovarian and uterine cycles must operate in synchrony to ensure proper reproductive function. If the two cycles are not properly coordinated, infertility results. A female who doesn't ovulate cannot conceive, even if her uterus is perfectly normal. A female who ovulates normally, but whose uterus is not ready to support an embryo, will also be infertile.

As in males, GnRH from the hypothalamus regulates reproductive function in females. However, in females, GnRH levels change throughout the course of the ovarian cycle.

HYPOTHALAMUS

1

Release of Gonadotropin-Releasing Hormone (GnRH)

The cycle begins with the release of GnRH, which stimulates the production and secretion of FSH and the production only of LH.

Release of GnRH

2

Follicular Phase of the Ovarian Cycle

The follicular phase begins when FSH stimulates growth and development of a group of tertiary ovarian follicles. Usually only one follicle becomes dominant.

As tertiary ovarian follicles develop, FSH levels decrease due to the negative feedback effects of inhibin.

Developing ovarian follicles also secrete estrogens, especially estradiol, the dominant hormone prior to ovulation.

In low concentrations, estrogens inhibit LH secretion. This inhibition gradually decreases as estrogen levels increase.

Negative feedback

ANTERIOR LOBE OF PITUITARY GLAND

Production and secretion of FSH

Production of LH

Secretion of LH

3

Luteal Phase of the Ovarian Cycle

The combination of increased GnRH pulse frequency and elevated estrogen levels stimulates LH secretion.

On or around day 14, a surge in LH level triggers (1) the completion of meiosis I by the primary oocyte, (2) the forceful rupture of the follicular wall, (3) ovulation, about 9 hours after the LH peak, and (4) formation of the corpus luteum.

The corpus luteum secretes progesterone, which stimulates and sustains endometrial development.

After ovulation, progesterone levels rise and estrogen levels fall. This suppresses GnRH secretion. If pregnancy does not occur, the corpus luteum will degenerate after 12 days, and as progesterone levels decrease, GnRH secretion increases, and a new cycle begins.

OVARY

Before day 10

- Ovarian follicle development
- Secretion of inhibin
- Secretion of estrogens

After day 10

Establishment and maintenance of female secondary sex characteristics

Maintenance of accessory glands and organs

Stimulation of endometrial growth and secretion

KEY

→ Stimulation
 || Inhibition

This illustration combines the key events in the ovarian and uterine cycles. The monthly hormonal fluctuations cause physiological changes that affect core body temperature. During the follicular phase—when estrogens are the dominant hormones—the **basal body temperature**, or the resting body temperature measured upon awakening in the morning, is about 0.3°C (0.5°F) lower than it is during the luteal phase, when progesterone dominates.

Early in the follicular phase of the ovarian cycle and prior to day 10, the levels of estrogens are low and the GnRH pulse frequency is 16–24 per day (one pulse every 60–90 minutes). At this frequency, FSH is the dominant hormone released by the anterior lobe of the pituitary gland. The estrogens released by developing follicles inhibit LH secretion. As tertiary ovarian follicles develop, the FSH level decreases due to the negative feedback effects of inhibin. Follicular development and maturation continue, however, supported by the combination of estrogens, FSH, and LH.

As one of the tertiary ovarian follicles becomes dominant, the concentration of circulating estrogens rises steeply. As a result, the GnRH pulse frequency increases to about 36 per day (one pulse every 30–60 minutes). The increased pulse frequency stimulates LH secretion. In addition, around day 10 of the cycle, the effect of estrogen on LH secretion switches from inhibition to stimulation. The changeover takes place only after the levels of estrogens have risen above a specific threshold value for about 36 hours. (The threshold value and the time required vary among individuals.) High levels of estrogens also increase gonadotrope sensitivity to GnRH. At about day 14, the estrogen levels have peaked, the gonadotropes are at maximum sensitivity, and the GnRH pulses are arriving about every 30 minutes. The result is a massive release of LH from the anterior lobe of the pituitary gland. This sudden surge in LH concentration triggers (1) the completion of meiosis I by the primary oocyte, (2) the forceful rupture of the follicular wall, and (3) ovulation. Typically, ovulation occurs 34–38 hours after the LH surge begins, about 9 hours after the LH peak.

Hormonal Regulation of the Ovarian Cycle

The phases of the ovarian cycle are regulated by various hormones. Follicle-stimulating hormone (FSH) and luteinizing hormone (LH) are the main hormones influencing the follicular phases. Progesterone is the dominant hormone directing the luteal phase. If implantation does not occur, the menstrual cycle begins. This section describes the hormonal regulation of the ovarian cycle.

Regulation of the Follicular Phase. Follicular development begins under FSH stimulation. Each month some of the tertiary ovarian follicles begin to grow, but only one will become dominant. As the follicles enlarge, thecal endocrine cells start producing *androstenedione*, a steroid hormone that is a key intermediate in the synthesis of estrogens and androgens. The granulosa cells absorb androstenedione and convert it to estrogens. In addition, thecal endocrine cells scattered throughout the ovarian stroma secrete small quantities of estrogens. Circulating estrogens are bound primarily to albumins, with lesser amounts carried by gonadal steroid-binding globulin (GBG).

Of the three estrogens circulating in the bloodstream—*estradiol*, *estrone*, and *estriol*—**estradiol** (es-tra-DĪ-ol) is the most abundant and has the most pronounced effects on target

tissues. It is the dominant hormone prior to ovulation. During estradiol synthesis, androstenedione is first converted to testosterone, which the enzyme aromatase converts to estradiol (**Figure 28–25**). The synthesis of both estrone and estriol proceeds directly from androstenedione.

Estrogens have multiple functions that affect the activities of many tissues and organs throughout the body. Among the important general functions of estrogens are (1) stimulating bone and muscle growth; (2) maintaining female secondary sex characteristics, such as body hair distribution and the location of adipose tissue deposits; (3) affecting CNS activity, especially in the hypothalamus, where estrogens increase the sexual drive; (4) maintaining functional accessory reproductive glands and organs; and (5) initiating the repair and growth of the endometrium.

Regulation of the Luteal Phase. The high LH level that triggers ovulation also promotes progesterone secretion and the formation of the corpus luteum. As the progesterone level rises and the levels of estrogens fall, the GnRH pulse frequency decreases sharply, soon reaching one to four pulses per day. This frequency of GnRH pulses stimulates LH secretion more than it does FSH secretion, and the LH maintains the structure and secretory function of the corpus luteum.

The corpus luteum secretes moderate amounts of estrogens, but progesterone is the main hormone of the luteal phase. Its primary function is to continue the preparation of the uterus for pregnancy. Progesterone enhances the blood supply to the functional layer and stimulates the secretion of uterine glands. The progesterone level remains high for the next week, but unless pregnancy occurs, the corpus luteum begins to degenerate.

About 12 days after ovulation, the corpus luteum becomes nonfunctional, and progesterone and estrogen levels fall markedly. The blood supply to the functional layer is restricted, and the endometrial tissues begin to deteriorate. As progesterone and estrogen levels decrease, the GnRH pulse frequency increases, stimulating FSH secretion by the anterior lobe of the pituitary gland, and the ovarian cycle begins again.

The hormonal changes involved with the ovarian cycle in turn affect the activities of other reproductive tissues and organs. At the uterus, the hormonal changes maintain the uterine cycle.

Hormonal Regulation of the Uterine Cycle

Spotlight Figure 28–24 also shows the changes in the endometrium during a single uterine cycle. Progesterone and estrogen levels decrease as the corpus luteum degenerates, resulting in menstruation. The shedding of endometrial tissue continues for several days, until rising levels of estrogens stimulate the repair and regeneration of the functional layer of the endometrium. The proliferative phase then continues until a rising progesterone level marks the arrival of the secretory phase. The combination of estrogen and progesterone then causes the uterine glands to enlarge and increase their secretions.

Figure 28–25 Pathways of Steroid Hormone Synthesis in Males and Females. All gonadal steroids are derived from cholesterol. In males, the pathway ends with the synthesis of testosterone, which may subsequently be converted to dihydrotestosterone. In females, an additional step after testosterone synthesis leads to estradiol synthesis. The synthesis of progesterone and estrogens other than estradiol involves alternative pathways.

What is the precursor for all steroid hormones in both males and females?

28-6 The autonomic nervous system influences male and female sexual physiology

Learning Outcome Discuss the physiology of sexual intercourse in males and females.

Sexual intercourse introduces semen into the female reproductive tract. The process, in which the autonomic nervous system plays a critical part, affects both the male and female reproductive

systems. Sexual intercourse can lead to several consequences, including pregnancy and sexually transmitted infections.

Human Sexual Function

Human sexual function refers to how the body reacts during the sexual response.

Male Sexual Function

Complex neural reflexes coordinate sexual function in males. The reflex pathways use the sympathetic and parasympathetic divisions of the autonomic nervous system (ANS). During sexual **arousal**, erotic thoughts, the stimulation of sensory nerves in the genital region, or both lead to an increase in parasympathetic outflow over the pelvic nerves. This outflow in turn leads to **erection** of the penis. The parasympathetic innervation of the penile arteries involves neurons that release nitric oxide at their axon terminals. The smooth muscles in the arterial walls relax when nitric oxide is released. At that time, the vessels dilate, blood flow increases, and the vascular channels become engorged with blood. The skin covering the

glans penis contains numerous sensory receptors, and erection tenses the skin and increases sensitivity. Subsequent stimulation can initiate the secretion of the bulbo-urethral glands, providing **lubrication** for the spongy urethra and the surface of the glans penis.

During intercourse, the sensory receptors of the penis are rhythmically stimulated. This stimulation eventually results in the coordinated processes of emission and ejaculation. **Emission** occurs under sympathetic stimulation. The process begins when the peristaltic contractions of the ampullae of the ductus deferentia push seminal fluid and sperm into the prostatic urethra. The seminal glands then begin contracting, and the contractions increase in force and duration over the next few seconds. Peristaltic contractions also appear in the walls of the prostate. The combination moves the seminal mixture into the membranous and penile portions of the urethra. As the contractions proceed, sympathetic commands also cause the contraction of the urinary bladder and the internal urethral sphincter. The combination of elevated pressure inside the bladder and the contraction of the sphincter effectively prevents semen from passing into the bladder.

Ejaculation occurs as powerful, rhythmic contractions appear in the *ischiocavernosus* and *bulbospongiosus*, two pairs of superficial skeletal muscles of the pelvic floor. The ischiocavernosus muscles insert along the sides of the penis. Their contractions serve primarily to stiffen that organ. The bulbospongiosus muscles wrap around the base of the penis. The contraction of these muscles pushes semen toward the external urethral opening. The contractions of both muscles are controlled by somatic motor neurons in the inferior lumbar and superior sacral segments of the spinal cord. (The positions of these muscles are shown in **Figure 11–13b**.) Contraction of the smooth muscle within the prostate acts to pinch off the urethra, preventing urine from passing through the erect penis.

Ejaculation is associated with intensely pleasurable sensations associated with perineal muscle contraction, an experience known as male **orgasm** (OR-gazm). Several other noteworthy physiological changes take place at this time, including pronounced but temporary increases in heart rate and blood pressure. After orgasm, a **resolution** phase occurs as heart rate and blood pressure decrease and blood begins to leave the erectile tissue and the erection begins to subside. This process of losing an erection, called **detumescence** (dē-tū-MES-ens), is mediated by the sympathetic nervous system. A *refractory period* occurs during the initial period of resolution in which it is generally impossible for another orgasm to occur.

In sum, arousal, erection, emission, ejaculation, orgasm, and resolution are controlled by a complex interplay between the sympathetic and parasympathetic divisions of the ANS. Higher centers, including the cerebral cortex, can facilitate or inhibit many of the important reflexes, modifying sexual function.

Any physical or psychological factor that affects a single component of the system can result in male sexual dysfunction. **Erectile dysfunction (ED)**, also called *impotence*, is an inability to achieve or maintain an erection. Various physical causes may be responsible for ED, because erection involves vascular changes as well as neural commands. For example, low blood pressure in the arteries supplying the penis, due to a circulatory blockage such as a plaque, will reduce the ability to attain an erection. Drugs, alcohol, trauma, or illnesses that affect the ANS or the CNS can have the same effect. But male sexual performance can also be strongly affected by the psychological state of the individual. Temporary periods of erectile dysfunction are common in healthy individuals who are experiencing severe stresses or emotional problems. Depression, anxiety, and fear of ED are examples of emotional factors that can result in sexual dysfunction. Prescription drugs, which enhance and prolong the effects of nitric oxide on the erectile tissue of the penis, have proven useful in treating many cases of erectile dysfunction.

Female Sexual Function

The events in female sexual function are largely comparable to those of male sexual function. During sexual arousal, parasympathetic activation leads to engorgement of the clitoris and vestibular bulbs and increased secretion from cervical mucous glands and greater vestibular glands. Clitoral erection increases the receptors' sensitivity to stimulation, and the cervical and vestibular glands lubricate the vaginal walls. A network of blood vessels in the vaginal walls becomes filled with blood at this time, and the vaginal surfaces are also moistened by fluid that moves across the epithelium from underlying connective tissues. (This process accelerates during intercourse as the result of mechanical stimulation.) Parasympathetic stimulation also causes contraction of subcutaneous smooth muscle of the nipples, making them more sensitive to touch and pressure.

During sexual intercourse, rhythmic contact of the penis with the clitoris and vaginal walls—reinforced by touch sensations from the breasts and other stimuli (visual, olfactory, and auditory)—provides stimulation that can lead to orgasm. Female orgasm is accompanied by peristaltic contractions of the uterine and vaginal walls and, through impulses traveling over the pudendal nerves, rhythmic contractions of the bulbospongiosus and ischiocavernosus muscles. The latter contractions give rise to the intensely pleasurable sensations of orgasm. Unlike resolution and the refractory period in males, females may have little delay in achieving further orgasms.

Contraception and Infertility

Many different methods can be used to promote or avoid pregnancy. For example, at the time of ovulation, the basal body temperature (BBT) decreases noticeably, making the

rise in temperature over the next day even more noticeable (**Spotlight Figure 28-24**). Urine tests that detect LH are available, and testing daily for several days before expected ovulation can detect the LH surge more reliably than the BBT changes. Because fertilization typically occurs within a day of ovulation, this information can be used to time intercourse according to the wishes of the couple. Using this to avoid conception is called the *rhythm method*.

Other forms of **contraception** (methods to prevent pregnancy) include abstinence, barrier methods, intrauterine devices, chemical methods such as “the pill,” and surgical methods.

Some couples find they have the opposite problem: They are unable to conceive. **Infertility** is defined as the inability to conceive or carry a pregnancy to term after 1 year of unprotected intercourse. Infertility, which affects about 10% of the U.S. population, can happen in both males and females.

For males, the most common issues are low sperm count and motility. Most males with lower sperm counts are infertile, because too few sperm survive the ascent of the female reproductive tract to perform fertilization. A low sperm count may reflect inflammation of the epididymis, ductus deferens, or prostate. Common abnormalities in sperm are malformed heads and “twin” sperm that did not separate at the time of spermiation.

For females, all their reproductive organs and hormonal regulation must work properly to conceive and carry a pregnancy to term. If menarche does not appear by age 16, or if the normal uterine cycle of an adult female is interrupted for 6 months or more, the condition of **amenorrhea** (ā-men-ō-RE-uh) exists. *Primary amenorrhea* is the failure to initiate menstruation. This condition may indicate developmental abnormalities, such as nonfunctional ovaries, the absence of a uterus, or an endocrine or genetic disorder. It can also result from malnutrition: Puberty is delayed if the leptin level is too low.

Severe physical or emotional stresses can cause transient *secondary amenorrhea*. In effect, the reproductive system gets “switched off.” Factors associated with amenorrhea include drastic weight loss, anorexia nervosa, and severe depression or grief. Amenorrhea has also been observed in marathon runners and other females engaged in training programs that require sustained high levels of exertion, which severely reduce body lipid reserves.

Sexually Transmitted Infections

Sexual activity carries with it the risk of infection with a variety of microorganisms. The consequences of such an infection may range from merely inconvenient to potentially lethal. **Sexually transmitted infections (STIs)**, also called **sexually**

transmitted diseases (STDs), are transferred from individual to individual, primarily or exclusively by sexual intercourse. At least two dozen bacterial, viral, and fungal infections are currently recognized as STIs. The bacterium *Chlamydia* can cause **pelvic inflammatory disease (PID)** and infertility. The *Zika virus* (ZIKV) is a cause of fetal brain defects, including microcephaly. Recent evidence indicates it can be spread through sexual contact. AIDS, caused by a virus, is deadly. The incidence of STIs is a significant health challenge in the United States.

Checkpoint

16. What happens when the arteries within the penis dilate?

28-7 Changes in levels of reproductive hormones cause functional changes throughout the life span

Learning Outcome Describe the reproductive system changes that occur with development and aging.

Sex hormones have widespread effects on the body and begin early in development. They affect brain development and behavioral drives, muscle mass, bone mass and density, body proportions, and the patterns of hair and body fat distribution. As noted earlier in the chapter, these systems become fully functional at puberty. At puberty, secretion of sex hormones in both sexes accelerates markedly, initiating sexual maturation and the appearance of secondary sex characteristics. Later, the aging process affects all body systems, including the reproductive systems of all individuals.

Development of the Genitalia

Male and female reproductive systems develop from an embryonic aggregation of cells, termed *primordial cells*. Primordial cells form the first trace of an organ. Both reproductive systems follow a similar pattern of development from the same primordial tissues. They become distinct from each other because of the influence of sex hormones.

Around weeks 5–6 of embryonic development, an embryo is said to be *sexually indifferent*, because the gonads and other

internal and external reproductive structures are similar in both sexes. Whether testicles or ovaries develop depends on the embryo's genetic makeup. (The basis of sex determination is discussed in Chapter 29.) The testicles begin to form during week 7. Ovaries begin forming about a week later. Once the testes have formed, they begin to secrete testosterone continuously throughout fetal development and until a few days after birth. Testosterone stimulates the differentiation and development of male reproductive structures. Without testosterone, the sexually indifferent embryo will develop female reproductive structures.

The development of male and female genitalia from a sexually indifferent stage is shown in **Figure 28–26**. At week 4 of development, a temporary cloacal opening marks the site of the future genitalia (**Figure 28–26a**). A *cloaca* is a cavity or chamber at the end of the digestive tract open to both excretory and reproductive products. By week 6, the cloacal opening becomes subdivided, thus isolating the digestive tract from future urogenital structures. An anterior urogenital membrane will eventually form the urethra and urinary bladder. The genital tubercle present in the sexually indifferent stage will give rise to the penis in the male and clitoris in the female (**Figure 28–26b,c**).

During fetal development, the testes form inside the body cavity adjacent to the kidneys. A bundle of connective tissue fibers—called the *gubernaculum testis* (gū-bur-NAK-ū-lum TES-tis; plural, *gubernacula*)—extends from each testis to the posterior wall of a small anterior and inferior pocket of the peritoneum. As the fetus grows, the gubernacula do not get any longer, so they lock the testes in position. As a result, the position of each testis changes as the body enlarges. The testis gradually moves inferiorly and anteriorly toward the anterior abdominal wall. During the seventh developmental month, fetal growth continues rapidly, and circulating hormones stimulate a contraction of the gubernaculum testis. During this time, each testis moves through the abdominal musculature, along with small pockets of the peritoneal cavity. This process is called the *descent of the testes* into the scrotum (**Figure 28–26b**). Descent of the female gonads is much less than that in males. The ovaries come to lie below the rim of the true pelvis. They are held in place by the suspensory ligament, ovarian ligament, and round ligament of the uterus (**Figure 28–16**).

In *cryptorchidism* (krip-TOR-ki-dizm; *crypto*, hidden + *orchis*, testis), one or both testes have not descended into the scrotum by the time of birth. Typically, the cryptorchid (abdominal) testes are lodged in the abdominal cavity or within the inguinal canal. Cryptorchidism occurs in about 3% of full-term deliveries and in about 30% of premature births. In most instances, normal descent takes place a few weeks later.

The condition can be surgically corrected if it persists. Corrective measures should be taken before *puberty* (sexual maturation), because a cryptorchid testis will not produce

sperm. If both testes are cryptorchid, the male will be *sterile* (*infertile*). If the testes cannot be moved into the scrotum, they will usually be removed. This surgical procedure to remove the testes is called an *orchietomy* (or-kē-EK-tō-mē). About 10% of males with uncorrected cryptorchid testes eventually develop testicular cancer.

As each testis moves through the body wall, the ductus deferens and the testicular blood vessels, nerves, and lymphatic vessels accompany it. Together, these structures form the body of the spermatic cord (**Figure 28–2**).

Effects of Aging

As aging occurs, reductions in sex hormone levels affect appearance, strength, and a variety of physiological functions. The most striking age-related changes in the female reproductive system occur at menopause. Comparable age-related changes in the male reproductive system occur more gradually and over a longer time frame.

The Male Climacteric

Changes in the male reproductive system take place more gradually than do those in the female reproductive system. The period of declining reproductive function, which corresponds to perimenopause in females, is known as the **male climacteric**, or *andropause*. The level of circulating testosterone begins to decrease between the ages of 50 and 60, and levels of circulating FSH and LH increase. However, sperm production continues in males throughout life. In males experiencing low libido (sexual drive), some clinicians suggest the use of testosterone replacement therapy, but this may increase the risk of prostate disease.

Menopause

Menopause is usually defined as the time when ovulation and menstruation cease. Menopause typically occurs at age 45–55, but in the years immediately preceding it, an interval called *perimenopause*, the ovarian and uterine cycles become irregular. A shortage of primordial ovarian follicles is the underlying cause of the irregular cycles. With the arrival of perimenopause, the number of primordial ovarian follicles responding each month begins to decrease markedly. As their numbers decrease, the levels of estrogens decrease and may not increase enough to trigger ovulation. By age 50, there are often no primordial ovarian follicles left to respond to FSH. In **premature menopause**, this depletion occurs before age 40.

Menopause is accompanied by a decrease in circulating concentrations of estrogens and progesterone, and a sharp and sustained increase in the production of GnRH, FSH, and LH. The decrease in the levels of estrogens leads to reductions in the size of the uterus and breasts, accompanied by a thinning

Figure 28-26 The Development of Male and Female Genitalia.

a Sexually Indifferent Stage

By 6 weeks, the cloacal opening has been subdivided into a posterior anal membrane and an anterior urogenital membrane. Urethral folds develop and prominent genital swellings form lateral to each urethral fold. The genital tubercle will develop into either the penis in males, or clitoris in females, depending on the presence or absence of testosterone.

b Development of the Male Genitalia

At 10 weeks, the tips of the urethral folds are moving together to form the spongy urethra, and paired scrotal swellings have developed from the genital swellings. At birth, the urethral folds have closed and testes have descended into the scrotum.

c Development of the Female Genitalia

In the female, the urethral folds do not fuse; they develop into the labia minora. The genital swellings will form the labia majora. The genital tubercle develops into the clitoris. The urethra opens to the exterior immediately posterior to the clitoris. The hymen remains as an elaboration of the urogenital membrane.

COMPARISON OF MALE AND FEMALE GENITALIA	
MALE	FEMALE
Penis	Clitoris
Corpora cavernosa	Erectile tissue
Corpus spongiosum	Vestibular bulbs
Proximal shaft of penis	Labia minora
Spongy urethra	Vestibule
Bulbo-urethral glands	Greater vestibular glands
Scrotum	Labia majora

of the urethral and vaginal epithelia. The decreased concentrations of estrogens have also been linked to the development of osteoporosis, presumably because bone deposition proceeds at a slower rate. A variety of neural effects are reported as well, including “hot flashes,” anxiety, and depression. Hot flashes typically begin while the levels of estrogens are decreasing, and they cease when the levels of estrogens reach minimal values. These intervals of increased body temperature are associated with surges in LH production. The hormonal mechanisms involved in other CNS effects of menopause are poorly understood. In addition, the risks of atherosclerosis and other forms of cardiovascular disease increase after menopause.

Some females experience only mild symptoms, but some experience acutely unpleasant symptoms in perimenopause or during or after menopause. Hormone replacement therapy, also known as menopausal hormone therapy, is a combination of estrogens and progesterone; it is used to relieve the unpleasant symptoms of menopause that result from the neural and vascular changes associated with menopause. The hormones are administered as pills, by injection, or by transdermal “estrogen patches.” However, large, randomized studies suggest that taking estrogen replacement therapy for more than 5 years increases the risk of heart disease, breast cancer, Alzheimer’s disease, blood clots, and stroke. Menopausal hormone therapy is recommended for use only after a full discussion and assessment of the potential risks and benefits; and therapy duration should be as short a time as possible.

28-8 The reproductive system secretes hormones affecting growth and metabolism of all body systems

Learning Outcome Give examples of interactions between the reproductive system and each of the other organ systems.

Normal human reproduction is a complex process that involves multiple systems. The hormones discussed in this chapter play a major role in coordinating reproductive events (**Table 28-1**). Physical factors also play a role. The sperm count must be adequate, the semen must have the correct pH and nutrients, and erection and ejaculation must occur in the proper sequence. The ovarian and uterine cycles must be properly coordinated; ovulation and oocyte transport must occur normally. The reproductive tract must provide a hospitable environment for

Table 28-1 Hormones of the Reproductive System

Hormone	Source	Regulation of Secretion	Primary Effects
Gonadotropin-releasing hormone (GnRH)	Hypothalamus	<i>Males:</i> inhibited by testosterone and possibly by inhibin <i>Females:</i> GnRH pulse frequency increased by estrogens, decreased by progesterone	<i>Males:</i> stimulates FSH secretion and LH synthesis <i>Females:</i> stimulates FSH secretion and LH synthesis
Follicle-stimulating hormone (FSH)	Anterior lobe of the pituitary gland	<i>Males:</i> stimulated by GnRH, inhibited by inhibin <i>Females:</i> stimulated by GnRH, inhibited by inhibin	<i>Males:</i> stimulates spermatogenesis and spermiogenesis through effects on nurse cells <i>Females:</i> stimulates follicle development, estrogen production, and oocyte maturation
Luteinizing hormone (LH)	Anterior lobe of the pituitary gland	<i>Males:</i> stimulated by GnRH <i>Females:</i> production stimulated by GnRH, secretion by the combination of high GnRH pulse frequencies and high estrogen levels	<i>Males:</i> stimulates interstitial cells to secrete testosterone <i>Females:</i> stimulates ovulation, formation of corpus luteum, and progesterone secretion
Androgens (primarily testosterone and dihydrotestosterone)	Interstitial endocrine cells of testes	Stimulated by LH	Establish and maintain male secondary sex characteristics and sexual behavior; promote maturation of sperm; inhibit GnRH secretion
Estrogens (primarily estradiol)	Granulosa and thecal endocrine cells of developing follicles; corpus luteum	Stimulated by FSH	Stimulate LH secretion (at high levels); establish and maintain female secondary sex characteristics and sexual behavior; stimulate repair and growth of endometrium; increase frequency of GnRH pulses
Progesterone	Granulosa cells from midcycle through functional life of corpus luteum	Stimulated by LH	Stimulates endometrial growth and glandular secretion; reduces frequency of GnRH pulses
Inhibin	Nurse cells of testes and granulosa cells of ovaries	Stimulated by factors released by developing sperm (male) and developing follicles (female)	Inhibits secretion of FSH (and possibly of GnRH)

Build Your Knowledge

Figure 28–27 Integration of the REPRODUCTIVE system with the other body systems presented so far.

the survival and movement of sperm, and for the subsequent fertilization of the oocyte. For these steps to occur, the reproductive, digestive, endocrine, nervous, cardiovascular, and urinary systems must all be functioning normally.

Even when all else is normal and fertilization occurs at the proper time and place, a healthy infant will not be produced unless the **zygote**—the union of an ovum with a sperm forming a single cell the size of a pinhead—manages to develop into a full-term fetus that typically weighs about 3 kg (6.6 lb). Chapter 29 considers the process of development, focusing on the mechanisms that determine both the structure of the body and the distinctive characteristics of people.

Even though the reproductive system's primary function—producing offspring—doesn't play a role in maintaining homeostasis, reproduction depends on a variety of physical, physiological,

and psychological factors. Many of these factors require intersystem cooperation. In addition, the hormones that control and coordinate sexual function have direct effects on the organs and tissues of other systems. For example, testosterone and estradiol affect both muscular development and bone density. Build Your Knowledge **Figure 28–27** summarizes the functional relationships between the reproductive system and other body systems.

28 Chapter Review

Study Outline

An Introduction to the Reproductive System

1. The *reproductive system* is the only system that is not essential to the life of an individual, but it ensures continuation of our species.

28-1 Male and female reproductive system structures produce gametes that combine to form a new individual

2. The human **reproductive system** produces, stores, nourishes, and transports functional **gametes** (reproductive cells). **Fertilization** is the fusion of male and female gametes.
3. The reproductive system includes **gonads** (**testes** or **ovaries**), ducts, accessory glands and organs, and the **external genitalia**.
4. In males, the testes produce **sperm**, which are expelled from the body in **semen** during *ejaculation*. The ovaries of a sexually mature female produce **oocytes** (immature **ova**) that travel along *uterine tubes* toward the *uterus*. The *vagina* connects the uterus with the exterior of the body.

28-2 The structures of the male reproductive system consist of the testes, duct system, accessory glands, and penis

5. Sperm travel along the *epididymis*, the *ductus deferens*, the *ejaculatory duct*, and the *urethra* before leaving the body. Accessory organs (notably the *seminal glands*, *prostate*, and *bulbo-urethral gland*) secrete fluids into the ejaculatory ducts and the urethra. The *scrotum* encloses the testes, and the *penis* is an erectile organ. (Figure 28–1)
6. The **raphe** marks the boundary between the two chambers in the **scrotum**. (Figure 28–3)

- PhysioEx

7. The **dartos** muscle tightens the scrotum, giving it a wrinkled appearance as it elevates the testes. The **cremaster** has skeletal muscle fibers that pull the testes close to the body.
8. The **tunica albuginea** surrounds each testis. Septa extend from the tunica albuginea to the region of the testis closest to the entrance to the epididymis, creating a series of **lobules**. (Figure 28–3)
9. **Seminiferous tubules** within each lobule are the sites of sperm production. From there, sperm pass through the **rete testis**. Seminiferous tubules connect to a **straight tubule**. **Efferent ductules** connect the rete testis to the epididymis. Between the seminiferous tubules are **interstitial cells**, which secrete sex hormones. (Figures 28–3, 28–4)
10. From the testis, the sperm enter the **epididymis**, an elongated tubule with **head**, **body**, and **tail** regions. The epididymis monitors and adjusts the composition of the fluid in the seminiferous tubules, serves as a recycling center for damaged sperm, stores and protects sperm, and facilitates their functional maturation. (Figure 28–5)
11. Each **ductus deferens**, or *vas deferens*, begins at the epididymis and passes through the inguinal canal as part of the spermatic cord. Near the prostate, the ductus deferens enlarges to form

the **ampulla of ductus deferens**. The junction of the base of the seminal gland and the ampulla creates the **ejaculatory duct**, which empties into the urethra. (Figures 28–5, 28–6)

12. The **urethra** extends from the urinary bladder to the tip of the penis. The urethra can be divided into *prostatic*, *membranous*, and *spongy* regions.
13. Each **seminal gland (seminal vesicle)** is an active secretory gland that contributes about 60% of the volume of semen. Its secretions contain fructose (which is easily metabolized by sperm), bicarbonate ions, prostaglandins, and fibrinogen. The **prostate** secretes slightly acidic **prostatic fluid**. Alkaline mucus secreted by the **bulbo-urethral glands** has lubricating properties. (Figures 28–6, 28–7)
14. A typical ejaculation releases 2–5 mL of semen (**ejaculate**), which contains 20–100 million sperm per milliliter. The fluid component of semen is **seminal fluid**.
15. The skin overlying the **penis** resembles that of the scrotum. Most of the **body** of the penis consists of three masses of **erectile tissue**. Beneath the superficial fascia are two **corpora cavernosa** and a single **corpus spongiosum**, which surrounds the urethra. Dilation of the blood vessels within the erectile tissue produces an **erection**. (Figure 28–7)

28-3 Spermatogenesis occurs in the testes, and hormones from the hypothalamus, pituitary gland, and testes control male reproductive functions

16. Seminiferous tubules contain **spermatogonia**, stem cells involved in **spermatogenesis** (the production of sperm).
17. **Nurse (Sertoli) cells** sustain and promote the development of sperm. (Figures 28–8, 28–9, 28–10)
18. Each **sperm** has a **head** capped by an **acrosome**, a **middle piece**, and a **tail**. (Figure 28–11)
19. Important regulatory hormones include **FSH** (*follicle-stimulating hormone*), **LH** (*luteinizing hormone*), and **GnRH** (*gonadotropin-releasing hormone*). *Testosterone* is the most important androgen. (Spotlight Figure 28–12)

28-4 The structures of the female reproductive system consist of the ovaries, uterine tubes, uterus, vagina, and external genitalia

20. Principal organs of the female reproductive system include the **ovaries**, **uterine tubes**, **uterus**, **vagina**, and external genitalia. (Figure 28–13)
21. The ovaries, uterine tubes, and uterus are enclosed within the **broad ligament**. The **mesovarium** supports and stabilizes each ovary. (Figure 28–14)
22. The ovaries are held in position by the **ovarian ligament** and the **suspensory ligament**. Major blood vessels enter the ovary at the **ovarian hilum**. Each ovary is covered by a **tunica albuginea**. (Figure 28–14)
23. Each **uterine tube** has an **infundibulum** with **fimbriae** (fingerlike projections), an **ampulla**, and an **isthmus**. Each uterine tube opens into the **uterine cavity**. For fertilization to occur, a secondary oocyte must encounter sperm during the first 12–24 hours of its passage from the infundibulum to the uterus. (Figure 28–15)
24. **Peg cells** lining the uterine tube secrete a fluid that completes the capacitation of sperm.
25. The **uterus** provides mechanical protection, nutritional support, and waste removal for the developing embryo and fetus.

Normally, the uterus bends anteriorly near its base (*anteflexion*). The **broad ligament**, **uterosacral ligaments**, **round ligaments**, and **lateral ligaments** stabilize the uterus. (Figure 28–16)

26. Major anatomical landmarks of the uterus include the **body**, **isthmus**, **cervix**, **external os** (*external orifice*), **uterine cavity**, **cervical canal**, and **internal os** (*internal orifice*). The uterine wall consists of an inner **endometrium**, a muscular **myometrium**, and a superficial **perimetrium** (an incomplete serous layer). (Figures 28–16, 28–17)
27. The **vagina** is a muscular tube extending between the uterus and the external genitalia; it is lined by a nonkeratinized stratified squamous epithelium. A thin epithelial fold, the **hymen**, partially blocks the entrance to the vagina until physical distortion ruptures the membrane. (Figures 28–18, 28–19)
28. The components of the **vulva** are the **vestibule**, **labia minora**, **urethral glands**, **clitoris**, **mons pubis**, **labia majora**, and **lesser** and **greater vestibular glands**. (Figure 28–19)
29. A newborn infant is nourished from milk secreted by the **mammary gland** in each breast. (Figure 28–20)

28-5 Oogenesis occurs in the ovaries, and hormones from the hypothalamus, pituitary gland, and ovaries control female reproductive functions

30. Ovaries are the site of **oogenesis** (ovum production), which occurs in **ovarian follicles**. Follicle development proceeds from **primordial ovarian follicles** through **primary**, **secondary**, and **tertiary ovarian follicles**. A dominant tertiary ovarian follicle forms during the **ovarian cycle**. The **ovarian cycle** is divided into a **follicular (preovulatory) phase** and a **luteal (postovulatory) phase**. (Figures 28–21, 28–22)
31. At **ovulation**, a **secondary oocyte** and the attached follicular cells of the **corona radiata** are released through the ruptured ovarian wall. The follicular cells remaining within the ovary form the **corpus luteum**, which later degenerates into scar tissue called a **corpus albicans**. (Figure 28–22)
32. A typical 28-day **uterine**, or **menstrual**, **cycle** begins with the onset of menstruation, also called **menses**, and the destruction of the **functional layer** of the endometrium. This process of **menstruation** continues from 1 to 7 days. (Figure 28–23)
33. After the **menstrual phase**, the **proliferative phase** begins, and the functional layer thickens and undergoes repair. The proliferative phase is followed by the **secretory phase**, during which uterine glands enlarge. Menstruation begins at **menarche** and continues until **menopause**. (Figure 28–23)
34. Hormonal regulation of the **female reproductive cycle** involves the coordination of the ovarian and uterine cycles. (Spotlight Figure 28–24)
35. **Estradiol**, the most important *estrogen*, is the dominant hormone of the follicular phase. Ovulation occurs in response to a midcycle surge in LH. (Spotlight Figure 28–24, Figure 28–25)
36. The hypothalamic secretion of GnRH occurs in pulses that trigger the pituitary secretion of FSH and LH. FSH initiates follicular development, and activated follicles and ovarian interstitial cells produce estrogens. High estrogen levels stimulate LH secretion, increase pituitary sensitivity to GnRH, and increase the GnRH pulse frequency. **Progesterone** is the main hormone of the luteal phase. Changes in estrogen and progesterone levels are responsible for maintaining the uterine cycle. (Spotlight Figure 28–24)

28-6 The autonomic nervous system influences male and female sexual physiology

37. During sexual **arousal** in males, erotic thoughts, sensory stimulation, or both lead to parasympathetic activity that produces erection. Stimuli accompanying **sexual intercourse** lead to **emission** and **ejaculation**. Contractions of the bulbospongiosus muscles are associated with **orgasm**. During **resolution**, the heart rate and blood pressure decrease and blood begins to leave the erectile tissue and the erection begins to subside.
38. The events of female sexual function resemble those of male sexual function, with parasympathetic arousal and skeletal muscle contractions associated with orgasm.
39. **Infertility** is the inability to conceive or carry a pregnancy to term after 1 year of unprotected intercourse.

28-7 Changes in levels of reproductive hormones cause functional changes throughout the life span

40. At weeks 5–6 of embryonic development, an embryo is said to be **sexually indifferent**, because the gonads and other

internal and external reproductive structures are similar in both sexes. The presence of testosterone stimulates the differentiation and development of male reproductive structures. Without testosterone, the sexually indifferent embryo will develop female reproductive structures. (Figure 28–26)

41. The **descent of the testes** through the *inguinal canals* begins during the seventh month of fetal development.
42. During the **male climacteric**, at ages 50–60, circulating testosterone levels decrease, and FSH and LH levels increase.
43. Menopause (the time that ovulation and menstruation stop) typically occurs at age 45–55. The production of GnRH, FSH, and LH rises, whereas circulating concentrations of estrogen and progesterone decrease.

28-8 The reproductive system secretes hormones affecting growth and metabolism of all body systems

44. Normal human reproduction depends on a variety of physical, physiological, and psychological factors, many of which require intersystem cooperation. (Figure 28–27; Table 28–1)

Review Questions

See the blue Answers tab at the back of the book.

LEVEL 1 Reviewing Facts and Terms

1. All of the following structures are part of the spermatic cord *except* the (a) ductus deferens, (b) pampiniform plexus, (c) genitofemoral nerve, (d) testicular artery, (e) epididymis.
2. The uterus (a) undergoes the uterine cycle every month, (b) has a thick, muscular myometrium, (c) has a tubular cervix that projects into the vagina, (d) does/has all of these.
3. In meiosis, sister chromatids separate during (a) prophase I, (b) metaphase I, (c) anaphase I, (d) anaphase II.
4. Gonadotropin-releasing hormone (a) stimulates FSH secretion and LH synthesis in only males, (b) stimulates FSH secretion and LH synthesis in only females, (c) stimulates FSH secretion and LH synthesis in both males and females, (d) is produced in the ovaries.
5. The main hormone of the postovulatory phase is (a) progesterone, (b) estradiol, (c) estrogen, (d) luteinizing hormone.
6. Which accessory structures contribute to the composition of semen? What are the functions of each structure?
7. What types of cells in the testes are responsible for functions related to reproductive activity? What are the functions of each cell type?
8. Which part of the nervous system controls sexual arousal?
9. List the functions of testosterone in males.
10. Describe the usual position of the uterus in the pelvic cavity.
11. Describe the way an egg moves from the ovary to the uterus.
12. What is the role of the clitoris in the female reproductive system?
13. Trace the path of milk flow from its site of production to outside the female.
14. Identify the main structures of the male reproductive system in the diagram on the right.

- | | | |
|-----------|-----------|-----------|
| (a) _____ | (b) _____ | (c) _____ |
| (d) _____ | (e) _____ | (f) _____ |
| (g) _____ | (h) _____ | (i) _____ |
| (j) _____ | (k) _____ | (l) _____ |

LEVEL 2 Reviewing Concepts

15. The immune system does not identify the developing sperm as a foreign matter because of the **(a)** blood-testis barrier, **(b)** capacitation of sperm, **(c)** secretion of dehydroepiandrosterone, **(d)** secretion of inhibin, **(e)** formation of acrosome.
16. Summarize the roles of the hormones in the ovarian and uterine cycles.
17. Compare the fates of parent cells undergoing meiosis in males and females.
18. Describe the erectile tissues of the penis. How does erection occur?
19. Describe each of the three phases of a typical 28-day uterine cycle.
20. Describe the hormonal events associated with the ovarian cycle.
21. Describe the hormonal events associated with the uterine (menstrual) cycle.
22. What is meant by the descent of the testes? Is there a comparable process in females?
23. How does the aging process affect the reproductive systems of males and females?

LEVEL 3 Critical Thinking and Clinical Applications

24. Andrew is 75-years-old and in good health. But he has recently started to experience lower back pain and painful urination. A rectal examination reveals an enlargement of the prostate. Explain why it is not unusual for elderly men to develop this condition.
25. In a condition known as endometriosis, endometrial cells are believed to migrate from the body of the uterus into the uterine tubes or by way of the uterine tubes into the peritoneal cavity, where they become established. A major symptom of endometriosis is periodic pain. Why does such pain occur?
26. Birth control pills contain estradiol and progesterone or they contain only progesterone. The pills are administered at programmed doses during the ovarian cycle to prevent tertiary ovarian follicle maturation and ovulation. Explain how such pills are effective.
27. Female bodybuilders and females with eating disorders such as anorexia nervosa commonly experience amenorrhea. What does this fact suggest about the relationship between body fat and menstruation? What effect would amenorrhea have on achieving a successful pregnancy?

CLINICAL CASE Wrap-Up And Baby Makes Three?

A basic rule of thumb is that a person who has been trying to get pregnant for 1 year is a candidate for a fertility workup. Fertility problems can originate in any person for known and unknown reasons.

A female's ability to get pregnant decreases with increasing age. Fertility depends on how many oocytes remain in the ovaries, how healthy the oocytes are, and—most importantly—if they are being released from the ovary. A healthy reproductive tract is needed for the oocyte to unite with a sperm, and then for the fertilized ovum to be conveyed to a healthy uterus to implant and complete gestation.

Is Leticia ovulating? That is the first thing to check, as it is the most common reason for female infertility. At home she can take her morning temperature, which should decrease and then spike with ovulation at day 14 and stay high through day 28 of her cycle under the influence of progesterone. Is her reproductive tract blocked by scarring from her earlier sexually transmitted infection? If so, surgery can open a blocked uterine tube.

Male infertility is most often due to problems with the sperm. The count may be too low or the motility of the sperm may be poor. Checking the quantity and quality of Carlos's sperm is simple. He can provide a sample for analysis in the lab. Carlos can change his running gear from briefs to boxers to provide a cooler environment in the testes for sperm production.

The Garcias have youth and general good health on their side. However, they do have risk factors for infertility that need to be addressed.

Baby Garcia may yet join the family!

1. Trace the path of Leticia's oocyte to meet Carlos's sperm. Where will a fertilized ovum travel next?
2. When should Leticia expect ovulation to occur during her cycle? How can ovulation be verified?

See the blue Answers tab at the back of the book.

Related Clinical Terms

cervical dysplasia: Abnormal growth of epithelial cells in the uterine cervix; may progress to cancer.

endometriosis: The growth of endometrial tissue outside the uterus.

genital herpes: A sexually transmitted disease caused by a herpes virus and characterized by painful blisters in the genital area.

gonorrhea: A sexually transmitted bacterial disease caused by *Neisseria gonorrhoeae*.

gynecology: The branch of medicine that deals with the functions and dysfunctions of the female reproductive system.

hydrocele: The accumulation of serous fluid in any body sac, but especially in the tunica vaginalis of the testis or along the spermatic cord.

hysterectomy: The surgical removal of the uterus.

menorrhagia: The condition of experiencing extremely heavy bleeding at menstruation.

oophorectomy: The surgical removal of one or both ovaries.

orchitis: Inflammation of one or both testicles.

ovarian cyst: A condition (usually harmless) in which fluid-filled sacs develop in or on the ovary.

polycystic ovary syndrome (PCOS): A condition in females that is characterized by irregular or no menstrual periods, acne, obesity, and excessive hair growth.

premature ejaculation: A common complaint of ejaculating semen sooner than the male desires while achieving orgasm during intercourse. An estimated 30% of males regularly experience the problem.

premenstrual dysphoric disorder (PMDD): A collection of physical and emotional symptoms that occurs 5 to 11 days before a female's period begins and goes away once menstruation starts. Over 150 signs and symptoms have been associated with the condition.

premenstrual syndrome: A condition occurring in the last half of the menstrual cycle after ovulation that is a combination of physical and mood disturbances that normally end with the onset of the menstrual flow.

salpingitis: Inflammation of a uterine tube.

uterine fibroids (leiomyomas): Benign tumors of the uterus composed of smooth muscle tissue that grows in the wall of the uterus of some females. Although not usually dangerous, they can cause problems such as very heavy menstrual periods and pain.

uterine prolapse: Condition that occurs when a female's pelvic floor muscles and ligaments stretch and weaken and provide inadequate support for the uterus, which then descends into the vaginal canal.

vasectomy: The surgical removal of a segment of each ductus (vas) deferens, making it impossible for sperm to reach the distal portions of the male reproductive tract.

vulvovaginal candidiasis: A common female vaginal infection caused by the yeast *Candida*, usually *Candida albicans*.

Development and Inheritance

Learning Outcomes

These Learning Outcomes correspond by number to this chapter's sections and indicate what you should be able to do after completing the chapter.

- 29-1 ■ Explain the relationship between cellular differentiation and development and specify the various stages of development.
- 29-2 ■ Describe the process of fertilization and explain how developmental processes are regulated.
- 29-3 ■ List the three stages of prenatal development and describe the major events of each.
- 29-4 ■ Explain how the three germ layers are involved in forming the extra-embryonic membranes, discuss the importance of the placenta as an endocrine organ, and describe embryonic sex determination.
- 29-5 ■ List several fetal changes that occur during the second and third trimesters.
- 29-6 ■ Describe the interplay between the maternal organ systems and the developing fetus and discuss the structural and functional changes in the uterus during gestation.
- 29-7 ■ List and discuss the events that occur during labor and delivery.
- 29-8 ■ Identify the features and physiological changes of the postnatal stages of life.
- 29-9 ■ Relate basic principles of genetics to the inheritance of human traits.

CLINICAL CASE The Twins Who Looked Nothing Alike

Annie and her twin, Ruth, are in Twinsburg, Ohio, for the Twins Day Festival, the largest annual celebration of twins in the world. There are thousands of identical twins in attendance, and a healthy representation of fraternal twins as well. Annie and Ruth are amazed to see so many twins who not only look alike but also move alike, sound alike, and smile alike.

As they walk through the festival grounds, Annie and Ruth notice tents set up to recruit twins for everything from FBI face-recognition software development to fingerprint and handwriting analysis. The festival is a popular event for “nature versus nurture” researchers who are looking for twins to enlist in their studies.

Another centerpiece of the festival is the awarding of medals to twins in various categories, including the oldest twins, the youngest twins, the “most-alike” twins, and the “least-alike” twins. This year, the “least-alike” twins medals are awarded to two boys, one who is short and fair-skinned with blonde hair and blue eyes and the other who is tall and dark-skinned with black hair and brown eyes. **Annie elbows Ruth**

and asks, “What do you think is the story with these twins?” To find out, turn to the Clinical Case Wrap-Up at the end of the chapter.

An Introduction to Development and Inheritance

The physiological processes we have studied so far are relatively brief. Many last only a fraction of a second, and others may take hours. But some important processes are measured in months, years, or even decades. In the process of **development**, a human being forms in the womb for 9 months and grows to maturity in 15 to 20 years. Humans may live the better part of a century and, in that time, are always changing. Birth, growth, maturation, aging, and death are all parts of a single, continuous process. That process does not end with the individual, because humans can pass at least some of their characteristics on to their offspring. Each generation gives rise to a new generation that will repeat the cycle.

In this chapter, we explore how genetics, environmental factors, and various physiological processes affect the events following the union of male and female *gametes*—sperm and oocytes. Our description begins with development before birth and continues through childhood and adolescence and into maturity and *senescence*, or aging.

development begins at birth and continues to **maturity**, the state of full development or completed growth.

Prenatal development, the primary focus of this chapter, begins at *fertilization*, or *conception*, when a sperm and oocyte fuse. We divide development into stages characterized by specific anatomical changes. **Pre-embryonic development** involves the processes that occur in the first 2 weeks after fertilization, producing an *embryo*. **Embryonic development** includes the events during the third through eighth weeks. The study of these events is called **embryology** (em-brē-OL-ō-jē). The development of the **fetus**, or **fetal development**, begins at the start of the ninth week and continues until birth.

The changes that occur during development are truly remarkable. In a mere 9 months, all the tissues, organs, and organ systems we have studied so far take shape and begin to function. What begins as a single egg cell slightly larger than the period at the end of this sentence becomes an individual whose body contains trillions of cells organized into a complex array of highly specialized structures. The formation of the different types of cells required in this process is called **cellular differentiation**.

Cellular differentiation occurs through selective changes in genetic activity. As development proceeds, some genes are turned off and others are turned on. Exactly which genes are turned off and on varies from one type of cell to another, and the patterns change over time.

All humans go through the same developmental stages, but this process produces individuals with distinctive characteristics. The term **inheritance**, or **heredity**, refers to the transfer of genetically determined characteristics from generation to generation. The study of the mechanisms responsible for inheritance is called **genetics**. In this chapter, we consider basic genetics as it applies to inherited characteristics, such as sex, hair color, and various diseases.

29-1 Directed by inherited genes, a fertilized ovum differentiates during prenatal development to form an individual; postnatal development brings that individual to maturity

Learning Outcome Explain the relationship between cellular differentiation and development and specify the various stages of development.

The gradual modification of anatomical structures and physiological characteristics that occurs before birth is referred to as **prenatal** (*natus*, birth) **development**. **Postnatal**

A basic understanding of human development gives important insights into anatomical structures. In addition, many of the processes of development and growth are similar to those that repair injuries. In this chapter, we focus on major aspects of development. We consider highlights of the developmental process rather than examine the events in detail. We also consider the regulatory mechanisms involved, and how developmental patterns can be modified.

Checkpoint

1. Define cellular differentiation.
2. What event marks the onset of development?
3. Define inheritance.

See the blue Answers tab at the back of the book.

29-2 Fertilization—the fusion of a secondary oocyte and a sperm—forms a zygote

Learning Outcome Describe the process of fertilization and explain how developmental processes are regulated.

Fertilization involves the fusion of two haploid (n) gametes, each containing 23 chromosomes. This process produces a **zygote** that contains 46 chromosomes, the normal diploid ($2n$) number in a human somatic cell. Fertilization typically takes place near the junction between the ampulla and isthmus of the uterine tube. It generally occurs within a day after ovulation. Let's examine how this process takes place, and the different roles of the sperm and oocyte.

The Secondary Oocyte and Sperm before Fertilization

The functional roles and contributions of a sperm and oocyte are very different. The **sperm** delivers the paternal chromosomes to the site of fertilization. It is a small, highly streamlined cell driven by a flagellum. In contrast, the **oocyte** provides all the cellular organelles and inclusions, nourishment, and genetic programming necessary to support development of the embryo for nearly a week after conception. For this reason, the volume of this gamete is much greater than that of the sperm. At fertilization, the diameter of the secondary oocyte is more than twice the entire length of the sperm (**Figure 29-1a**). The ratio of their volumes is even more striking—approximately 2000:1.

Recall from Chapter 28 that ovulation releases a **secondary oocyte**. The secondary oocyte is surrounded by a thick, glycoprotein-rich envelope called the **zona pellucida**. Outside of that envelope is a protective layer of follicle cells called the **corona radiata** (**Figure 29-1b**). The cells of the corona radiata protect the secondary oocyte as it passes through the

ruptured follicular wall, across the surface of the ovary, and into the infundibulum of the uterine tube. The oocyte then generally travels a few centimeters into the ampulla toward the isthmus.

The secondary oocyte begins meiosis II in the tertiary ovarian follicle, but the process is suspended in metaphase of meiosis II. The secondary oocyte is then ovulated in this state. The cell's metabolic operations await the stimulus of fertilization for further development. If fertilization does not take place, the oocyte disintegrates without completing meiosis.

To have a chance of fertilizing a secondary oocyte, a sperm must travel the relatively long distance between the vagina and the ampulla of the uterine tube. The sperm deposited in the vagina are already motile, because of contact with secretions of the seminal glands—the first step of **capacitation**. Capacitation is the functional maturation of the sperm in which the receptors are uncovered when the glycoprotein layer of the sperm membrane is removed. This also alters the acrosome, enabling the acrosome reaction, and allowing a sperm to penetrate and fertilize an oocyte. (Unidentified substances secreted by the epididymis appear to prevent premature capacitation.) The sperm, however, cannot accomplish fertilization until they have been exposed to conditions in the female reproductive tract. Uterine tube peg cell secretions help with capacitation, but the exact mechanism responsible for capacitation remains unknown. Furthermore, how sperm “find” the oocyte remains a rich field of investigation. A sperm can propel itself at speeds of only about $34\text{ }\mu\text{m}$ per second, or about 12.5 cm (5 in.) per hour. In theory it should take sperm several hours to reach the upper portions of the uterine tubes. The actual time, however, ranges from 2 hours to as little as 30 minutes. Contractions of the uterine musculature and ciliary currents in the uterine tubes may help the sperm travel from the vagina to the site of fertilization.

Of the nearly 200 million sperm introduced into the vagina in a typical ejaculation, only about 10,000 enter the uterine tube, and fewer than 100 reach the isthmus. In general, a male with a total sperm count below 20 million per milliliter is functionally sterile because too few sperm survive to reach and fertilize an oocyte. While it is true that only one sperm fertilizes an oocyte, dozens of sperm are required for successful fertilization, as we will learn next.

The Process of Fertilization

Fertilization and the events that follow are diagrammed in **Figure 29-1b**. Before the physical process of fertilization can occur, a sperm must penetrate the corona radiata. This is aided by the **acrosome reaction**, which frees the enzymes contained in the acrosome of each sperm, including **hyaluronidase** ($\text{h}\bar{\text{i}}\text{-uh-l}\bar{\text{u}}\text{-RON-i-d}\bar{\text{a}}\text{s}$). Hyaluronidase breaks down the bonds between adjacent follicle cells. Dozens of sperm must

Figure 29–1 Fertilization.

a A secondary oocyte and numerous sperm at the time of fertilization. Notice the difference in size between the gametes.

release hyaluronidase before the connections between the follicle cells of the corona radiata break down enough to allow an intact sperm to reach the oocyte. No matter how many sperm slip through the gap in the corona radiata, only a single sperm fertilizes the oocyte (**Figure 29–1b 1**). That sperm must have an intact acrosome. The first step is the binding of the sperm to specific *sperm receptors* in the zona pellucida. This binding triggers the rupture of the acrosome. The hyaluronidase and **acrosin**, another protein-digesting enzyme, then digest a path through the zona pellucida toward the surface of the oocyte. When the sperm contacts the oocyte membrane, the sperm and oocyte membranes begin to fuse.

Events after Fertilization

The fusion of these membranes triggers **oocyte activation**, which involves a series of changes in the metabolic activity of the oocyte. This process leads to increased permeability of the oocyte membrane to sodium ions; the entry of sodium ions causes the membrane to depolarize. This depolarization in turn causes the release of calcium ions from the smooth endoplasmic reticulum into the oocyte cytoplasm.

Oocyte at Ovulation

Ovulation releases a secondary oocyte and the first polar body; both are surrounded by the corona radiata. The oocyte is suspended in metaphase of meiosis II.

1 Fertilization and Oocyte Activation

Acrosomal enzymes from multiple sperm create gaps in the corona radiata. A single sperm then makes contact with the oocyte membrane, and membrane fusion occurs, triggering oocyte activation and the completion of meiosis.

2 Pronuclei Develop and DNA Synthesis Occurs

The sperm is absorbed into the cytoplasm, and the female pronucleus develops. As the male pronucleus develops, most remaining sperm break down.

5 First Cleavage Forms Two Blastomeres

The first cleavage division nears completion about 30 hours after fertilization.

4 Amphimixis Occurs and Cleavage Begins

Maternal and paternal chromosomes align on metaphase plate

3 Spindle Formation Begins

Pronuclei chromatin condenses into chromosomes, and spindle fibers appear in preparation for the first cell division.

b Fertilization and the preparations for cleavage.

The sudden increase in the calcium ion level has important effects, including the following:

- *Exocytosis of Vesicles Adjacent to the Oocyte Membrane.* This process, called the *cortical reaction*, releases enzymes called *zonal inhibiting proteins*, or *ZIPs*, that both inactivate the sperm receptors and harden the zona pellucida. This combination that prevents fertilization by more than one sperm is known as the **block to polyspermy**. Polyspermy would create a zygote incapable of normal development. (Prior to completion of the cortical reaction, depolarization of the oocyte membrane probably prevents fertilization by any other sperm that penetrate the zona pellucida.)
- *Completion of Meiosis II and Formation of the Second Polar Body.* Once the sperm enters the secondary oocyte, the oocyte can complete meiosis II. The fertilized oocyte is now called an **ovum**.
- *Activation of Enzymes That Cause a Rapid Increase in the Ovum's Metabolic Rate.* The cytoplasm of the ovum contains many mRNA strands that have been inactivated by special proteins. The mRNA strands are now activated, so protein synthesis accelerates quickly. Most of the proteins synthesized are required for development to proceed.

After oocyte activation and the completion of meiosis, the nuclear material remaining within the ovum reorganizes into the **female pronucleus**. While these changes are under way, the nucleus of the sperm swells. As it forms the **male pronucleus**, the rest of the sperm breaks down (except for its centrosome). DNA synthesis then takes place in both the male and female pronuclei (**Figure 29-1b** (2)). The male and female pronuclei move toward each other, their chromatin begins to condense into chromosomes (each now consisting of two duplicate chromatids), and the male-donated centrioles duplicate and begin to form spindle fibers (3). The pronuclei membranes dissolve and their maternal and paternal chromosomes all line up on the metaphase plate. The combining of the male and female chromosomes is called *amphimixis* (am-fi-MIK-sis; “both mixed together”) (4). The cell is now a zygote that contains the normal diploid complement of 46 chromosomes, and fertilization is complete. This is the “moment of conception.” The first cleavage yields two daughter cells called *blastomeres* (5). The cell divisions of cleavage subdivide the cytoplasm of the zygote.

✓ Checkpoint

4. Name two sperm enzymes important to secondary oocyte penetration.
5. How many chromosomes are contained within a human zygote?

See the blue Answers tab at the back of the book.

29-3 Gestation consists of three stages of prenatal development: the first, second, and third trimesters

Learning Outcome List the three stages of prenatal development and describe the major events of each.

The time spent in prenatal development is known as **gestation** (jes-TĀ-shun). For convenience, we usually think of the gestation period as three integrated **trimesters**, each lasting 3 months:

1. The **first trimester** is the period of pre-embryonic, embryonic, and early fetal development. During this time, the beginnings of all the major organ systems appear.
2. The **second trimester** is dominated by the development of fetal organs and organ systems. This process nears completion by the end of the sixth month. During this time, body shape and proportions change. By the end of this trimester, the fetus looks distinctively human.
3. The **third trimester** is characterized by rapid fetal growth and deposition of adipose tissue. Early in the third trimester, most of the major organ systems of the fetus become fully functional. An infant is a child between birth and the first birthday; infants born 1 month or even 2 months prematurely have a reasonable chance of survival with medical intervention.

✓ Checkpoint

6. Define gestation.
7. Characterize the key features of each trimester.

See the blue Answers tab at the back of the book.

29-4 The first trimester includes pre-embryonic and embryonic development, involving the processes of cleavage, implantation, placentation, and embryogenesis

Learning Outcome Explain how the three germ layers are involved in forming the extra-embryonic membranes, discuss the importance of the placenta as an endocrine organ, and describe embryonic sex determination.

At the moment of conception, the fertilized ovum is a single cell about 0.135 mm (0.005 in.) in diameter. It weighs approximately 150 µg. By convention, pregnancies are clinically dated from the last menstrual period (LMP), which is usually 2 weeks before ovulation and conception. At the end of the first trimester (12 weeks from LMP, but only 10 developmental weeks), the fetus is almost 75 mm (3 in.) long and weighs perhaps 14 g (0.5 oz).

Many important and complex developmental events occur during the first trimester. Here we focus on four general processes: Two occur in the pre-embryonic period (cleavage and

implantation) and two occur in the embryonic period (placental and embryogenesis, including sex determination).

1. **Cleavage** (KLĒV-ij) is a sequence of cell divisions that begins immediately after fertilization (**Figure 29-1b**). During cleavage, the zygote becomes a **pre-embryo**, which develops into a multicellular complex known as a **blastocyst**. Cleavage ends when the blastocyst first contacts the uterine wall.
2. **Implantation** begins when the blastocyst attaches to the endometrium of the uterus. The process continues as the blastocyst invades maternal tissues. Important events during implantation set the stage for the formation of vital embryonic structures.
3. **Placentation** (plas-en-TĀ-shun) occurs as blood vessels form around the periphery of the blastocyst, and as the placenta develops. The **placenta** is a complex organ that permits exchange between maternal and embryonic blood. It supports the early fetus from its formation in the first trimester until just after birth, when the placenta stops functioning and is expelled from the uterus. From that point on, the newborn is physically separate from the pregnant individual.
4. **Embryogenesis** (em-brĕ-JEN-e-sis) is the formation of a viable **embryo**. This process establishes the foundations for all major organ systems.

These processes are both complex and vital to the survival of the embryo. Perhaps because the events in the first trimester are so complex, it is the most dangerous prenatal stage. Only about 40% of conceptions produce embryos that survive the first trimester. For that reason, pregnant individuals are warned to avoid drugs, alcohol, tobacco, and other disruptive stresses during the first trimester, in the hope of preventing an error in the developmental processes that are under way. Each of these stages is described next.

The Pre-Embryonic Period

The pre-embryonic period is the first 14 days after fertilization, before implantation in the uterus. At this stage, tissue differentiation has not occurred.

Cleavage and Blastocyst Formation

Cleavage is a series of cell divisions that subdivides the cytoplasm of the zygote, producing an ever-increasing number of smaller and smaller daughter cells (**Figure 29-2**). Soon after the secondary oocyte completes meiosis, the chromosomes line up along a metaphase plate, and the cell prepares to divide. The first cleavage division is completed about 30 hours after fertilization. The first cleavage produces a pre-embryo consisting of two identical cells called **blastomeres** (day 0 in **Figure 29-2**). Subsequent divisions take place at intervals of 10–12 hours. During the initial divisions, all the blastomeres

divide simultaneously. As the number of blastomeres increases, the timing becomes less predictable.

After 3 days of cleavage (days 1–3 in **Figure 29-2**), the pre-embryo is a solid ball of cells resembling a rounded mulberry. This stage is called the **morula** (MOR-yū-luh; *morus*, mulberry). The morula typically reaches the uterus on day 4 or 5. Over the next 2 days, the blastomeres in the morula form a **blastocyst**, a hollow ball with an inner cavity known as the **blastocoele** (BLAS-tō-sēl) (day 6 in **Figure 29-2**). The blastomeres are now no longer identical in size and shape. The outer layer of cells is called the **trophoblast** (TRŌ-fō-blast). As the word *trophoblast* implies (*trophos*, food + *blast*, precursor), cells in this layer provide nutrients to the developing embryo. The trophoblast also releases enzymes that erode an opening in the zona pellucida, which is then shed in a process known as *hatching* (**Figure 29-2**). In the blastocyst, a second group of cells, the **inner cell mass**, lies clustered at one end. These cells are exposed only to the blastocoele and are insulated from contact with the outside uterine environment by the trophoblast. In time, the inner cell mass will form the embryo.

Implantation

Once the blastocyst is hatched, it is freely exposed to glycogen-rich fluid within the uterine cavity. This fluid is secreted by uterine glands. Throughout the previous few days, the pre-embryo and early blastocyst had been absorbing fluid and nutrients from their surroundings. The process now accelerates, and the blastocyst enlarges. When fully formed, the blastocyst contacts the endometrium, and implantation takes place (**Figure 29-3**).

Implantation begins as the surface of the blastocyst closest to the inner cell mass adheres to the uterine lining (day 7 in **Figure 29-3**). At the point of contact, the trophoblast cells divide rapidly, making the trophoblast several layers thick. The cells closest to the interior of the blastocyst remain intact, forming an inner cellular layer of the trophoblast called the **cytotrophoblast**. Near the endometrial wall, however, the plasma membranes separating the trophoblast cells disappear, creating a layer of cytoplasm with multiple nuclei (day 8). This outer layer is called the **syncytiotrophoblast**.

The syncytiotrophoblast erodes a path through the uterine epithelium by secreting hyaluronidase. This enzyme dissolves the proteoglycans between adjacent epithelial cells, just as hyaluronidase released by sperm dissolved the connections between cells of the corona radiata. At first, the erosion creates a gap in the uterine lining, but maternal epithelial cells migrate and divide and soon repair the surface. Once the blastocyst has lost contact with the uterine cavity, its further development occurs entirely within the functional layer of the endometrium.

As implantation proceeds, the syncytiotrophoblast continues to enlarge and spread into the surrounding endometrium (day 9 in **Figure 29-3**). The erosion of uterine glands releases nutrients that are absorbed by the syncytiotrophoblast. They

Figure 29-2 Cleavage and Blastocyst Formation.

What is the name and function of the outer cell layer of a blastocyst?

then diffuse through the underlying cytotrophoblast to the inner cell mass. These nutrients provide the energy needed for the early stages of embryo formation. Trophoblastic extensions grow around endometrial capillaries. As the capillary walls are destroyed, maternal blood begins to percolate through trophoblastic channels known as **lacunae** (*lacuna*, singular). Fingerlike **villi** extend away from the trophoblast into the surrounding endometrium, gradually increasing in size and complexity until about day 21. As the syncytiotrophoblast spreads, it begins breaking down larger endometrial veins and arteries, and blood flow through the lacunae accelerates.

The inner cell mass has little apparent organization early in the blastocyst stage. Yet by the time of implantation, the inner cell mass has separated from the trophoblast. The separation gradually increases, creating a fluid-filled chamber called the **amniotic** (am-nē-OT-ik) **cavity** (day 9 in **Figure 29-3**). When the amniotic cavity first appears, the cells of the inner cell mass are organized into an oval sheet that is two layers

thick. A superficial layer faces the amniotic cavity, and a deeper layer is exposed to the fluid contents of the blastocoele.

In most cases, implantation occurs in the fundus or in the body of the uterus. In an **ectopic pregnancy**, implantation occurs somewhere other than within the uterus, such as in one of the uterine tubes. Approximately 0.6% of pregnancies are ectopic pregnancies. They do not produce a viable embryo and can be life threatening to the pregnant individual.

The Embryonic Period

The embryonic period comprises the events from implantation to week 9. During this time, hormonal changes occur that help maintain the pregnancy: Trophoblast cells and later the chorion secrete human chorionic gonadotropin (hCG), the corpus luteum secretes progesterone and estrogen, and by the end of the second month, the placenta begins secreting progesterone and estrogen.

Figure 29-3 Stages in Implantation.

Regulation of Cellular Differentiation

During prenatal development, a single cell ultimately forms an infant weighing about 7.7 lb (3.5 kg). One of the most fascinating aspects of development is its apparent order. Continuity exists at all levels and at all times. Nothing “leaps” into existence without apparent precursors. Cellular differentiation and increasing structural complexity are closely associated.

Cellular differentiation involves changes in the genetic activity of some cells but not others. A continuous exchange of information takes place between the nucleus and the cytoplasm in a cell. Activity in the nucleus varies in response to chemical messages that arrive from the surrounding cytoplasm. In turn, ongoing nuclear activity alters conditions within the cytoplasm by directing the synthesis of specific proteins. In this way, the nucleus can affect enzyme activity, cell structure, and membrane properties.

In development, differences in the cytoplasmic composition of individual cells trigger changes in genetic activity. These changes in turn lead to further alterations in the cytoplasm, and the process continues in a sequence. But if all the cells of the embryo are derived from cell divisions of a zygote, how do the cytoplasmic differences originate? What sets the process in motion? The important first step occurs before fertilization, while the oocyte is in the ovary.

Before ovulation, the growing oocyte accepts amino acids, nucleotides, and glucose, as well as more complex materials such as phospholipids, mRNA molecules, and proteins, from the surrounding granulosa cells. The contents of the cytoplasm are not evenly distributed because not all follicle cells manufacture and deliver the same nutrients and instructions to the oocyte. After fertilization, the zygote divides into ever-smaller cells that differ from one another in cytoplasmic composition. These differences alter the genetic activity of each cell, creating cell lines with increasingly diverse fates.

As development proceeds, some of the cells release chemical substances, including RNA molecules, polypeptides, and small proteins that affect the differentiation of other embryonic cells. This type of chemical interplay among developing cells is called *induction* (in-DUK-shun). It works over very short distances, such as when two types of cells are in direct contact. It may also operate over longer distances, with the inducing chemicals functioning as hormones.

This type of regulation, which involves an integrated series of interacting steps, can control highly complex processes. The mechanism is not always error-free, however. An abnormal or inappropriate inducer can change the course of development.

Early Embryogenesis: Formation of the Germ Layers and Extra-Embryonic Membranes

Embryogenesis is a phase of prenatal development in which embryonic structures are formed. It is usually regarded as the time from the end of the second week, when the embryonic

disc is formed from the inner cell mass, to the end of the eighth week, when the embryo becomes a fetus. In week 3, the two-layered embryonic disc becomes a three-layered embryo as the primary germ layers (ectoderm, mesoderm, and endoderm) and the extra-embryonic membranes develop.

Gastrulation and Germ Layer Formation. Around day 15, a third layer of cells begins to form between the superficial and deep layers of the inner cell mass through a cell migration process called **gastrulation** (gas-trū-LĀ-shun) (Figure 29-4). Together, the three layers of cells are called **germ layers**. The layers are known as the **ectoderm**, **mesoderm**, and **endoderm**. The germ layers separate the

trophoblast from the amniotic cavity. **Table 29-1** contains a listing of the structures derived from each germ layer to form the body systems described in earlier chapters.

The **embryonic disc** becomes an oval, three-layered sheet during gastrulation. This disc will form the body of the embryo, whereas all other cells of the blastocyst will be part of the *extra-embryonic membranes* (**Spotlight Figure 29-5**, step 1).

Shortly after gastrulation begins, the body of the embryo begins to separate itself from the rest of the embryonic disc. The body of the embryo and its internal organs now start to form. This process, embryogenesis, begins as folding and differential growth of the embryonic disc produce a bulge that projects into the amniotic cavity (**Spotlight Figure 29-5**, step 2). This

Figure 29-4 The Inner Cell Mass and Gastrulation.

What is the name of the third germ layer that forms during gastrulation?

The germ layers introduced in Figure 29–4 also form four **extra-embryonic membranes**: (1) The **yolk sac** (endoderm and mesoderm), (2) the **amnion** (ectoderm and mesoderm), (3) the **allantois** (endoderm and mesoderm), and (4) the **chorion** (mesoderm and trophoblast). These membranes support embryonic and fetal development, but few traces of their existence remain in adults.

Yolk sac

The yolk sac begins as a layer of cells spreads out around the outer edges of the blastocoele to form a complete pouch. It is the primary nutrient source for early embryonic development, and becomes an important site for blood cell formation.

Amnion

Ectodermal cells spread over the inner surface of the amniotic cavity, soon followed by mesodermal cells. Amniotic fluid is produced, which cushions the developing embryo.

1 Week 2

Migration of mesoderm around the inner surface of the cytotrophoblast forms the chorion. Mesodermal migration around the outside of the amniotic cavity, between the ectodermal cells and the trophoblast, forms the amnion. Mesodermal migration around the endodermal pouch forms the yolk sac.

2 Week 3

The embryonic disc bulges into the amniotic cavity at the head fold. The allantois, an endodermal extension surrounded by mesoderm, extends toward the trophoblast.

3 Week 4

The embryo now has a head fold and a tail fold. Constriction of the connections between the embryo and the surrounding trophoblast narrows the yolk stalk and body stalk.

Allantois

The allantois begins as an outpocket of the endoderm near the base of the yolk sac. The free endodermal tip then grows toward the wall of the blastocyst, surrounded by a mass of mesodermal cells. The base of the allantois eventually gives rise to the urinary bladder.

Chorion

The mesoderm associated with the allantois spreads around the entire blastocyst, separating the cytotrophoblast from the blastocoele. The appearance of blood vessels in the chorion is the first step in the creation of a functional placenta. By the third week of development, the mesoderm extends along the core of each trophoblastic villus, forming chorionic villi in contact with maternal tissues and blood vessels. These villi continue to enlarge and branch, forming the placenta, the exchange platform between mother and fetus for nutrients, oxygen, and wastes.

4 Week 5

The developing embryo and extra-embryonic membranes bulge into the uterine cavity. The cytotrophoblast pushing out into the uterine cavity remains covered by endometrium but no longer participates in nutrient absorption and embryo support. The embryo moves away from the placenta, and the body stalk and yolk stalk fuse to form an umbilical stalk.

5 Week 10

The amnion has expanded greatly, filling the uterine cavity. The fetus is connected to the placenta by an elongated umbilical cord that contains a portion of the allantois, blood vessels, and the remnants of the yolk stalk. A mucus plug forms, preventing bacteria from entering the uterus.

Table 29-1 The Fates of the Germ Layers

Ectodermal Derivatives	
Integumentary system:	epidermis, hair follicles and hairs, nails, and glands communicating with the skin (sweat glands, mammary glands, and sebaceous glands)
Skeletal system:	pharyngeal cartilages and their derivatives in adults (portion of sphenoid, the auditory ossicles, the styloid processes of the temporal bones, the cornu [horns] and superior rim [body] of the hyoid bone)*
Nervous system:	all neural tissue, including brain and spinal cord
Endocrine system:	pituitary gland and adrenal medullae
Respiratory system:	mucous epithelium of nasal passageways
Digestive system:	mucous epithelium of mouth and anus, salivary glands
Mesodermal Derivatives	
Integumentary system:	dermis and subcutaneous layer (hypodermis)
Skeletal system:	all structures except some pharyngeal derivatives
Muscular system:	all structures
Endocrine system:	adrenal cortex, endocrine tissues of heart, kidneys, and gonads
Cardiovascular system:	all structures
Lymphatic system:	all structures
Urinary system:	the kidneys, including the nephrons and the initial portions of the collecting system
Reproductive system:	the gonads and the adjacent portions of the duct systems
Miscellaneous:	the lining of the pleural, pericardial, and peritoneal cavities and the connective tissues that support all organ systems
Endodermal Derivatives	
Endocrine system:	thymus, thyroid gland, and pancreas
Respiratory system:	respiratory epithelium (except nasal passageways) and associated mucous glands
Digestive system:	mucous epithelium (except mouth and anus), exocrine glands (except salivary glands), liver, and pancreas
Urinary system:	urinary bladder and distal portions of the duct system
Reproductive system:	distal portions of the duct system, stem cells that produce gametes

*The neural crest is derived from ectoderm and contributes to the formation of the skull and the skeletal derivatives of the embryonic pharyngeal arches.

projection is the **head fold**. Similar movements lead to the formation of a **tail fold** (**Spotlight Figure 29-5**, step 3).

Formation of the Extra-Embryonic Membranes. The germ layers also form four **extra-embryonic membranes**: the **yolk sac**, **amnion** (AM-nē-on), **allantois** (ah-LAN-tō-is), and **chorion** (KŌ-rē-on). **Spotlight Figure 29-5** illustrates and describes the developmental processes of these extra-embryonic membranes.

Focus more on the chorion here because of its early role in the maternal-embryo exchange of nutrients, gases, and wastes. When implantation first occurs, the nutrients absorbed by the trophoblast can easily reach the inner cell mass by simple diffusion. But as the embryo and the trophoblast enlarge, the distance between them increases, so diffusion alone can no longer keep pace with the demands of the developing embryo. Blood vessels now begin to develop within the mesoderm of the chorion. The appearance of these blood vessels is the first step in the formation of a functional placenta, a rapid-transit system for nutrients that links the embryo with the trophoblast.

Placentation

Placentation is the formation of the placenta from embryonic and maternal tissues. Embryonic tissues form the chorion and

chorionic villi. The maternal endometrial tissues that surround the blood-filled lacunae become restricted to a specialized region. The placenta is fully formed and functional by the end of the third month.

Formation of the Placenta. By the third week of development (**Spotlight Figure 29-5**, step 2), the mesoderm extends along the core of each trophoblastic villus, forming **chorionic villi** in contact with maternal tissues and blood vessels. Chorionic villi continue to enlarge and branch, creating an intricate network within the endometrium. Embryonic blood vessels develop within each villus. Blood flow through those chorionic vessels begins early in the third week of development, when the embryonic heart starts beating. The blood supply to the chorionic villi arises from the allantoic arteries and veins.

At first, the entire blastocyst is surrounded by chorionic villi. The chorion continues to enlarge, expanding like a balloon within the endometrium. By week 4, the embryo, amnion, and yolk sac are suspended within an expansive, fluid-filled chamber (**Spotlight Figure 29-5**, step 3). The **body stalk**, the connection between embryo and chorion, contains the distal portions of the allantois and blood vessels that carry blood to and from the placenta. The narrow connection between the endoderm of the embryo and the yolk sac is called the **yolk stalk**.

As the chorionic villi enlarge, more maternal blood vessels are eroded. The placenta does not continue to enlarge indefinitely. Regional differences in placental organization begin to develop as expansion of the placenta creates a prominent bulge in the endometrial surface. This relatively thin portion of the endometrium, called the **capsular decidua** (dĕ-SID-yū-uh; *deciduus*, a falling off), or *decidua capsularis*, no longer exchanges nutrients, and the chorionic villi in the region disappear (**Spotlight Figure 29–5**, step 4, and **Figure 29–6a**). Placental functions are now concentrated in a disc-shaped area in the deepest portion of the endometrium, a region called the **basal decidua** (*decidua basalis*). The rest of the uterine endometrium, which has no contact with the chorion, is called the **parietal decidua** (*decidua parietalis*).

As the end of the first trimester approaches, the fetus moves farther from the placenta (**Spotlight Figure 29–5**, steps 4 and 5). The fetus and placenta remain connected by the **umbilical cord**, which contains the allantois, the placental blood vessels, and the yolk stalk.

Tips

Like a deep-sea diver's air hose or a space-walking astronaut's tether, the umbilical cord supplies the fetus with life-sustaining substances and removes wastes.

Placental Circulation. **Figure 29–6a** illustrates placental circulation at the end of the first trimester. Blood flows from the fetus to the placenta through the paired **umbilical arteries** and returns in a single **umbilical vein**.

The chorionic villi provide the surface area for active and passive exchanges of gases, nutrients, and wastes between the fetal and maternal bloodstreams. The blood in the umbilical arteries is deoxygenated and contains wastes generated by fetal tissues. Maternal blood moves slowly through complex lacunae lined by the syncytiotrophoblast. Chorionic blood vessels pass close by, and gases and nutrients diffuse between the embryonic and maternal circulations across the layers of the trophoblast. Maternal blood at the placenta has a relatively low P_{O_2} . Fetal hemoglobin has a higher affinity for oxygen than does maternal hemoglobin, thus enabling fetal hemoglobin to strip oxygen from maternal hemoglobin. At the placenta, oxygen supplies are replenished, nutrients are added, and carbon dioxide and other wastes are removed. Maternal blood then reenters the venous system of the pregnant individual through the broken walls of small uterine veins. No mixing of maternal and fetal blood takes place because layers of trophoblast always separate the two.

The placenta places a considerable demand on the maternal cardiovascular system, and blood flow to the uterus and placenta is extensive. If the placenta is torn or otherwise damaged, the consequences may prove fatal to both fetus and pregnant individual.

Late Embryogenesis and Organogenesis

At about week 4 of development, the embryo is physically as well as developmentally distinct from the embryonic disc and

the extra-embryonic membranes. The definitive orientation of the embryo is now visible, complete with posterior and anterior surfaces and left and right sides. The changes in proportions and appearance that occur between the second developmental week and the end of the first trimester are summarized in **Figure 29–7**.

The first trimester is a critical period for development, because events in the first 12 weeks establish the basis for **organogenesis**, the process of organ formation. The rudiments of all the major organ systems have formed by the end of the first trimester. **Table 29–2** provides an overview of the development of the major organs and body systems in the first trimester (as well as subsequent development).

Sex Determination in the Embryo

Humans two sex chromosomes are designated X and Y. Typically, the sex chromosomes in males are XY and, in females, XX. The determination of sex in an embryo involves the sex-determining region of the Y chromosome (SRY gene) and the protein it encodes, testis-determining factor (TDF). Unlike the X chromosome, the smaller Y chromosome carries the SRY gene. TDF is a protein in embryos that directs the formation of testes and the development of the internal duct system and external genitalia of a male. Without TDF, female reproductive structures develop (**Figure 29–8**).

The human embryo is sexually indifferent through approximately week 8 of development. Prior to reproductive anatomy development, which occurs between weeks 8 and 12, the developing embryo has reproductive tissue associated with both anatomical males and anatomical females. The tissues that lead to the development of anatomical male reproductive structures are the **mesonephric ducts** (also called *Wolffian ducts*). Mesonephric ducts appear early in embryonic development (between days 25 and 30). Anatomical female reproductive structures originate from tissue referred to as **paramesonephric ducts** (also called *Müllerian ducts*). Paramesonephric ducts develop between days 40 and 48.

What determines which embryonic reproductive tissues develop? The presence of the SRY gene determines if the mesonephric ducts or paramesonephric ducts will develop. The SRY gene codes for a DNA-binding protein called **testis-determining factor** (TDF). The presence of TDF stimulates embryonic tissue of the mesonephric ducts to start forming testes. As the testes develop, interstitial endocrine cells (*Leydig cells*) begin secreting testosterone. Testosterone is converted into dihydrotestosterone (DHT), a powerful androgen that initiates further development of the mesonephric ducts to form each epididymis, ductus deferens, seminal gland, and ejaculatory duct. Nurse cells (*Sertoli cells*) within the developing testes secrete a gonadal hormone called Müllerian-inhibiting substance (MIS) that inhibits the development of the paramesonephric (Müllerian) ducts. Without paramesonephric ducts, anatomical female reproductive structures do not form, and the tissue degenerates (is broken down) and is absorbed.

Figure 29-6 Anatomy of the Placenta after the First Trimester.

Figure 29–7 The First 12 Weeks of Development.**a Week 3.** Diagram showing the formation of the CNS from neural plate ectoderm. Size: about 2.25 mm (0.08 in.).**b Week 4.** Fiberoptic view of human development at week 4. Size: about 5.0 mm (0.2 in.).**c Week 8.** Fiberoptic view of human development at week 8. Size: about 1.6 cm (0.6 in.).**d Week 12.** Fiberoptic view of human development at week 12. Size: about 5.4 cm (2.1 in.).

Without a Y chromosome there will be no *SRY* gene to coordinate the production and release of TDF and MIS. The lack of MIS results in the development of the paramesonephric (Müllerian) ducts, which leads to forming anatomical female reproductive structures, the uterine tubes, uterus, cervix, and posterior one-third of the vagina. Without testosterone, mesonephric (Wolffian) ducts degenerate and the tissue is absorbed.

Under typical conditions, only one set of reproductive tissue will develop. However, ambiguous external genitalia can result for several reasons. For example, absence of functioning androgen-sensitive receptors, mutations within the *SRY* gene, low production of androgen, or absence or oversecretion of gonadal hormones can

lead to the development of anatomical reproductive structures that do not align with the genetic sex of an individual (**Figure 29–8**).

Figure 29–8 The Role of the *SRY* Gene in Sex Determination.

29-5 During the second and third trimesters, fetal development involves growth and organ function

Learning Outcome List several fetal changes that occur during the second and third trimesters.

During the second trimester, the fetus grows to a weight of about 0.6 kg (1.32 lb). Encircled by the amnion, the fetus

grows faster than the surrounding placenta during this period. When the mesoderm on the outer surface of the amnion contacts the mesoderm on the inner surface of the chorion, these layers fuse, creating a compound *amniochorionic membrane*. **Figure 29–9a** shows a 5-month-old fetus, while **Figure 29–9b** shows a 6-month-old fetus.

During the third trimester, most organ systems become ready for normal functioning without maternal assistance.

Figure 29–9 Fetal Development in the Second and Third Trimesters.

a A 5-month-old fetus seen through a fiberoptic endoscope. Size: about 19 cm (7.5 in.).

b Head of a 6-month-old fetus, revealed through ultrasound. Size: about 30 cm (11.8 in.).

The rate of growth starts to slow, but weight gain is the greatest during this trimester. In the last 3 months of gestation, the fetus gains about 2.6 kg (5.7 lb), reaching a full-term weight of approximately 3.2 kg (7.05 lb).

Gestational age is measured from the first day of the last menstrual period to the current date. **Table 29–2** summarizes gestational development.

✓ Checkpoint

11. Explain how fetal size is measured between weeks 8 and 20 and between week 20 and birth.

See the blue Answers tab at the back of the book.

29-6 During gestation, maternal organ systems support the developing fetus; the reproductive system undergoes structural and functional changes

Learning Outcome Describe the interplay between the maternal organ systems and the developing fetus and discuss the structural and functional changes in the uterus during gestation.

Hormonal and anatomical changes are effects of pregnancy. Placental hormones play a role in maintaining the pregnancy,

fetal growth, and breast maturation. Throughout the pregnancy, the uterus expands into most of the abdominal cavity.

Hormonal Regulation during Gestation

In addition to its role in the nutrition of the fetus, the placenta is an endocrine organ. Several hormones—including *human chorionic gonadotropin*, *human placental lactogen*, *placental prolactin*, *relaxin*, *progesterone*, and *estrogens*—are synthesized by the syncytiotrophoblast and released into the maternal bloodstream.

Human Chorionic Gonadotropin

The hormone **human chorionic gonadotropin (hCG)** appears in the maternal bloodstream soon after implantation. The presence of hCG in blood or urine samples is a reliable indication of pregnancy. Home pregnancy tests detect the presence of hCG in the urine.

In function, hCG resembles luteinizing hormone (LH), because it maintains the integrity of the corpus luteum and promotes the continued secretion of progesterone. As a result, the endometrial lining remains perfectly functional, and menstruation does not normally occur. Without hCG, the pregnancy ends, because another uterine cycle begins and the functional layer of the endometrium disintegrates.

Table 29-2 An Overview of Prenatal Development

From 4 weeks to about 20 weeks, the embryonic and fetal length is measured from the top of the head (crown) to the bottom of the buttocks (rump). From 20 weeks to birth, the baby is measured from crown to heel.

With hCG, the corpus luteum persists for 3 to 4 months before gradually decreasing in size and secretory function. These changes do not trigger the return of uterine cycles, because by the end of the first trimester, the placenta actively secretes both estrogens and progesterone.

Human Placental Lactogen and Placental Prolactin

Human placental lactogen (hPL) helps prepare the mammary glands for milk production. It also has a stimulatory effect on other maternal tissues comparable to that of growth hormone (GH), ensuring that glucose and protein are available for the fetus. At the mammary glands, the conversion from inactive to active status requires placental hormones (hPL, **placental prolactin**, estrogens, and progesterone) and several maternal hormones (GH, prolactin, and thyroid hormones).

Relaxin

Relaxin is a peptide hormone secreted by the placenta and the corpus luteum during pregnancy. Relaxin (1) increases the flexibility of the pubic symphysis, permitting the pelvis to expand during delivery; (2) causes the cervix to dilate, making it easier for the fetus to enter the vaginal canal; and (3) suppresses the release of oxytocin by the hypothalamus and delays the onset of labor contractions.

Progesterone and Estrogens

After the first trimester, the placenta produces enough progesterone to maintain the endometrial lining and continue the pregnancy. As the end of the third trimester approaches, estrogen production by the placenta accelerates. Section 29-7 discusses the role that increasing levels of estrogens play in stimulating labor and delivery.

Changes in Maternal Organ Systems

Pregnancy affects the maternal respiratory, cardiovascular, digestive, and urinary systems. The tidal volume increases, blood volume and blood pressure increase, morning sickness and constipation are common, and urine production increases due to increased metabolism and fetal wastes.

Changes in the Respiratory, Cardiovascular, Digestive, and Urinary Systems

The developing fetus is totally dependent on maternal organ systems for nourishment, respiration, and waste removal. Maternal systems perform these functions in addition to their normal operations. For example, the pregnant individual must absorb enough oxygen, nutrients, and vitamins for herself and for her fetus and must eliminate all the wastes that are generated. This is not a burden over the initial weeks of gestation, but the demands placed on the pregnant individual become significant as the fetus grows. For the pregnant individual to survive under these conditions, maternal systems must

compensate for changes introduced by the fetus. In practical terms, the pregnant individual must breathe, eat, and excrete for two. The major changes in maternal systems include the following:

- *Maternal respiratory rate increases and tidal volume increases.* As a result, the pregnant individual's lungs deliver the extra oxygen required and remove the excess carbon dioxide generated by the fetus.
- *Maternal blood volume increases.* This increase occurs because blood flowing into the placenta decreases the volume in the rest of the systemic circuit, and because fetal metabolic activity both decreases blood P_{O_2} and increases P_{CO_2} . The latter combination stimulates the production of renin and erythropoietin, leading to an increase in maternal blood volume through mechanisms detailed in Chapter 21 (**Figure 21-15**). By the end of gestation, maternal blood volume has increased by almost 50%.
- *Maternal requirements for nutrients increase 10–30%.* Pregnant individuals tend to have increased appetites because they must nourish both themselves and their fetus.
- *Maternal glomerular filtration rate increases by approximately 50%.* This increase corresponds to the increase in blood volume and accelerates the excretion of metabolic wastes generated by the fetus. Pregnant individuals need to urinate frequently because the volume of urine produced increases and the weight of the uterus presses down on the urinary bladder.

Changes in the Reproductive System

At the end of gestation, a typical uterus has undergone a tremendous increase in size, from 7.5 cm (3 in.) in length and 30–40 g (1–1.4 oz) in weight to 30 cm (12 in.) in length and 1100 g (2.4 lb) in weight. This remarkable expansion occurs through the enlargement (hypertrophy) of existing cells, especially smooth muscle fibers, rather than by an increase in the total number of cells. **Figure 29-10a,b,d** shows the positions of the uterus, fetus, and placenta from 16 weeks to *full term* (9 months). The uterus may then contain 2 liters of fluid, plus fetus and placenta, for a total weight of about 6–7 kg (13–15.4 lb). When the pregnancy is at full term, the uterus and fetus push many of the maternal abdominal organs out of their normal positions (compare **Figure 29-10c** with **Figure 29-10d**).

In addition, the mammary glands increase in size, and secretory activity begins. Mammary gland development requires a combination of hormones, including human placental lactogen and placental prolactin from the placenta, and prolactin (PRL), estrogens, progesterone, GH, and thyroxine from maternal endocrine organs. By the end of the sixth month of pregnancy, the mammary glands are fully developed and begin to produce clear secretions that are stored in the duct system and may be expressed from the nipple.

Note the positions of the uterus and full-term fetus within the abdomen, and the displacement of abdominal organs.

+ Clinical Note Abortion

Abortion is the termination of a pregnancy. **Spontaneous abortions**, or *miscarriages*, result from developmental problems (such as chromosomal defects in the embryo) or from hormonal problems, including abnormally low luteinizing hormone (LH) production by the maternal pituitary gland, reduced LH sensitivity at the corpus luteum, insufficient progesterone sensitivity in the endometrium, or insufficient placental production of human chorionic gonadotropin (hCG). Spontaneous abortions occur in at least 15% of recognized pregnancies. **Medical abortions**, done during the first trimester of pregnancy, use medicine to end a pregnancy and do not require surgery or anesthesia. These types of abortion are physiologically indistinguishable from a spontaneous abortion. **Surgical abortions** are healthcare procedures done by physicians using suction curettage (scraping) to remove the pregnancy.

29-7 Childbirth occurs through the process of labor, which consists of the dilation, expulsion, and placental stages

Learning Outcome List and discuss the events that occur during labor and delivery.

Parturition (par-tū-RISH-un), or *childbirth*, is the forcible expulsion of the fetus from the uterus through the cervix and vagina. This occurs by a series of strong, rhythmic uterine contractions called **labor**. This section looks at how labor starts, the three stages of the process, and difficulties that may occur during this process.

Initiation of Labor

The tremendous stretching of the uterus that occurs during pregnancy is associated with a gradual increase in the rate of spontaneous smooth muscle contractions in the myometrium. In the early stages of pregnancy, the contractions are weak, painless, and brief. Evidence indicates that progesterone released by the placenta has an inhibitory effect on uterine smooth muscle, preventing more extensive and more powerful

contractions. Late in pregnancy, some individuals experience occasional spasms in the uterine musculature, but these contractions are not regular or persistent. Such contractions are called **Braxton Hicks contractions** (*false labor*).

Placental and fetal factors are involved in the initiation of **true labor** and delivery (**Figure 29-11**). When labor begins, the fetal pituitary gland secretes oxytocin, which is released into the maternal bloodstream at the placenta. This may be the actual trigger for the onset of true labor, as it increases myometrial contractions and prostaglandin production, on top of the priming effects of estrogens and maternal oxytocin.

The Stages of Labor

Once labor contractions have begun in the myometrium, positive feedback ensures that they will continue until delivery has been completed. During labor, each contraction begins near the superior portion of the uterus and sweeps in a wave toward the cervix. The contractions are strong and occur at regular intervals. As parturition approaches, the contractions increase in force and frequency, changing the position of the fetus and moving it toward the cervical canal. Labor has traditionally been divided into three stages: the *dilation stage*, the *expulsion stage*, and the *placental stage* (**Figure 29-12**).

The Dilation Stage

The **dilation stage** begins with the onset of true labor, as the cervix dilates and the fetus begins to shift toward the cervical canal, moved by gravity and uterine contractions (stage 1 in **Figure 29-12**). This stage is highly variable in length but typically lasts 8 or more hours. At the start of the dilation stage, labor contractions last up to half a minute and occur once every 10–30 minutes. Their frequency increases steadily. Late in this stage, the amniochorionic membrane ruptures, an event sometimes referred to as having the “water break.” If this event occurs before other events of the dilation stage, the life of the fetus may be at risk from infection. If the risk is sufficiently great, labor can be induced.

The Expulsion Stage

The **expulsion stage** begins as the cervix, pushed open by the approaching fetus, completes its dilation to about 10 cm (4 in.) (stage 2 in **Figure 29-12**). In this stage, contractions reach maximum intensity. They occur at perhaps 2- or 3-minute intervals and last a full minute. Expulsion continues until the fetus has emerged from the vagina. In most cases, the expulsion stage lasts less than 2 hours. The arrival of the newborn infant into the outside world is **delivery**, or birth.

If the vaginal canal is too small to permit the passage of the fetus, posing acute danger of perineal tearing, a clinician may temporarily enlarge the passageway by performing an **episiotomy** (eh-piz-ē-OT-ō-mē), an incision through the perineal musculature. After delivery, this surgical cut is repaired

Figure 29–11 Factors Involved in the Initiation of Labor and Delivery.

What hormones stimulate and increase the excitability of the myometrium?

with sutures, a much simpler procedure than suturing the jagged edges associated with an extensive perineal tear.

Immediately after birth, clinicians assess the newborn's health in five areas: heart rate, breathing, skin color, muscle tone, and reflex response. This assessment is called an **Apgar score**. Each criterion is scored from 0 to 2, with 8–10 indicating a healthy baby.

The Placental Stage

During the **placental stage** of labor, muscle tension builds in the walls of the partially empty uterus, which gradually decreases in size (stage 3 in Figure 29–12). This uterine contraction tears the connections between the endometrium and the placenta. In general, within an hour of delivery, the placental stage ends with the ejection of the placenta, or *afterbirth*. The disruption of the placenta is accompanied by a loss of blood,

but associated uterine contraction compresses the uterine vessels and usually restricts this flow. Because maternal blood volume has increased greatly during pregnancy, the blood loss can normally be tolerated without difficulty.

Difficulties of Labor and Delivery and Multiple Births

Common complications of labor include issues with the umbilical cord looping around the baby's neck, an abnormal fetal heart rate (normal is 110–160 beats per minute), and stalled labor. Others include premature ("preterm") labor, a condition in which uterine contractions cause the cervix to open too soon, or difficult deliveries, which can stress the pregnant individual and/or the baby and sometimes cause severe complications.

Figure 29–12 The Stages of Labor.

Premature Labor

Premature labor occurs when true labor begins before the fetus has completed normal development. The newborn's chances of surviving are directly related to its body weight at delivery. Even with massive supportive efforts, newborns weighing less than 400 g (14 oz) at birth will not survive, primarily because their respiratory, cardiovascular, and urinary systems are unable to support life without aid from maternal systems. As a result, the dividing line between spontaneous abortion and **immature delivery** is usually set at 500 g (17.6 oz), the normal weight near the end of the second trimester.

Most fetuses born at 25–27 weeks of gestation (a birth weight under 600 g or 21.1 oz) die despite intensive neonatal care. Survivors have a high risk of developmental abnormalities. **Premature birth** refers to delivery before 37 weeks of pregnancy.

Difficult Deliveries

By the end of gestation in most pregnancies, the fetus has rotated within the uterus to transit the birth canal headfirst, facing the pregnant individual's sacrum. In about six percent of deliveries, the fetus faces the pregnant individual's pubis instead. These babies can be delivered normally, given enough time, but risks to infant and pregnant individual are reduced by a *forceps delivery*. Forceps resemble large, curved salad tongs that can be separated for insertion into the vaginal canal, one side at a time. Once in place, they are reunited and used to grasp the head of the fetus. An intermittent pull is applied, so that the forces on the head resemble those of normal delivery.

Clinical Note C-Section

According to the Centers for Disease Control and Prevention (CDC), about one in three pregnant individuals give birth by **cesarean section**, or **C-section**, in the United States. This high rate appears to accompany new risk factors for birth such as older females, females with diabetes or obesity, or the occurrence of multiple births (twins or triplets).

During this procedure, which typically lasts 1 to 2 hours, the pregnant individual first receives regional anesthesia to the pelvis (an “epidural”). The surgeon makes a low horizontal incision in the abdominal wall, just above the pubic hair line. Another horizontal cut is then made to open the uterus, the amniochorionic membrane is ruptured, and the infant is taken out. The infant’s umbilical cord is cut and the placenta is removed. The uterus is then carefully repaired with dissolvable sutures, and the abdomen is often closed with removable staples. Recovery takes a few days.

In three to four percent of deliveries, the legs or buttocks of the fetus enter the vaginal canal first. Such deliveries are **breech births**. Risks to the fetus are higher in breech births than in normal deliveries because the umbilical cord can become constricted, cutting off placental blood flow.

The head is normally the widest part of the fetus. The pregnant individual’s cervix may dilate enough to pass the baby’s legs and body, but not the head. This entrapment compresses the umbilical cord, prolongs delivery, and subjects the fetus to severe distress and potential injury. If attempts to reposition the fetus or promote further dilation are unsuccessful over the short term, delivery by *cesarean section*, or *C-section*, may be required.

Multiple Births

Multiple births (twins, triplets, quadruplets, and so forth) can take place for several reasons, including the growing use of fertility drugs and assisted reproductive technology. Another reason is the rise in the average age of females giving birth (older females are more likely to release more than one oocyte in a cycle). According to the CDC, the rate of twin births in the United States is 33.7 twin births out of every 1000 deliveries. “Fraternal twins,” or **dizygotic** (dī-zī-GOT-ik) **twins**, develop when two separate oocytes are ovulated and fertilized. Because chromosomes are shuffled during meiosis, the odds against any two zygotes from the same parents having identical genes exceed 1 in 8.4 million.

“Identical twins” or **monozygotic twins**, result either from the separation of blastomeres early in cleavage or from the splitting of the inner cell mass before gastrulation. In either event, the genetic makeup of the twins is identical because both formed from the same pair of gametes.

Triplets, quadruplets, and larger multiples can result from multiple ovulations, blastomere splitting, or some combination of the two. For unknown reasons, the rates of naturally occurring multiple births fall into a pattern: Twins occur in 1 of every 89 births, triplets in 1 of every 89² (or 7921) births, quadruplets in 1 of every 89³ (704,969) births, and so forth. Taking fertility drugs that stimulate the maturation of abnormally high numbers of follicles can increase the incidence of multiple births.

Pregnancies with multiple fetuses pose special problems because the strains on the pregnant individual are multiplied. The chances of premature labor are increased, and the risks to the pregnant individual are higher than for single births. Increased risks also extend to the fetuses during gestation, and to the newborns, because even at full term such newborns have lower-than-average birth weights. They are also more likely to have problems during delivery. For example, in more than half of twin deliveries, one or both fetuses enter the vaginal canal in an abnormal position.

If the splitting of the blastomeres or of the embryonic disc is not complete, **conjoined twins** may develop. These genetically identical twins typically share some skin, a portion of the liver, and perhaps other internal organs as well. Some infants can be surgically separated with some success.

Checkpoint

15. Identify three major factors opposing the calming action of progesterone on the uterus.
16. Name the three stages of labor.
17. Differentiate between immature delivery and premature birth.
18. Give the biological terms for fraternal twins and identical twins.

See the blue Answers tab at the back of the book.

29-8 Postnatal stages are the neonatal period, infancy, childhood, adolescence, and maturity, followed by senescence and death

Learning Outcome Identify the features and physiological changes of the postnatal stages of life.

Developmental processes do not stop at delivery. Newborns have few of the anatomical, functional, or physiological characteristics of mature adults. The course of postnatal development typically includes five **life stages**: (1) the *neonatal period*, (2) *infancy*, (3) *childhood*, (4) *adolescence*, and (5) *maturity*. Each stage is typified by a distinctive combination of characteristics and abilities. These stages are familiar parts of human experience. Each stage has distinctive features, but the transitions between them are gradual, and the boundaries indistinct. At maturity, development ends and the process of aging, or *senescence*, begins, leading ultimately to death.

The Neonatal Period, Infancy, and Childhood

The **neonatal period** extends from birth to 1 month of age. **Infancy**, or babyhood, then continues through the first year of life. **Childhood** lasts from infancy until **adolescence** (puberty), the period of sexual and physical maturation. Two major events are under way during these developmental stages:

1. The organ systems (except those associated with reproduction) become fully operational and gradually acquire the functional characteristics of adult structures.
2. The individual grows rapidly, and body proportions change significantly.

Pediatrics is the medical specialty that focuses on post-natal development from infancy through adolescence. Infants and young children cannot clearly describe the problems they are experiencing, so pediatricians and parents must be skilled observers. Standardized tests are used to assess developmental progress relative to average values.

The Neonatal Period

The neonatal period is the 4-week period immediately after birth. During this time, the newborn adjusts to life outside the womb as extensive and ongoing system transitions occur.

Adjustments of the Neonate. Physiological and anatomical changes take place as the fetus completes the transition to the status of newborn, or **neonate**. The neonatal period is the time from birth through 28 days. Before delivery, dissolved gases, nutrients, wastes, hormones, and antibodies were transferred across the placenta. At birth, the neonate must become relatively self-sufficient, performing respiration, digestion, and excretion using its own specialized organs and organ systems. The transition from fetus to neonate can be summarized as follows:

- At birth, the lungs are collapsed and filled with fluid. Filling them with air requires a massive and powerful inhalation.
- When the lungs expand, the pattern of cardiovascular circulation changes due to alterations in blood pressure and flow rates. The ductus arteriosus closes, isolating the pulmonary and systemic trunks. Closure of the foramen ovale separates the atria of the heart, completing the separation of the pulmonary and systemic circuits.
- Typical neonatal heart rates (120–140 beats per minute) are lower than fetal heart rates (averaging 150 beats per minute). Both the neonatal heart rate and respiratory rate (30 breaths per minute) are considerably higher than in adults.
- Before birth, the digestive system is relatively inactive, although it does accumulate a mixture of bile secretions, mucus, and epithelial cells. This collection of debris, called *meconium*, is excreted during the first few days of life. During that period, the newborn begins to nurse.

- As wastes build up in the arterial blood, the kidneys excrete them. Glomerular filtration is normal, but the neonate's kidneys cannot concentrate urine to any significant degree. As a result, urinary water losses are high, and neonatal fluid requirements are proportionally much greater than those of adults.
- The neonate has little ability to control its body temperature, particularly in the first few days after delivery. As the infant grows larger and its insulating subcutaneous adipose "blanket" gets thicker, its metabolic rate also increases. Daily and even hourly shifts in body temperature continue throughout childhood.
- During embryonic and fetal development, the pregnant individual's body is at normal body temperature. At birth, the neonate has little ability to control its body temperature. Neonates also lose heat very quickly because they have a high surface-area-to-volume ratio. To maintain a constant body temperature, their cellular metabolic rates must be high. In fact, the metabolic rate per unit of body weight in neonates is approximately twice that of adults.

Over the entire neonatal period, the newborn is dependent on nutrients contained in milk, typically breast milk secreted by the mammary glands.

Maternal Adjustments, Including Lactation. By the end of the sixth month of pregnancy, the mammary glands are fully developed, and the gland cells begin to secrete **colostrum** (kō-LOS-trum). Ingested by the infant during the first 2 or 3 days of life, colostrum contains more proteins and far less fat than breast milk. Many of the proteins are antibodies that may help the infant ward off infections until its own immune system becomes functional. In addition, the mucins present in both colostrum and milk can inhibit the replication of a family of viruses (*rotaviruses*) that can cause dangerous forms of gastroenteritis and diarrhea in infants.

As colostrum production drops, the mammary glands convert to milk production. Breast milk consists of water, proteins, amino acids, lipids, sugars, and salts. It also contains large quantities of *lysozyme*, an enzyme with antibiotic properties. In terms of energy, human milk provides about 750 kilocalories per liter. The secretory rate varies with the demand, but a 5- to 6-kg (11- to 13-lb) infant usually requires about 850 mL (3.6 cups) of milk per day. (Chapter 18 details the hormones involved with human milk production.)

Milk becomes available to infants through the **milk ejection (milk let-down) reflex** (Figure 29-13). This reflex continues to function until *weaning*, the withdrawal of milk, typically 1 to 2 years after birth. Milk production stops soon after, and the mammary glands gradually return to a resting state. Earlier weaning is a common practice in the United States, where caregivers take advantage of commercially

prepared milk-based or soy-based infant formulas that approximate the composition of natural breast milk. The major difference between such substitutes and natural milk is that the substitutes lack antibodies and lysozyme, which play important roles in maintaining the health of the infant. Consequently, early weaning is associated with an increased risk of infections and allergies in the infant.

Infancy and Childhood

The most rapid growth occurs during prenatal development, and the growth rate decreases after delivery. Growth during infancy and childhood occurs under the direction of circulating hormones, notably growth hormone, adrenal steroids, and thyroid hormones. These hormones affect each tissue and organ in specific ways, depending on the sensitivities of the individual cells. As a result, growth does not occur uniformly, so body proportions gradually change. The head, for example, is relatively large at birth but decreases in proportion to the rest of the body as the child grows to adulthood (**Figure 29–14**).

Figure 29–13 The Milk Ejection Reflex.

Figure 29–14 Prenatal and Postnatal Growth and Changes in Body Form and Proportion. The views at 4, 8, and 16 weeks of gestation are presented at actual size. Notice the changes in body form and proportions as development proceeds. For example, the head, which contains the brain and sense organs, is proportionately large at birth.

Adolescence and Maturity

Adolescence begins at **puberty**, the period of sexual maturation, and ends when growth is completed. Three major hormonal events interact at the onset of puberty:

1. The hypothalamic production of gonadotropin-releasing hormone (GnRH) increases. Evidence indicates that this increase is dependent on adequate levels of *leptin*, a hormone released by adipose tissues.
2. Endocrine cells in the anterior lobe of the pituitary gland become more sensitive to the presence of GnRH, so circulating levels of FSH and LH increase rapidly.
3. Ovarian or testicular cells become more sensitive to FSH and LH. These cells initiate (1) gamete production; (2) the secretion of sex hormones that stimulate the appearance of secondary sex characteristics and behaviors; and (3) a sudden acceleration in the growth rate, ending with closure of the epiphyseal cartilages.

The age at which puberty begins varies. In the United States today, puberty generally starts at about age 12 in males and age 11 in females, but the normal ranges are broad (ages 10–15 in males, ages 9–14 in females). Sex-specific differences in structure and function develop as many body systems alter their activities in response to circulating sex hormones and to the presence of growth hormone, thyroid hormones, prolactin, and adrenocortical hormones.

At puberty, endocrine system changes induce characteristic changes in various body systems:

- *Integumentary System.* Testosterone stimulates the development of terminal hairs on the face and chest of males. Under estrogen stimulation those follicles continue to produce fine hairs in females. The hairline recedes under testosterone stimulation. Both testosterone and estrogen stimulate terminal hair growth in the axillae and in the genital area. Androgens, which are present in both sexes, also stimulate sebaceous gland secretion and may cause acne. Adipose tissues respond differently to testosterone than to estrogens, and this difference produces changes in the distribution of subcutaneous body fat. In females, the combination of estrogens, prolactin, growth hormone, and thyroid hormones promotes the initial development of the mammary glands. The duct system becomes more elaborate, but true secretory alveoli do not yet develop. Much of the growth of the breasts during this period reflects increased deposition of fat rather than glandular tissue.
- *Skeletal System.* Both testosterone and estrogen accelerate bone deposition and skeletal growth. In the process, they promote closure of the epiphyseal cartilages and thus place a limit on growth in height. Females generally do not

grow as tall as males because estrogens cause more rapid epiphyseal cartilage closure than does testosterone, and the period of skeletal growth ends at an earlier age in females than in males. Females grow most rapidly between ages 10 and 13, whereas males grow most rapidly between ages 12 and 15.

- *Muscular System.* Sex hormones stimulate the growth of skeletal muscle fibers, increasing strength and endurance. The effects of testosterone greatly exceed those of the estrogens, and the increased muscle mass accounts for significant sex differences in body mass, even for males and females of the same height. The stimulatory effects of testosterone on muscle mass have led to the use of anabolic steroids among competitive athletes of both sexes.
- *Nervous System.* Sex hormones affect central nervous system centers concerned with sexual drive and sexual behaviors. These centers differentiated in sex-specific ways during the second and third trimesters, when the fetal gonads secrete either testosterone (in males) or estrogens (in females). The surge in sex hormone secretion at puberty activates the CNS centers.
- *Cardiovascular System.* Testosterone stimulates erythropoiesis, increasing blood volume and the hematocrit. In females whose uterine cycles have begun, the iron loss associated with menstruation increases the risk of developing iron-deficiency anemia. Late in each uterine cycle, estrogens and progesterone promote the movement of water from plasma into interstitial fluid, leading to an increase in tissue water content. Estrogens decrease plasma cholesterol levels and slow the formation of plaque. As a result, premenopausal females have a lower risk of atherosclerosis (“hardening of the arteries”) than do adult males.
- *Respiratory System.* Testosterone stimulates growth of the larynx and a thickening and lengthening of the vocal cords. These changes cause a gradual deepening of the voice of males compared with those of females.
- *Reproductive System.* In males, testosterone stimulates the functional development of the accessory reproductive glands, such as the prostate and seminal glands, and helps promote spermatogenesis. In females, estrogens target the uterus, promoting a thickening of the myometrium, increasing blood flow to the endometrium, and stimulating cervical mucus production. Estrogens also promote the functional development of accessory reproductive organs in females. The first few uterine cycles may or may not be accompanied by ovulation. After the initial stage, the female will be fertile, even though her growth and physical maturation will continue for several years.

After puberty, the continued background secretion of estrogens or androgens maintains sex-specific differences. In both sexes, growth continues at a slower pace until age 18–21. By that time most of the epiphyseal cartilages have closed. The boundary between adolescence and maturity is indistinct because it has physical, emotional, and behavioral components. Adolescence is often said to be over when growth stops, in the late teens or early 20s. The individual is then considered physically mature.

Senescence and Death

Physical growth may stop at maturity, but physiological changes continue. The sex-specific differences produced at puberty remain, but further changes take place when sex hormone levels decrease at menopause or the male climacteric (andropause). All these changes are part of the process of **senescence** (*senesco*, to grow old), or aging, which reduces the functional capabilities of the person. Even without disease or injury, senescence-related changes at the molecular level ultimately cause a person's **death**.

Table 29–3 summarizes the age-related changes in organ systems discussed in earlier chapters. Taken together, these changes both decrease the functional abilities of the individual and affect homeostatic mechanisms. As a result, older people are less able to make homeostatic adjustments in response to internal or environmental stresses. The risks of contracting a variety of infectious diseases are proportionately increased as immune function deteriorates. Age-induced changes in vital systems cause problems such as infections, cancers, heart disease, strokes, arthritis, senile dementia, and anemia.

Physicians can attempt to adjust homeostatic mechanisms and treat cancers and infections. **Geriatrics** (*geras*, old age) is the medical specialty that deals with the problems associated with aging. Physicians trained in geriatrics are known as **geriatricians**.

Eventually, however, this deterioration leads to drastic physiological changes that affect all internal systems. Death ultimately occurs when the body's existing homeostatic mechanisms cannot counter some combination of stresses.

Checkpoint

19. Name the postnatal stages of development.
20. Describe the time frame for each of the following stages: neonatal period, infancy, and adolescence.
21. What is the difference between colostrum and breast milk?
22. Increases in the blood levels of GnRH, FSH, LH, and sex hormones mark the onset of which stage of development?

See the blue Answers tab at the back of the book.

Table 29–3 Effects of Aging on Organ Systems

The characteristic physical and functional changes that are part of the aging process affect all organ systems. Examples discussed in previous chapters include the following:

- A loss of elasticity in the skin that produces sagging and wrinkling.
- A decrease in the rate of bone deposition, leading to weak bones, and degenerative changes in joints that make them less mobile.
- Reductions in muscular strength and ability.
- Impairment of coordination, memory, and intellectual function.
- Reductions in the production of, and sensitivity to, circulating hormones.
- Appearance of cardiovascular problems and a reduction in peripheral blood flow that can affect a variety of vital organs.
- Reduced sensitivity and responsiveness of the immune system, leading to infection, cancer, or both.
- Reduced elasticity in the lungs, leading to decreased respiratory function.
- Decreased peristalsis and muscle tone along the digestive tract.
- Decreased peristalsis and muscle tone in the urinary system, coupled with a reduction in the glomerular filtration rate.
- Functional impairment of the reproductive system, which eventually becomes inactive when menopause or the male climacteric occurs.

29-9 Genes and chromosomes determine patterns of inheritance

Learning Outcome Relate basic principles of genetics to the inheritance of human traits.

Recall that **chromosomes** are made up of **DNA** and proteins, and **genes** are functional segments of DNA. Each gene carries the information needed to direct the synthesis of a specific polypeptide. Chromosome structure and the functions of genes were introduced in Chapter 3. Our discussion of genetics begins with the basic patterns of inheritance and their implications. The mechanisms responsible for regulating the activities of the genes during prenatal development are then examined.

Genotype and Phenotype

Every nucleated somatic cell in the body carries copies of the original 46 chromosomes that were present at the zygote stage. Those chromosomes and their genes make up the **genotype** (jĒN-ō-tīp; *geno*-, gene).

Through development and cellular differentiation, the instructions contained in the genotype are **expressed**, or carried out, in many ways. No single cell or tissue uses all the information contained in the genotype. For example, in muscle fibers, the genes involved in the formation of excitable membranes and contractile proteins are active, but in cells of the pancreatic islets, another set of genes is at work. Collectively,

however, the instructions in the genotype determine the anatomical and physiological characteristics that make a unique person. Those anatomical and physiological characteristics are the **phenotype** (FĒ-nō-tīp; *phaino*, to display). The phenotype results from the interaction between the person's genotype and the environment. In architectural terms, the genotype is a set of construction plans, and the phenotype is the finished building. Observable features, such as hair or eye color, are called phenotypic *characters*. Specific character variants, such as brown hair or eyes, are called phenotypic *traits*.

The genotype is derived from the genotypes of the biological parents. Yet individuals are not an exact copy of either biological parent. Nor are individuals an easily identifiable mixture of their characteristics.

Homologous Chromosomes and Alleles

The 46 chromosomes carried by each human somatic cell occur in pairs. Every somatic cell contains 23 pairs of chromosomes. At amphimixis, the sperm supplies the paternal member of each pair, and the ovum supplies the maternal member. Recall that the two members of each of the 22 pairs are known as **homologous chromosomes**. Those 22 chromosome pairs are called **autosomes**. Most of the genes of autosomes affect somatic, or body, characteristics, such as hair color and skin pigmentation. The chromosomes of the 23rd pair are not truly homologous and are known as the **sex chromosomes**. One of their functions is to determine whether the individual is genetically male or female. **Figure 29–15** shows the **karyotype** (*karyon*, nucleus + *typos*, mark), or entire set of chromosomes, of a normal male. A karyotype is prepared from dividing cells that have been stopped in the metaphase stage of the cell cycle, when they are most condensed. The following discussion deals with the inheritance of traits carried on the autosomal chromosomes. The patterns of inheritance by the sex chromosomes are examined later in this section.

The two chromosomes in an autosomal homologous pair have the same structure and carry genes that affect the same traits. For example, suppose that one member of the pair contains three genes in a row, with the first gene determining hair color, the second eye color, and the third skin pigmentation. The other chromosome, or *homolog*, carries genes that affect the same traits, and the genes are in the same sequence. The genes are also located at equivalent positions on their respective chromosomes. A gene's position on a chromosome is called a **locus** (LŌ-kus).

Because the two chromosomes of a homologous pair have different origins, one paternal and the other maternal, they may not carry the same *form*, or version, of each gene. The various forms of a given gene are called **alleles** (uh-LĒLZ). These *alternative forms* determine the precise effect of the gene on phenotype. If the two chromosomes of a homologous pair

Figure 29–15 A Human Male Karyotype.

Explain why this is a karyotype of a male and not a female.

carry the same allele of a particular gene, a person is termed **homozygous** (hō-mō-ZĪ-gus; *homos*, the same) for the trait affected by that gene. If a person has two different alleles for the same gene, they are considered **heterozygous** (het-er-ō-ZĪ-gus; *heteros*, other) for the trait determined by that gene.

Autosomal Patterns of Inheritance

In **simple inheritance**, the phenotype is determined by interactions between a single pair of alleles. Some phenotypic traits are determined by interactions among several genes. Such interactions constitute **polygenic inheritance**. The potential interactions, which include examples of normal and abnormal phenotypic traits, are diagrammed in **Figure 29–16**.

Simple Inheritance

If a person is homozygous for a particular trait, that allele will then indeed be expressed in their phenotype. For example, receiving a gene for freckles from the biological father and a gene for freckles from the biological mother will result in the person being homozygous for freckles—and they will have freckles. About 80% of an individual's genome consists of homozygous alleles.

The phenotype that results from a heterozygous genotype depends on the nature of the interaction between the corresponding alleles. For example, if an individual received a gene for curly hair from their biological father, but a gene for straight

Figure 29–16 Major Patterns of Inheritance.

What types of inheritance are involved in the following phenotypes: nearsightedness, normal vision, and red–green color blindness?

hair from their biological mother, whether that individual will have curly hair, straight hair, or even wavy hair depends on the relationship between the alleles for those traits. The relationship can be one of *strict dominance*, *codominance*, or *incomplete dominance*, as follows:

- In **strict dominance**, an allele that is **dominant** will be expressed in the phenotype, *regardless of any conflicting instructions carried by the other allele*. For instance, an individual with only one allele for freckles will have freckles, because that allele is dominant over the “nonfreckles” allele.

An allele that is **recessive** will be expressed in the phenotype only if that same allele is present on *both chromosomes* of a homologous pair. For example, in Chapter 5 it was noted that people with albinism cannot synthesize the yellow-brown pigment *melanin*. The presence of one allele that directs melanin production will result in normal skin color. Two recessive alleles must be present to produce an individual with albinism. A single gene can have many different alleles *in a population*, some dominant and others recessive. An individual can have a maximum of only two alleles—one from the biological mother and one from the biological father. If both biological parents have the same alleles, then an individual has only one kind of allele, but two copies of it, and is, thus, homozygous.

- In **codominance**, an individual who is heterozygous (has different alleles) for a given trait exhibits both phenotypes for that trait. Blood type in humans is determined by codominance. The alleles for type A and type B blood are dominant over the allele for type O blood, but a person with one type A allele and one type B allele has type AB blood, not A or B. The red blood cells that make up type AB blood express *both* type A antigens and type B antigens.
- In **incomplete dominance**, heterozygous alleles produce a phenotype that is intermediate (not completely dominant) to the phenotypes of individuals who are homozygous for one allele or the other. A good example is the sickling gene that affects the shape of red blood cells. Individuals with homozygous alleles that carry instructions for normal adult hemoglobin A have red blood cells of normal shape. Individuals with homozygous alleles for hemoglobin S, an abnormal form, have red blood cells that become sickle shaped in peripheral capillaries when the P_{O_2} decreases. These individuals develop *sickle cell disease*. Individuals who are heterozygous for this trait do not develop anemia, but their red blood cells may sickle when tissue oxygen levels are extremely low. The distinction between incomplete dominance and codominance is not always clear-cut. For example, a person who has alleles for hemoglobin A and hemoglobin S shows incomplete dominance for RBC shape, but codominance for hemoglobin. Each red blood cell contains a mixture of hemoglobin A and hemoglobin S. Incomplete dominance is relatively rare in humans.

Predicting Simple Inheritance: The Punnett Square To understand genetics, and the societal and medical changes in which trans men (legally recognized as males) are using their reproductive organs to give birth, we must agree on some terms to refer to the individuals whose genes make up our genotype. Thus, for the purpose of this discussion, the terms *maternal* and *paternal* refer to the biological mother (female who contributed genes) and biological father (male who contributed genes). To-

gether, the *biological mother* and *biological father* are the *biological parents*. In many cases, the term *biological* can also be replaced with the word *genetic* in reference to the *genetic mother*, *genetic father*, and *genetic parents*. When an allele can be neatly characterized as dominant or recessive, you can predict the possible phenotypic ratios of the biological parents' offspring.

In such calculations, dominant alleles are traditionally indicated by capitalized abbreviations, and recessive alleles by lowercase abbreviations. Thus, for a given trait, the possible genotypes are indicated by AA (homozygous dominant), Aa (heterozygous), or aa (homozygous recessive). Each gamete involved in fertilization contributes a single allele for a given trait. That allele must be one of the two alleles contained by all cells in the biological parent's body. For example, consider the possible offspring of a female with albinism (no skin pigmentation) and a male with normal skin pigmentation. The alleles of the female genotype are abbreviated aa because albinism is a homozygous recessive trait. No matter which of her oocytes is fertilized, it will carry the recessive a allele. The male has normal pigmentation, a dominant trait. His genotype therefore is either homozygous dominant *or* heterozygous for this trait, because both AA and Aa will produce the same phenotype: normal skin pigmentation. Every sperm produced by a homozygous dominant biological father will carry the A allele. In contrast, half the sperm produced by a heterozygous biological father will carry the dominant allele A, and the other half will carry the recessive allele a.

A simple box diagram known as a **Punnett square** helps to predict the probabilities that children will have particular phenotypic traits by showing the various combinations of biological parental alleles they can inherit. In the Punnett squares shown in **Figure 29–17**, the maternal alleles for skin pigmentation are listed along the horizontal axis and the paternal ones along the vertical axis. The combinations of alleles appear in the small boxes. **Figure 29–17a** shows the possible offspring of an aa biological mother and an AA biological father. All the children will have the genotype Aa, so all will have normal skin pigmentation. Compare these results with those of **Figure 29–17b**, for a heterozygous biological father (Aa) and an aa biological mother. The heterozygous male produces two types of gametes, A and a. The female's secondary oocyte, carrying an a allele, may be fertilized by either one. As a result, the probability is 50% that a child of such a biological father will inherit the genotype Aa and so have normal skin pigmentation. The probability of inheriting the genotype aa, and thus having the albinism phenotype, is also 50%.

A Punnett square can also be used to draw conclusions about the identity and genotype of a biological parent. For example, in our scenario, a male with the genotype AA cannot be the biological parent of a child with albinism (genotype aa).

We can also predict the frequency of appearance of any inherited disorder that results from simple inheritance by using a Punnett square. Although they are rare in terms of overall

Figure 29–17 Predicting Phenotypic Traits by Using Punnett Squares.

numbers, more than 1200 inherited disorders have been identified that reflect the presence of one or two abnormal alleles for a single gene.

Polygenic Inheritance

We cannot predict the presence or absence of phenotypic traits inherited in a polygenic manner using a simple Punnett square, because the resulting phenotype depends not only on the nature of the alleles but also on how those alleles interact. In *suppression*, one gene suppresses the other. As a result, the second gene has no effect on the phenotype. In *complementary gene action*, dominant alleles on two genes interact to produce a phenotype different from that seen when one gene contains recessive alleles. The risks of developing several important adult disorders, including hypertension and coronary artery disease, are linked to polygenic inheritance.

Many of the developmental disorders responsible for fetal deaths and congenital malformations result from polygenic inheritance. In these cases, an individual's genetic composition does not by itself determine the onset of the disease. Instead, the conditions regulated by these genes establish a susceptibility to specific environmental influences. As a result, not every individual with the genetic tendency for a certain condition will develop that condition. For this reason, it is difficult to track polygenic conditions through successive generations. However, steps can be taken to prevent a crisis because many inherited polygenic conditions are *likely* (but not *guaranteed*) to occur. For example, an individual can reduce hypertension by controlling their diet and fluid volume, and an individual

can lessen the risk of coronary artery disease by lowering their blood serum cholesterol levels.

Sex-Linked Patterns of Inheritance

Sex-linked inheritance involves genes on the sex chromosomes (Figure 29–16). Unlike the other 22 chromosomal pairs, the sex chromosomes are not identical in appearance and gene content. There are two types of sex chromosomes: an **X chromosome** and a **Y chromosome**. X chromosomes are considerably larger and have more genes than do Y chromosomes (about 900 to 55). The smaller Y chromosome carries the **SRY** gene not found on the X chromosome. It specifies that an individual with that chromosome will be male. The typical pair of sex chromosomes in males is XY. Females do not have a Y chromosome. Their sex chromosome pair is XX.

All oocytes carry an X chromosome, because the only sex chromosomes females have are X chromosomes. But each sperm carries either an X or a Y chromosome because males have one of each and can pass along either one during meiosis. As a Punnett square shows, the ratio of males to females in offspring should be 1:1. The worldwide birth statistics differ slightly from that prediction, with 107 males born for every 100 females. It has been suggested that more males are born because a sperm that carries the Y chromosome can reach the oocyte first, because that sperm does not have to carry the extra weight of the larger X chromosome.

The X chromosome also carries genes that affect somatic structures. Genes found on the X chromosome but not on the Y chromosome are called **X-linked**. The inheritance of characteristics, or

traits, regulated by these X-linked genes does not follow the pattern of alleles on autosomal chromosomes. The sex-determining region on the Y chromosome (*SRY* gene) that determines anatomical male development is an example of a Y-linked gene.

The inheritance of color blindness shows the differences between sex-linked inheritance and autosomal inheritance. The presence of a dominant allele, *C*, on the X chromosome (X^C) results in normal color vision. A recessive allele, *c*, on the X chromosome (X^c) results in red–green color blindness. A female, with her two X chromosomes, can be either homozygous dominant ($X^C X^C$) or heterozygous ($X^C X^c$) and still have normal color vision. She will be unable to distinguish reds from greens only if she carries two recessive alleles, $X^c X^c$. But a male has only one X chromosome, so whichever allele that X chromosome carries determines whether he has normal color vision or has red–green color blindness. The Punnett square in **Figure 29–18** reveals that the sons produced by a biological father with normal vision and a heterozygous (carrier) biological mother have a 50% chance of being red–green color blind. Any female offspring have normal color vision. Recessive alleles on X chromosomes produce genetic disorders in males at a higher frequency than in females.

Several other clinical disorders noted earlier in the text are X-linked traits, including certain forms of hemophilia, diabetes insipidus, and muscular dystrophy. In several instances, advances in molecular genetics techniques have enabled geneticists to locate the specific genes on the X chromosome. These techniques provide a reasonably direct method of screening for the presence of a particular condition before any signs or symptoms appear, and even before birth.

Figure 29–18 Inheritance of an X-Linked Trait.

Sources of Individual Variation

Just as individuals are not a copy of either of their biological parents, individuals also are not a 50–50 mixture of their characteristics. One reason for this was noted in Chapter 28: During meiosis, maternal and paternal chromosomes are randomly distributed, so each gamete has a unique combination of maternal and paternal chromosomes. For this reason, an individual may have an allele for freckles from their biological father and an allele for nonfreckles from their biological mother, even though their biological sister received an allele for nonfreckles from each of their biological parents.

Only in very rare cases does an individual receive both alleles from one biological parent. The few documented cases appear to have resulted when duplicate maternal chromatids failed to separate during meiosis II and the corresponding chromosome provided by the sperm did not participate in amphimixis. This condition, called *uniparental disomy*, generally remains undetected because the individuals are phenotypically normal.

Genetic Recombination

During meiosis, various changes can occur in chromosome structure, producing gametes with chromosomes that differ from those of each parent. **Genetic recombination** greatly increases the genetic variation among gametes, and thus among the genotypes formed when those gametes combine in fertilization.

In one normal form of recombination, parts of homologous chromosomes become rearranged during synapsis of meiosis I (**Figure 29–19**). When tetrads form, adjacent chromatids may overlap. The chromatids may then break, and the overlapping segments trade places, an event called **crossing over**. In contrast, genetic recombination between nonhomologous chromosomes is called **translocation**. During recombination, portions

Figure 29–19 Crossing Over and Recombination.

of chromosomes may also break away and be *deleted* (lost). This event is abnormal, and it can have severe or even lethal effects on the zygote, depending on the nature of the lost genes.

Recombination that results in abnormal chromosome shapes or numbers is lethal for the zygote in almost all cases. Approximately 10% of zygotes have **chromosomal abnormalities**—that is, damaged, broken, missing, or extra copies of chromosomes—but only about 0.5% of newborns have such variations. Few individuals with chromosomal abnormalities survive to full term. *Down syndrome* (*trisomy 21*), which involves one of the smallest chromosomes in humans, is an exception.

In addition to contributing to prenatal mortality, chromosomal abnormalities produce a variety of serious clinical conditions. The high mortality rate and the severity of the problems reflect the fact that large numbers of genes have been added or deleted. Females who become pregnant later in life run a higher risk of birth defects and miscarriage due to chromosomal abnormalities in the oocyte. It seems that the longer the oocyte remains suspended in meiosis I, the more likely are recombination errors when meiosis is completed.

However, a lack of specific gene expression in a zygote is not necessarily due to chromosomal aberrations or deletions. Genes can be present yet be prevented from being fully expressed. A genetic process called **genomic imprinting** is particularly important in the early embryo. Imprinting does not change the DNA itself. Instead, it results in specific (and usually reversible) chemical

modifications, or markings, of DNA and its associated proteins. These changes then dictate whether the gene is expressed or not (silenced). As gametes mature, a proportion of their genes develop characteristic, maternal and paternal specific, imprinting markings.

+ Clinical Note Amniocentesis

Many genetic conditions can be detected before birth through the analysis of fetal cells. In **amniocentesis**, a sample of **amniotic fluid** is removed and the fetal cells it contains are analyzed. This procedure permits the identification of many congenital conditions, including Down syndrome, sickle cell disease, and neural tube defects. The needle inserted to obtain a fluid sample is guided into position during an ultrasound procedure.

Because the sampling procedure represents a potential threat to the health of both the fetus and the pregnant individual, amniocentesis is generally offered only to pregnant individuals who have a significant risk for genetic diseases.

Sampling cannot safely be performed until the volume of amniotic fluid is large enough that the fetus will not be injured during the process. The usual time for amniocentesis is between the 15th and 18th week of pregnancy. Results are usually available within 2–3 weeks.

+ Clinical Note Chromosomal Abnormalities

Embryos that have abnormal autosomal chromosomes (chromosomes 1–22) rarely survive. However, *translocation defects* and *trisomy* are two types of autosomal abnormalities that do not invariably result in prenatal death.

In a **translocation defect**, an exchange occurs between different (nonhomologous) chromosome pairs. For example, a piece of chromosome 8 may become attached to chromosome 14. The genes moved to their new position may function abnormally, becoming inactive or overactive. In a balanced translocation, where there is no net loss or gain of chromosomal material, embryos may survive.

In **trisomy**, a mistake occurs in meiosis. One of the gametes involved in fertilization carries an extra copy of one chromosome, so the zygote then has three copies of this chromosome rather than two. (The nature of the trisomy is indicated by the number of the chromosome involved. For example, individuals with trisomy 13 have three copies of chromosome 13.) Zygotes with extra copies of chromosomes seldom survive. The notable exception is trisomy 21.

Trisomy 21, or **Down syndrome**, is the most common viable chromosomal abnormality. The degree of

developmental disability ranges from moderate to severe. Anatomical problems affecting the cardiovascular system often prove fatal during childhood or early adulthood. Although some individuals survive to moderate old age, many develop Alzheimer's disease while still relatively young (before age 40).

For unknown reasons, there is a direct correlation between advancing maternal age and the risk of having a child with trisomy 21. This is becoming increasingly significant because many females are delaying childbearing until their mid-30s or later.

These markings persist after fertilization and can regulate whether the maternally or the paternally derived gene is transcribed during embryonic development. Many of the genes known to be affected by genomic imprinting regulate many aspects of early development, including rates of prenatal and postnatal growth, behavior, and language development. Imprinting is a normal process that acts as a “volume control” for parental genes since it results in one active copy of an imprinted gene.

Incorrectly imprinted genes can have the same effect as deletion of the same gene. This is exemplified by two human genetic disorders linked to genes in a specific portion of chromosome 15 and their differential imprinting during sperm or oocyte formation. *Angelman syndrome*, which results in hyperactivity, severe developmental disability, and seizures, occurs when the maternal genes are inactive. *Prader–Willi syndrome*, which results in short stature, reduced muscle tone and skin pigmentation, underdeveloped gonads, and some degree of developmental disability, occurs when paternal genes are inactive.

Epigenetics is the study of inherited traits that are *not* due to changes in a person’s genotype or DNA sequences. Like genomic imprinting, it acts at a level “above” the DNA by activating or inactivating specific genes. Such gene regulation occurs in several ways. One way is by chemically marking DNA and its histone proteins with methyl or acetyl groups, which permit or restrict transcription, respectively. Understanding the role of epigenetics in human clinical disorders, disease, and early development is an area of active study.

Mutations

Variations at the level of the individual gene can result from *mutations*—changes in the nucleotide sequence of an allele. **Spontaneous mutations** result from random errors in DNA replication. Such errors are relatively common, but in most cases the error is detected and repaired by DNA repair enzymes in the nucleus. Those errors that go undetected and unrepaired have the potential to change the phenotype in some way.

Mutations occurring during meiosis can produce gametes that contain abnormal alleles. These alleles may be dominant or recessive, and they may occur on autosomal chromosomes or on sex chromosomes. Most mutations make the zygote incapable of completing normal development. Mutation, rather than chromosomal abnormalities, is probably the primary cause of the high mortality rate among pre-embryos and embryos.

If the abnormal allele is dominant but does not affect gestational survival, the individual’s phenotype will show the effects of the mutation. If the abnormal allele is recessive and is on an autosomal chromosome, it will not affect the individual’s phenotype if the zygote contains a normal allele contributed by the other parent at fertilization. Over generations, a recessive autosomal allele can spread through the population, remaining undetected until a fertilization occurs in which the two gametes contribute identical recessive alleles. This individual, who will be

homozygous for the abnormal allele, will be the first to show the phenotypic effects of the original mutation. Individuals who are heterozygous for an abnormal allele but do not show the effects of the mutation are called **carriers**. Available genetic tests can determine whether an individual is a carrier for any of several autosomal recessive disorders. The information obtained from these tests can be useful in counseling prospective parents. For example, if both biological parents are carriers of the same disorder, they have a 25% probability of producing a child with the disease. This information may affect their decision to conceive.

Effect of Environmental Factors: Penetrance and Expressivity

Differences in genotype lead to distinct variations in phenotype, but the relationships are not always predictable. The presence of a particular pair of alleles does not affect the phenotype in the same way in every individual. **Penetrance** is the percentage of individuals with a particular genotype that show the “expected” phenotype. In other individuals, the activity of other genes or environmental factors may override the effects of that genotype. For example, *emphysema*, a respiratory disorder discussed in Chapter 23, has been linked to a specific abnormal genotype. However, about 20% of the individuals with this genotype do not develop emphysema, making the penetrance of this genotype approximately 80%. The effects of environmental factors are apparent: Most people who develop emphysema are cigarette smokers.

If a given genotype *does* affect the phenotype, it can do so to various degrees, again depending on the activity of other genes or environmental stimuli. For example, even though identical twins have the same genotype, they do not have the same fingerprints. The extent to which a particular allele is expressed when it is present is termed its **expressivity**.

Environmental effects on genetic expression are particularly evident during embryonic and fetal development. Drugs, including certain antibiotics, alcohol, and nicotine in cigarette smoke, can disrupt fetal development. Factors that result in abnormal development are called **teratogens** (TER-ah-tō-jenz).

The Human Genome

The **human genome** is the full set of genetic material (DNA) in our chromosomes. As a result of the Human Genome Project (HGP), begun in 1990, we now know the gapless nucleotide sequences for all chromosomes from telomere to telomere, except chromosome Y. This reference genome sequence has uncovered the positions of 3.05 billion base pairs, as well as over 16,000 base pairs of the mitochondrial genome. It also indicates that our genome contains slightly less than 21,000 protein-coding genes (once estimated at more than 100,000). The HGP has also contributed to a description of approximately 10,000 different single-gene disorders. Most are very rare, but collectively they may affect 1 in every 200 births. Several examples are included in **Figure 29–20**. Genetic screening

Figure 29–20 A Map of Human Chromosomes. The banding patterns of typical chromosomes in a male, and the general locations of the mutated genes associated with specific inherited disorders. The chromosomes are not drawn to scale.

* One form of the disease

and diagnostic tests for abnormal genes are now performed for many of these disorders.

29

The HGP found that protein-coding genes occupied less than 3% of the human genome. Further studies found that many of the non-protein-coding bases help determine when a gene is turned on or off. Such gene regulation is what makes one cell a liver cell or, for instance, a muscle cell. **Gene therapy** is a medical approach aimed at treating disorders or diseases caused by genetic defects. The field has advanced from inserting corrective genes made in a laboratory into a patient's cells to *genome editing* in which molecular tools are used on a cell's existing DNA to repair a gene, turn genes on or off, or remove a gene.

We all are variations on a basic genomic theme. Understanding the scope of human genetic variation beyond the HGP reference genome is being addressed by the Human Pangenome Project (HPP). Its goal is to sequence 350 more genomes from 26 diverse populations around the world.

Moreover, as we improve our abilities to modify the expression of a gene or correct an abnormal gene, we will face many additional ethical and legal dilemmas. In the years to come, we will have to find answers to these dilemmas that are acceptable to us all.

✓ Checkpoint

23. Describe the relationship between genotype and phenotype.
24. Define heterozygous.
25. Tongue rolling is an autosomal dominant trait. What would be the phenotype of a person who is heterozygous for this trait?
26. Why are children not identical copies of their biological parents?

29 Chapter Review

Study Outline

An Introduction to Development and Inheritance

1. Humans develop in the womb, grow to maturity, and live for most of a century.
2. An interplay between genes and the environment shapes physiological processes.

29-1 Directed by inherited genes, a fertilized ovum differentiates during prenatal development to form an individual; postnatal development brings that individual to maturity

3. **Development** is the gradual modification of anatomical structures and physiological characteristics from conception to maturity. The formation of different types of cells is **cellular differentiation**.
4. **Prenatal development** occurs before birth; **postnatal development** begins at birth and continues to **maturity**, when aging begins. **Inheritance** is the transfer of genetically determined characteristics from generation to generation. **Genetics** is the study of the mechanisms of inheritance.

29-2 Fertilization—the fusion of a secondary oocyte and a sperm—forms a zygote

5. **Fertilization**, or *conception*, normally occurs in the uterine tube within a day after ovulation. Sperm cannot fertilize a secondary oocyte until they have undergone *capacitation*. (Figure 29–1)
6. The acrosomes of the sperm release **hyaluronidase** and **acrosin**, enzymes required for sperm to penetrate the corona radiata and zona pellucida of the oocyte. When a single sperm contacts the oocyte membrane, fertilization begins and **oocyte activation** follows. (Figure 29–1)
7. During activation, the oocyte completes meiosis II and thus becomes a functionally mature ovum. Membrane depolarization and the *cortical reaction* act as a **block to polyspermy**.
8. After activation, the **female pronucleus** and the **male pronucleus** replicate their DNA before fusing in a process called *amphimixis*. (Figure 29–1)

29-3 Gestation consists of three stages of prenatal development: the first, second, and third trimesters

9. The 9-month **gestation** period can be divided into three trimesters.

29-4 The first trimester includes pre-embryonic and embryonic development, involving the processes of cleavage, implantation, placentation, and embryogenesis

10. In the **first trimester**, **cleavage** subdivides the cytoplasm of the zygote in a series of mitotic divisions; the zygote becomes a **pre-embryo** and then a **blastocyst**. During **implantation**,

Media Resources:

- Chapter Quizzes, Chapter Practice Test, MP3 Tutor Sessions, and Clinical Case Studies
- Practice Anatomy Lab
- A&P Flix
- Interactive Physiology
- PhysioEx

the blastocyst becomes enclosed within the uterine endometrium. **Placentation** occurs as blood vessels form around the blastocyst and the **placenta** develops. **Embryogenesis** is the formation of a viable embryo.

11. The blastocyst consists of an outer **trophoblast** and an **inner cell mass**. (Figure 29–2)
12. Implantation occurs about 7 days after fertilization as the blastocyst adheres to the uterine lining. (Figure 29–3)
13. As the **syncytiotrophoblast** enlarges and spreads, maternal blood flows through open **lacunae**. After **gastrulation**, there is an **embryonic disc** composed of **endoderm**, **ectoderm**, and an intervening **mesoderm**. It is from these **germ layers** that the body systems differentiate. (Figure 29–4; Table 29–1)
14. During prenatal development, differences in the cytoplasmic composition of individual cells trigger changes in genetic activity. The chemical interplay among developing cells is **induction**.
15. Germ layers are involved in forming four **extra-embryonic membranes**: the yolk sac, amnion, allantois, and chorion. (Spotlight Figure 29–5)
16. The **yolk sac** is an important site of blood cell formation. The **amnion** encloses fluid that surrounds and cushions the developing embryo. The base of the **allantois** later gives rise to the urinary bladder. Circulation within the vessels of the **chorion** provides a rapid-transit system that links the embryo with the trophoblast. (Spotlight Figure 29–5, Figure 29–6)
17. **Chorionic villi** extend outward into the maternal tissues, forming an intricate, branching network through which maternal blood flows. As development proceeds, the **umbilical cord** connects the fetus to the placenta. (Figure 29–6)
18. The first trimester is critical, because events in the first 12 weeks establish the basis for **organogenesis** (organ formation). (Figure 29–7; Table 29–2)
19. The SRY gene on the Y sex chromosome plays a role in forming anatomically male structures. In its presence, **testis-determining factor** (TDF) is produced, leading to the degeneration of paramesonephric ducts, and development of mesonephric ducts and testes. The X chromosome lacks the SRY gene, which leads to the development of the paramesonephric ducts into anatomically female structures. SRY gene mutations lead to ambiguous sex structures. (Figure 29–8)
20. **Paramesonephric ducts** (*Müllerian ducts*) are paired tubes in the embryo that develop into the uterine tubes, uterus, cervix, and one-third of the vagina. **Mesonephric ducts** (*Wolffian ducts*) are paired tubes in the embryo that develop into the epididymis, vas deferens, seminal gland, and the ejaculatory duct. (Figure 29–8)

29-5 During the second and third trimesters, fetal development involves growth and organ function

21. In the **second trimester**, the organ systems increase in complexity. During the **third trimester**, many of the organ systems become fully functional. (*Figure 29-9; Table 29-2*)
22. The fetus undergoes its largest weight gain in the third trimester. At the end of gestation, the fetus and the enlarged uterus displace many of the pregnant individual's abdominal organs. (*Figure 29-10*)

29-6 During gestation, maternal organ systems support the developing fetus; the reproductive system undergoes structural and functional changes

23. The syncytiotrophoblast synthesizes **human chorionic gonadotropin (hCG)**, **human placental lactogen (hPL)**, **placental prolactin**, **relaxin**, **progesterone**, and **estrogens**.
24. The developing fetus is totally dependent on maternal organs for nourishment, respiration, and waste removal. Maternal adaptations include increases in respiratory rate, tidal volume, blood volume, nutrient and vitamin intake, and glomerular filtration rate, as well as changes in the size of the uterus and mammary glands.

29-7 Childbirth occurs through the process of labor, which consists of the dilation, expulsion, and placental stages

25. Progesterone produced by the placenta has an inhibitory effect on uterine muscles. Estrogens, oxytocin, and prostaglandins oppose its calming action. At some point, multiple factors interact to produce **labor contractions** in the uterine wall. (*Figure 29-11*)
26. The goal of **true labor** is **parturition**, the forcible expulsion of the fetus.
27. Labor can be divided into three stages: the **dilation stage**, the **expulsion stage**, and the **placental stage**. The Apgar score is used to assess the overall health of a newborn. (*Figure 29-12*)
28. **Premature labor** may result in **premature birth**.
29. Difficult deliveries can include *forceps deliveries* and **breech births**—deliveries in which the legs or buttocks of the fetus, rather than the head, enter the vaginal canal first.
30. Twins are either **dizygotic** (fraternal) **twins** or **monozygotic** (identical) **twins**.

29-8 Postnatal stages are the neonatal period, infancy, childhood, adolescence, and maturity, followed by senescence and death

31. Postnatal development involves a series of five **life stages**: the neonatal period, infancy, childhood, adolescence, and maturity. *Senescence*, or aging, begins at maturity and ends in the death of the individual.
32. The **neonatal period** extends from birth to 1 month. In the transition from fetus to **neonate**, the respiratory, circulatory, digestive, and urinary systems of the infant begin functioning independently. The newborn must also begin thermoregulation.
33. Mammary gland cells produce protein-rich **colostrum** during the neonate's first few days of life and then convert to milk production. These secretions are released because of the **milk ejection (milk let-down) reflex**. (*Figure 29-13*)
34. Body proportions gradually change during **infancy** (from age 1 month to 1 year) and during **childhood** (from age 1 year to puberty). (*Figure 29-14*)

35. **Adolescence** begins at **puberty**, when (1) the hypothalamus increases its production of GnRH, (2) circulating levels of FSH and LH rise rapidly, and (3) ovarian or testicular cells become more sensitive to FSH and LH. These changes initiate gamete formation, the production of sex hormones, and a sudden increase in the growth rate. The hormonal changes at puberty, especially changes in sex hormone levels, produce sex-specific differences in the structure and function of many systems; these differences will be retained. Adolescence continues until growth is completed. Further changes occur when sex hormone levels decrease at menopause or the male climacteric.
36. **Senescence** then begins, producing gradual reductions in the functional capabilities of all systems. (*Table 29-3*)

29-9 Genes and chromosomes determine patterns of inheritance

37. Every somatic cell carries copies of the original 46 chromosomes in the zygote; these chromosomes and their genes make up the individual's **genotype**. The physical expression of the genotype is the individual's **phenotype**.
38. Every somatic human cell contains 23 pairs of chromosomes; 22 pairs consist of **homologous chromosomes**. These 22 pairs are called **autosomes**. The chromosomes of the 23rd pair are the **sex chromosomes**; they differ between the sexes. (*Figure 29-15*)
39. Chromosomes contain DNA, and genes are functional segments of DNA. The various forms of a given gene are called **alleles**. If both homologous chromosomes carry the same allele of a particular gene, the individual is **homozygous**; if they carry different alleles, the individual is **heterozygous**.
40. In **simple inheritance**, phenotypic traits are determined by interactions between a single pair of alleles. **Polygenic inheritance** involves interactions among alleles on several genes. (*Figure 29-16*)
41. Alleles are either **dominant** or **recessive**, depending on how their traits are expressed.
42. Combining maternal and paternal alleles in a **Punnett square** helps us predict the characteristics of offspring. (*Figure 29-17*)
43. The two types of sex chromosomes are an **X chromosome** and a **Y chromosome**. The normal sex chromosome complement of males is XY; that of females is XX. **Sex-linked inheritance** involves genes on the sex chromosomes. The X chromosome carries **X-linked genes**, which affect somatic structures but have no corresponding alleles on the Y chromosome. (*Figure 29-18*)
44. **Genetic recombination**, the gene reshuffling in **crossing over** and **translocation** during meiosis, increases the genetic variation of male and female gametes. (*Figure 29-19*)
45. **Spontaneous mutations** are the result of random errors in DNA replication. Such mutations can cause the production of abnormal alleles.
46. The **human genome** contains some 20,000–21,000 protein-coding genes. Thousands of single-gene disorders have been identified, including some of those responsible for inherited disorders. (*Figure 29-20*)
47. **Gene therapy** techniques include inserting corrective genes made in a laboratory into a patient's cells to treat disorders or diseases caused by genetic defects and genome editing in which molecular tools are used on a cell's existing DNA to repair a gene, turn genes on or off, or remove a gene.

Review Questions

See the blue Answers tab at the back of the book.

LEVEL 1 Reviewing Facts and Terms

1. Fertilization typically takes place **(a)** in the ovaries, **(b)** in the endometrium of the uterus, **(c)** in the cavity of the uterus, **(d)** in the vaginal fornix, **(e)** near the junction between the ampulla and isthmus of the uterine tube.
2. Identify the two extra-embryonic membranes and the three different regions of the endometrium at week 10 of development in the following diagram.

- | | |
|------------------|------------------|
| (a) _____ | (b) _____ |
| (c) _____ | (d) _____ |
| (e) _____ | |

3. An enzyme released from the acrosome of a sperm by the acrosome reaction is the **(a)** zonal inhibiting protein, **(b)** hyaluronidase, **(c)** progesterone, **(d)** DNA repair enzyme, **(e)** lysozyme.
4. Recessive X-linked traits **(a)** are passed from fathers to their sons, **(b)** are more likely to be expressed in males, **(c)** always affect some aspect of the reproductive system, **(d)** are never expressed in females, **(e)** cannot be passed from biological mothers to biological daughters.
5. The blastocyst consists of an inner cell mass and the **(a)** corona radiata, **(b)** zona pellucida, **(c)** amniotic cavity, **(d)** trophoblast.
6. The pre-embryo develops into a multicellular complex known as a **(a)** blastocyst, **(b)** trophoblast, **(c)** lacuna, **(d)** blastomere.
7. The structure(s) that allow(s) active and passive exchange between the fetal and maternal bloodstreams is/are the **(a)** yolk stalk, **(b)** chorionic villi, **(c)** umbilical veins, **(d)** umbilical arteries.
8. If the presence of an allele on one of the parental chromosomes is sufficient to affect the phenotype, the allele is said to be **(a)** dominant, **(b)** recessive, **(c)** complementary, **(d)** heterozygous.
9. Describe the changes that occur in the oocyte immediately after fertilization.
10. **(a)** Which three layers constitute the embryo in week 3? **(b)** From which layers are the thymus, pancreas, nails, brain, kidneys, dermis, liver, salivary glands, and heart derived?
11. Identify the three stages of labor and describe the events that characterize each stage.
12. List the factors involved in initiating labor contractions.
13. Identify the three life stages that occur between birth and approximately age 10. Describe the timing and characteristics of each stage.

14. What hormonal events are responsible for puberty? Which life stage does puberty initiate?

LEVEL 2 Reviewing Concepts

15. A woman with normal vision, whose father was red-green color blind, marries a man with normal vision. What is the probability that they would have a color-blind child? **(a)** 100 percent, **(b)** 50 percent, **(c)** 25 percent, **(d)** 12.5 percent, **(e)** 6.25 percent.
16. One of the events that prevents polyspermy is **(a)** the completion of meiosis II, **(b)** an increase in the ovum's metabolic rate, **(c)** the formation of the female pronucleus, **(d)** membrane depolarization, **(e)** amphimixis.
17. The mesoderm contributes to the formation of **(a)** the lining of the pleural, pericardial, and peritoneal cavities, **(b)** pituitary gland and adrenal medullae, **(c)** epidermis, hair follicles, and hairs, **(d)** thymus, thyroid gland, and pancreas, **(e)** all neural tissue.
18. Why is colostrum important for neonates? Which hormone is involved in milk ejection?
19. Name the primary placental hormones and their functions.
20. Discuss the changes that occur in maternal systems during pregnancy. Why are these changes functionally significant?
21. What is the danger associated with breech births?
22. What physiological adjustments must an infant make during the neonatal period to survive?
23. Distinguish between the following paired terms: **(a)** genotype and phenotype, **(b)** heterozygous and homozygous, **(c)** simple inheritance and polygenic inheritance.
24. Indicate the type of inheritance involved in each of the following situations. **(a)** Children who exhibit the trait have at least one biological parent who also exhibits it. **(b)** Children exhibit the trait even though neither biological parent does. **(c)** The trait is expressed more commonly in male offspring than in female offspring. **(d)** The trait is expressed equally in female offspring and male offspring.

LEVEL 3 Critical Thinking and Clinical Applications

25. Hemophilia A, a condition in which blood does not clot properly, is a recessive trait located on the X chromosome (X^h). Suppose that a female who is heterozygous for this trait (XX^h) has children with a normal male (XY). What is the probability that the couple will have female offspring with hemophilia? What is the probability that the couple will have male offspring with hemophilia?
26. Hiroki and Angela desperately want to have children, and although they have tried for 2 years, they have not been successful. Finally, each of them consults a physician, and it turns out that Hiroki has oligospermia (a low sperm count). He confides to you that he doesn't understand why this would interfere with his ability to have children since he remembers from biology class that it only takes one sperm to fertilize an egg. What should you tell him?
27. Alina has just given birth to a little girl. When the nurses take the infant back to the nursery, she becomes cyanotic, a condition characterized by bluish discoloration of the skin. The episode passes, but when the infant is bathed, she becomes cyanotic again. Blood gas levels indicate that arterial blood is only 60% saturated. Physical examination reveals no structural deformities involving the respiratory or digestive system. What might be causing the problem?
28. Jie is very happy to be pregnant, but she is experiencing heavy abdominal pain and there is also a small amount of vaginal bleeding. Blood tests and a pelvic ultrasound reveal an ectopic pregnancy. What could have led to this condition?

CLINICAL CASE Wrap-Up The Twins Who Looked Nothing Alike

The winners of the “least-alike” twins prize are named Daan and Hendrik. These charming young males traveled all the way from the Netherlands to win this award in Twinsburg.

Daan’s and Hendrik’s parents used the services of a prestigious fertility clinic in the Netherlands. Their mother’s ovaries were hormonally stimulated, and the secondary oocytes that were released were harvested laparoscopically (by abdominal surgery through small holes). These oocytes were then fertilized with sperm in the laboratory. On the sixth postfertilization day, coinciding with the time a normally fertilized blastocyst would be finishing its journey through the uterine tube into the uterus, two blastocysts were transferred to their mother’s uterus. Both had a successful implantation, placentation, embryogenesis, fetal development, and birth.

Why, then, do Daan and Hendrik look so different? As it turned out, the technician performing the *in vitro* fertilization mistakenly used a previously used pipette to transfer the sperm. The couple that visited the clinic just before Daan’s and Hendrik’s parents were very dark-skinned people, and the man’s sperm was still present in the pipette. As a result, one oocyte was fertilized by sperm from one male, and the other was fertilized by sperm from another male.

1. Why were the fertilized blastocysts implanted in Daan’s and Hendrik’s mother on her sixth day after ovulation?
2. Are Daan and Hendrik monozygotic twins or dizygotic twins?

See the blue Answers tab at the back of the book.

Related Clinical Terms

eclampsia: A condition in which one or more convulsions occur in a pregnant individual who has high blood pressure, often followed by coma and posing a threat to the health of pregnant individual and developing fetus.

gamete intrafallopian transfer (GIFT): An assisted reproductive procedure in which a female’s eggs are removed, mixed with sperm, and replaced into the female’s uterine tube where the fertilization takes place, rather than in the laboratory.

in vitro fertilization: Fertilization outside the body, generally in a petri dish.

infertility: The inability to achieve pregnancy after engaging in 1 year of appropriately timed sexual intercourse.

neural tube defects (NTDs): Major birth defects caused by an abnormal development of the neural tube—the structure present during the embryonic stage that later becomes the central nervous system. These are very common birth defects that cause infant mortality and disability and include anencephaly and spina bifida.

placenta abruptio: Condition in which there is separation of the placenta from the uterine site of implantation before delivery of the baby.

placenta previa: Condition during pregnancy in which the placenta is abnormally placed, causing the placenta to cover the cervix totally or partially.

pre-eclampsia: A condition in pregnancy characterized by sudden hypertension, albuminuria, and edema of the hands, feet, and face. It is the most common complication of pregnancy, affecting about 5% of pregnancies.

therapeutic cloning: A procedure that usually takes skin cells from a patient and inserts a skin cell nucleus into a fertilized egg whose nucleus has been removed to create a new cell. That new cell divides repeatedly to form a blastocyst from which stem cells can be extracted to grow new tissue that is genetically matched to the patient.

Appendices

Appendix A Normal Physiological Values

Tables 1 and 2 present normal averages or ranges for the chemical composition of body fluids. These values are approximations rather than absolute values because test results vary from laboratory to laboratory as a result of differences in procedures, equipment, normal solutions, or other factors. Blanks in the tabular data appear where data are not available. The following locations in the text contain additional information about body fluid analysis:

Table 19–2 presents data on the formed elements of the blood.

Table 26–2 compares the normal values for solutes in plasma and urine.

Table 26–5 gives the general characteristics of normal urine, and Table 26–6 shows the typical values of substances in a standard urinalysis.

Table 1 The Composition of Body Fluids

Test	Normal Averages or Ranges					
	Perilymph	Endolymph	Synovial Fluid	Sweat	Saliva	Semen
pH			7.4	4–6.8	6.4*	7.19
Specific gravity			1.008–1.015	1.001–1.008	1.007	1.028
Electrolytes (mEq/L)						
Potassium	5.5–6.3	140–160	4.0	4.3–14.2	21	31.3

Immunoglobulins	S: 1.0–2.2	1.1–1.7	3.1
Fibrinogen	P: 0.2–0.4	0.65	0

*S = serum, P = plasma, WB = whole blood.

[†]Because urinary output averages just over 1 liter per day, these electrolyte values are comparable to mEq/L.

[‡]Because urinary metabolite and protein data approximate mg/L or g/L, these data must be divided by 10 for comparison with CSF or blood concentrations.

[§]Venous blood sample.

Appendix B Gas Pressure Measurements

To understand the principles of blood flow, capillary exchange, respiratory gas exchange, and the mechanics of breathing, we must know the pressures of blood and gases in peripheral tis-

sues, in the bloodstream, and inside and outside the respiratory tract. Blood and gas pressures are measured and reported in several ways. Table 3 shows four common reporting methods.

Table 3 Four Common Methods of Reporting Gas Pressure

Measurement Units	Description
millimeters of mercury (mm Hg)	This is the most common method of reporting blood pressure and gas pressures. Normal atmospheric pressure is approximately 760 mm Hg.
torr	This unit of measurement is preferred by many respiratory therapists; it is also commonly used in Europe and in some technical journals. Note that 1 torr is equivalent to 1 mm Hg; in other words, normal atmospheric pressure is equal to 760 torr.
centimeters of water (cm H ₂ O)	In a hospital setting, anesthetic gas pressures and oxygen pressures are commonly measured in centimeters of water. Note that 1 cm H ₂ O is equivalent to 0.735 mm Hg; normal atmospheric pressure is 1033.6 cm H ₂ O.
pounds per square inch (psi)	Pressures in compressed gas cylinders and other industrial applications are generally reported in psi. Normal atmospheric pressure at sea level is approximately 15 psi.

Appendix C Turnover Times for Selected Cells

Most of the organic molecules in a cell are replaced at intervals ranging from hours to months. The average time between synthesis

and breakdown is known as the *turnover time*. This table lists the turnover times of the organic components of representative cells.

Table 4 Turnover Times of the Organic Components of Four Cell Types

Cell Type	Component	Average Recycling Time*
Liver	Total protein	5–6 days
	Enzymes	1 hour to several days, depending on the enzyme
	Glycogen	1–2 days
	Cholesterol	5–7 days
Muscle	Total protein	30 days
	Glycogen	12–24 hours
Nerve	Phospholipids	200 days
	Cholesterol	100+ days
Fat	Triglycerides	15–20 days

*Most values were obtained from studies on mammals other than humans.

Appendix D Codon Chart/Genetic Code

A codon is a sequence of three consecutive nucleotides in mRNA that codes for a particular amino acid or signals to stop protein synthesis. Because each mRNA codon consists of three nucleotides, the four nucleotides in mRNA (A, U, G, and C) can produce 64 different combinations. Of these, 61 codons correspond to amino acids and 3 act as stop signals

of protein synthesis. Only 20 different amino acids are used to synthesize proteins, so most amino acids are represented by more than one codon. One codon, AUG, has a dual role. AUG codes for the amino acid methionine and also acts as the start signal for protein synthesis. It is always the first codon in a strand of mRNA.

Table 5 The Genetic Code

Genetic Code (mRNA codons)					
First nucleotide	Second nucleotide				Third nucleotide
	U	C	A	G

Appendix E The Periodic Table

temperature and pressure, and none reacts readily with other elements. These elements, highlighted in blue, are known as the noble, or inert, gases. In contrast, the elements of the left-most column below hydrogen—lithium, sodium, potassium, rubidium, cesium, and francium—are silvery, soft metals that are so highly reactive that pure forms cannot be found in nature. The fourth and fifth electron levels can each hold up to 18 electrons. Table inserts are used for the so-called lanthanoids (atomic numbers 57–71) and actinoids (atomic numbers 89–103) to save space, as higher levels can store up to 32 electrons. Elements of particular importance to our discussion of human anatomy and physiology are highlighted in pink.

The periodic table presents the known elements in order of their atomic weights. Each horizontal row represents a single electron shell. The number of elements in that row is determined by the maximum number of electrons that can be stored at that energy level. The element at the left end of each row contains a single electron in its outermost electron shell; the element at the right end of the row has a filled outer electron shell. This organization highlights similarities that reflect the composition of the outer electron shell, or valence shell. These similarities are evident when you examine the vertical columns. All the elements of the right-most column—helium, neon, argon, krypton, xenon, and radon—have full electron shells; each is a gas at normal atmospheric

Answers to Checkpoints, Review Questions, Clinical Case Wrap-Ups, and Figure-Based Questions

Chapter 1

Answers to Checkpoints

PAGE 31 1. A learning outcome is an educational objective that uses key verbs to target specific skills, goals, aims, and achievements. In essence, learning outcomes describe what the reader should be able to do after completing a particular section. 2. To enhance learning, the text and the art should be read together. That is, after reading the text, the reader should look at and study the accompanying art. Research has shown that reading the text and viewing the art together enhances learning. **PAGE 33** 3. Anatomy is the study of internal and external body structures. 4. Physiology is the study of how living organisms perform functions. 5. Anatomy and physiology are closely related because all specific functions are performed by specific structures. 6. Gross anatomy (often referred to as macroscopic anatomy) involves studying body structures that can be seen with the unaided eye. Microscopic anatomy is the study of body structures using a microscope to magnify the objects. 7. Several specialties of physiology are cell physiology, organ physiology, systemic physiology, and pathological physiology. 8. It is difficult to separate anatomy from physiology because the structures of body parts are so closely related to their functions; put another way, function follows form. **PAGE 34** 9. The major levels of organization of the human body from the simplest to the most complex are as follows: chemical level → cellular level → tissue level → organ level → organ system level → organism level. 10. Major organ systems (and some structures of each) are the integumentary system (skin, hair, sweat glands, and nails), skeletal system (bones, cartilages, associated ligaments, and bone marrow), muscular system (skeletal muscles and associated tendons), nervous system (brain, spinal cord, peripheral nerves, and sense organs), endocrine system (pituitary gland, thyroid gland, pancreas, adrenal glands, gonads, and other endocrine tissues), cardiovascular system (heart, blood, and blood vessels), lymphatic system (spleen, thymus, lymphatic vessels, lymph nodes, and tonsils), respiratory system (nasal cavities, sinuses, larynx, trachea, bronchi, lungs, and alveoli), digestive system (teeth, tongue, pharynx, esophagus, stomach, small intestine, large intestine, liver, gallbladder, and pancreas), urinary system (kidneys, ureters, urinary bladder, and urethra), male reproductive system (testes, epididymides, ductus deferentia, seminal glands, prostate, penis, and scrotum), and female reproductive system (ovaries, uterine tubes, uterus, vagina, labia, clitoris, and mammary glands). 11. A histologist investigates structures and properties at the tissue level of organization. **PAGE 35** 12. Medical terminology is the use of word roots, prefixes, suffixes, and combining forms to construct anatomical, physiological, or medical terms. 13. An eponym is a commemorative name for a structure or clinical condition that was originally named for a real or mythical person. 14. The book used as the international standard for anatomical vocabulary is *Terminologia Anatomica*. **PAGE 41** 15. The purpose of anatomical terms is to provide a standardized frame of reference for describing the human body. 16. In the anatomical position, an anterior view is seen from the front and a posterior view is from the back.

PAGE 46 17. Body cavities protect internal organs and cushion them from thumps and bumps that occur while walking, running, or jumping. Body cavities also permit the organs that they surround to change in size and shape without disrupting the activities of nearby organs. 18. The thoracic cavity includes the pleural and pericardial cavities, which enclose the lungs and heart, respectively. The diaphragm forms the boundary between the superior thoracic cavity and the inferior abdominopelvic cavity. The abdominopelvic cavity contains the peritoneal cavity, which contains the superior abdominal cavity and the inferior pelvic cavity. **PAGE 47** 19. Homeostasis refers to the existence of a stable internal environment. 20. Extrinsic regulation is a type of homeostatic regulation resulting from activities of the nervous system or endocrine system. 21. Physiological systems can function normally only under carefully controlled conditions. Homeostatic regulation prevents potentially disruptive changes in the body's internal environment. **PAGE 52** 22. Negative feedback systems provide long-term control over the body's internal conditions—that is, they maintain homeostasis—by counteracting the effects of a stimulus or environmental change. 23. When homeostasis fails, organ systems function less efficiently or even malfunction. The result is the state that we call disease. If the situation is not corrected, death can result. 24. A positive feedback system amplifies or enhances the effects of a stimulus. 25. Positive feedback is useful in processes that must be completed quickly, such as blood clotting. In contrast, it is harmful in situations in which a stable condition must be maintained, because it tends to increase any departure from the desired condition. Positive feedback in the regulation of body temperature, for example, would cause a slight fever to spiral out of control, with fatal results. For this reason, physiological systems are typically regulated by negative feedback, which tends to oppose any departure from the norm. 26. Equilibrium is a dynamic (constantly changing) state in which two opposing forces or processes are in balance. 27. When the body continuously adapts by using homeostatic mechanisms, it is said to be in a state of dynamic equilibrium.

Answers to Review Questions

Level 2 Reviewing Concepts

25. (a) Anatomy is the study of internal and external body structures and their physical relationships among other body parts. (b) Physiology is the study of how living organisms perform their vital functions. 26. d 27. Autoregulation occurs when the activities of a cell, tissue, organ, or organ system change automatically

(that is, without neural or endocrine input) when faced with some environmental change. Extrinsic regulation results from the activities of the nervous or endocrine systems. It causes more extensive and potentially more effective adjustments in activities. **28.** The body is erect, and the hands are at the sides with the palms facing forward. **29.** c **30.** c

Level 3 Critical Thinking and Clinical Applications

31. Insulin is released when blood glucose levels are increased. This hormone should bring about a decrease in blood glucose levels, thus decreasing the stimulus for its own release. **32.** A lack of blood flow to the hypothalamus of the brain would cause brain cells there to die. Since this is where the body's thermoregulatory center lies, then control of body temperature would be affected.

Answers to Clinical Case Wrap-Up

PAGE 54 **1.** In addition to the liver and most of the large intestine, the abdominal cavity contains the stomach, spleen, and small intestine. **2.** A deep knife wound superior to the diaphragm would have entered the thoracic cavity, which contains the lungs and heart; associated organs of the respiratory, cardiovascular, and lymphatic systems; the inferior portions of the esophagus; and the thymus.

Chapter 2

Answers to Checkpoints

PAGE 60 **1.** An atom is the smallest stable unit of matter. **2.** Atoms of the same element that have the same atomic number but different numbers of neutrons are called isotopes. **3.** Hydrogen has three isotopes: hydrogen-1, with a mass number of 1; deuterium, with a mass number of 2; and tritium, with a mass number of 3. The heavier sample must contain a higher proportion of one or both of the heavier isotopes. **PAGE 65** **4.** A chemical bond is an attractive force acting between two atoms that may be strong enough to hold them together in a molecule or compound. The strongest attractive forces result from the gain, loss, or sharing of electrons. Examples of such chemical bonds are ionic bonds and covalent bonds. In contrast, the weaker hydrogen bonds occur between molecules or compounds. **5.** The atoms in a water molecule are held together by polar covalent bonds. Water molecules are attracted to one another by hydrogen bonds. **6.** Atoms combine with each other to gain a complete set of electrons in their outer energy level or valence shell. Oxygen atoms do not have a full outer energy level, so they readily react with many other elements to attain this stable arrangement. Neon already has a full outer energy level so it cannot combine with other elements. **PAGE 67** **7.** Using chemical notation, an ion is represented by a superscript plus or minus sign following the symbol of an element. If more than one electron has been lost or gained, the electric charge on the ion is represented by a number preceding the plus or minus sign. **8.** The molecular formula for glucose, a compound composed of 6 carbon atoms, 12 hydrogen atoms, and 6 oxygen atoms, is $C_6H_{12}O_6$. **9.** Three types of

chemical reactions important to the study of human physiology are decomposition reactions, synthesis reactions, and exchange reactions. In a decomposition reaction, a chemical reaction breaks a molecule into smaller fragments. A synthesis reaction assembles smaller molecules into larger ones. In an exchange reaction, parts of the reacting molecules are shuffled around to produce new products. **10.** This reaction involves a large molecule being broken down into two smaller ones, so it is a decomposition reaction. **PAGE 68** **11.** An enzyme is a protein that lowers the activation energy of a chemical reaction, which is the amount of energy required to start the reaction. **12.** Without enzymes, chemical reactions would proceed only under conditions that the cells could not tolerate (e.g., high temperatures). By lowering the activation energy, enzymes make it possible for chemical reactions to rapidly proceed under conditions compatible with life.

13. Organic compounds always contain carbon and hydrogen. Inorganic compounds do not contain carbon and hydrogen atoms as structural components. **PAGE 71** **14.** Specific chemical properties of water that make life possible include its strong polarity (enables it to be an excellent solvent), its reactivity (it participates in many chemical reactions), its high heat capacity (it absorbs and releases heat slowly), and its ability to serve as a lubricant.

PAGE 72 **15.** The pH is a measure of the concentration of hydrogen ions in fluids. Acid and base concentrations are measured in pH, which is the negative logarithm of hydrogen ion concentration, expressed in moles per liter. On the pH scale, 7 represents a neutral solution; values below 7 indicate acidic solutions, and values above 7 indicate basic (alkaline) solutions. **16.** If the body is to maintain homeostasis and thus health, the pH of different body fluids must remain within a narrow range. **17.** An acid is a compound whose dissociation in solution releases a hydrogen ion and an anion; a base is a compound whose dissociation releases a hydroxide ion (OH^-) or removes a hydrogen ion (H^+) from the solution; a salt is an inorganic compound consisting of a cation other than H^+ and an anion other than OH^- . **18.** Stomach discomfort is commonly the result of excessive stomach acidity ("acid indigestion"). Antacids contain a weak base that neutralizes the excess acid.

PAGE 73 **19.** The macromolecules important to life are carbohydrates, lipids, proteins, and nucleic acids. **20.** The functional group that acts as an acid is the carboxyl group $-COOH$. **PAGE 75** **21.** The monomer common to both plant starch and glycogen is glucose. **PAGE 79** **22.** Lipids are a diverse group of compounds that include fatty acids, eicosanoids, glycerides, steroids, phospholipids, and glycolipids. They are organic compounds that contain carbon, hydrogen, and oxygen in a ratio that does not approximate 1:2:1. **23.** Human plasma membranes contain mainly phospholipids, plus small amounts of cholesterol and glycolipids. **PAGE 85** **24.** Proteins are organic compounds formed from amino acids that contain a central carbon atom, a hydrogen atom, an amino group ($-NH_2$), a carboxyl group ($-COOH$), and an R group or variable side chain. Proteins function in support, movement, transport, buffering, metabolic regulation, coordination and control, and defense. **25.** The heat of boiling breaks bonds that maintain the protein's tertiary structure, quaternary structure, or both. The resulting structural change, known as denaturation, affects the ability of the protein molecule to perform its normal biological functions. **PAGE 87** **26.** A nucleic acid is a large organic molecule made of carbon, hydrogen, oxygen, nitrogen, and phosphorus. Nucleic acids regulate protein synthesis and make up the genetic material in cells. **27.** Both DNA (deoxyribonucleic acid) and RNA (ribonucleic acid) contain nitrogenous bases and

phosphate groups, but the nucleic acid described is RNA because it contains the sugar ribose. **PAGE 88** **28.** Adenosine triphosphate (ATP) is a high-energy compound consisting of adenosine to which three phosphate groups are attached. The second and third phosphate groups are each attached by a high-energy bond. **29.** Phosphorylation of an ADP molecule yields a molecule of ATP.

Answers to Review Questions

PAGE 91

Level 1 Reviewing Facts and Terms

1. (a)

(b) Two more electrons can fit into the outermost energy level of an oxygen atom. **2.** condensation **3.** d **4.** d **5.** a **6.** c **7.** a **8.** b **9.** b **10.** b **11.** c **12.** c **13.** e **14.** a **15.** a **16.** protons, neutrons, and electrons **17.** monosaccharides, disaccharides, and polysaccharides **18.** Triglycerides (1) provide a significant energy reserve, (2) serve as insulation and thus act in heat conservation, and (3) protect organs by cushioning them. **19.** (1) support (structural proteins); (2) movement (contractile proteins); (3) transport (transport proteins); (4) buffering; (5) metabolic regulation; (6) coordination and control (hormones and neurotransmitters); and (7) defense (antibodies) **20.** (a) DNA: deoxyribose, phosphate, and nitrogenous bases (A, T, C, G); (b) RNA: ribose, phosphate, and nitrogenous bases (A, U, C, G) **21.** storing: conversion of ADP to ATP; releasing: breakdown of ATP to ADP

Level 2 Reviewing Concepts

22. c **23.** c **24.** The radiation which strongly radioactive isotopes produce can alter the number of electrons in atoms. It can break apart molecules and destroy cells and tissues. **25.** A buffer is a compound that stabilizes the pH of a solution by removing or replacing hydrogen ions. Buffers and buffer systems help maintain the pH of body fluids within normal limits, which is important for biochemical reactions to take place. **26.** Potential energy is stored energy that has the potential to do work, whereas kinetic energy is the energy that can be transferred to another object and do work. **27.** d **28.** c **29.** The molecule is a nucleic acid. Carbohydrates and lipids do not contain nitrogen. Although both proteins and nucleic acids contain nitrogen, only nucleic acids normally contain phosphorus.

Level 3 Critical Thinking and Clinical Applications

30. (a) number of electrons = 12; (b) atomic number = 12; (c) atomic weight = 24; (d) 2 electrons in first energy level, 8 in second energy level, 2 in third energy level (valence shell) **31.** Decreasing the amount of enzyme at the second step would slow down the remaining steps of the pathway because less substrate would be available for the next two steps. The net result would be a decrease in the amount of product. **32.** The human body is perfectly capable of synthesizing the amount of cholesterol it needs. It is not necessary for vegetarians to obtain cholesterol from eating animal products containing the steroid.

Answers to Clinical Case Wrap-Up

PAGE 92 **1.** Baby Sean's stools contained undigested lipids and carbohydrates, which gave them a fatty or greasy appearance. **2.** Digestive enzymes aid in the decomposition reactions that break down lipids and carbohydrates in food, so they can be absorbed from the digestive tract. If these large molecules cannot be broken down, they cannot be used as energy sources or chemical building blocks.

Answers to Figure-Based Questions

FIGURE 2-3 The second energy level can hold 8 electrons when filled.

FIGURE 2-24 Adenine and guanine are purines, which means they are double-ringed molecules. Cytosine, thymine, and uracil are pyrimidines, which means they are single-ringed molecules.

FIGURE 2-26 AMP undergoes two phosphorylations, which adds two phosphate groups (for a total of three phosphates) to form ATP.

Chapter 3

Answers to Checkpoints

PAGE 99 **1.** The general functions of the plasma membrane include physical isolation, regulation of exchange with the environment, sensitivity to the environment, and structural support. **2.** The components of the plasma membrane that allow it to perform its characteristic functions are membrane lipids, membrane proteins, and membrane carbohydrates. **3.** The phospholipid bilayer of the plasma membrane forms a physical barrier between the cell's internal and external environments. **4.** Channel proteins are integral proteins that allow water, ions, and small water-soluble solutes to pass through the plasma membrane. **PAGE 110** **5.** Cytoplasm is the material between the plasma membrane and the nuclear membrane. Cytosol is the fluid portion of the cytoplasm; cytosol is also called intracellular fluid. It is a mixture of water and various dissolved and insoluble materials, in which the organelles and inclusions are suspended. **6.** Cytosol has a higher concentration of potassium ions and suspended proteins, and a lower concentration of sodium ions, than does extracellular fluid. Cytosol also includes small quantities of carbohydrates and large reserves of amino acids and lipids. **7.** The nonmembranous organelles and their functions include (1) centriole = essential for movement of chromosomes during cell division; organization of microtubules in cytoskeleton; (2) cilia = movement of materials over cell surface (motile cilia), environmental sensor (primary cilium); flagella = propel sperm;

(3) cytoskeleton = strength and support; movement of cellular structures and materials; cell movement; (4) microvilli = increase surface area to facilitate absorption of extracellular materials; (5) proteasomes = breakdown and recycling of intracellular proteins; (6) ribosomes = protein synthesis. **8.** The membranous organelles and their functions include (1) endoplasmic reticulum = synthesis of secretory products; intracellular storage and transport; (2) smooth ER = lipid and carbohydrate synthesis; (3) rough ER = modification and packaging of newly synthesized proteins; (4) Golgi apparatus = storage, modification, and packaging of secretory products and lysosomal enzymes; (5) lysosomes = intracellular removal of damaged organelles or pathogens; (6) peroxisomes = neutralization of toxic compounds; (7) mitochondria = production of 95% of the ATP required by the cell. **9.** The SER synthesizes lipids, such as steroids. Ovaries and testes produce large amounts of steroid hormones, which are lipids, and thus need large amounts of SER. **10.** Mitochondria produce energy, in the form of ATP molecules, for the cell. Many mitochondria in a cell indicates a high demand for energy. **PAGE 113** **11.** The nucleus is a cellular organelle that contains DNA, RNA, enzymes, and proteins. The nuclear envelope is a double membrane that surrounds the nucleus; the perinuclear space is the region between this double membrane. Nuclear pores enable chemical communication between the nucleus and the cytosol. **12.** A gene is a portion of a DNA strand that functions as a hereditary unit. Each gene is located at a particular site on a specific chromosome and codes for a specific protein. **PAGE 118** **13.** Gene activation is the process of uncoiling the segment of DNA containing the nucleotide sequence of that gene, and temporarily removing histones, so that the gene can affect the cell. **14.** Transcription is the synthesis of RNA from a DNA template. Translation uses the information from an mRNA strand to form a linear chain of amino acids, or protein. **15.** A cell that lacked the enzyme RNA polymerase would not be able to transcribe RNA from DNA. **PAGE 122** **16.** A selectively permeable membrane allows the passage of some substances and restricts the passage of others. It lies between two extremes: impermeable, which allows no substances to pass, and freely permeable, which permits the passage of any substance. **17.** Diffusion is the passive movement of a substance from an area of higher concentration to an area of lower concentration. Diffusion proceeds until the concentration gradient is eliminated (equilibrium is reached). **18.** Five factors that influence the diffusion of substances in the body are (1) distance, (2) ion or molecule size, (3) temperature, (4) concentration gradient, and (5) electrical forces. **19.** Diffusion is driven by a concentration gradient. The steeper the concentration gradient, the faster the rate of diffusion, and the less steep the concentration gradient, the slower the rate of diffusion. If the concentration of oxygen in the lungs were to decrease, the concentration gradient between oxygen in the lungs and oxygen in the blood would decrease (if the oxygen level of the blood remained constant). Thus, oxygen would diffuse more slowly into the blood. **20.** Osmosis is the diffusion of water across a selectively permeable membrane from one solution to another solution that contains a higher solute concentration. **21.** The 10% salt solution is hypertonic with respect to the cells lining the nasal cavity because it contains a higher salt (solute) concentration than do the cells. The hypertonic solution would draw water out of the cells, causing the cells to shrink and adding water to the mucus, thereby diluting it and relieving congestion. **PAGE 127** **22.** In carrier-mediated transport, integral proteins bind specific ions or organic substrates and carry them across the plasma membrane. All forms of

carrier-mediated transport are specific, have saturation limits, and are regulated (usually by hormones). **23.** An active transport process must be involved because it takes an expenditure of energy to move the hydrogen ions against their concentration gradient—that is, from a region where they are less concentrated (the cells lining the stomach) to a region where they are more concentrated (the interior of the stomach). **24.** Endocytosis is the movement of relatively large volumes of extracellular material into the cytoplasm by the formation of a membranous vesicle at the cell surface. Types of endocytosis are receptor-mediated endocytosis, the clathrin-coated vesicle-mediated movement into the cytoplasm of specific target molecules (ligands); pinocytosis, the vesicle-mediated movement into the cytoplasm of extracellular fluid and its contents; and phagocytosis, the vesicle-mediated movement into the cytoplasm of extracellular solids, especially bacteria and debris. **25.** Exocytosis is the ejection of cytoplasmic materials by the fusion of a membranous vesicle with the plasma membrane. **26.** The process by which certain white blood cells engulf bacteria is called phagocytosis. **PAGE 130** **27.** The membrane potential of a cell is the difference in electrical potential that results from the uneven distribution of positive and negative charges across the plasma membrane. It is expressed in millivolts (mV). **28.** If the plasma membrane of a cell were freely permeable to sodium ions, more of these positively charged ions would move into the cell, and the membrane potential would become less negative (move closer to zero). **PAGE 131** **29.** The biological term for cellular reproduction is cell division, and the term for cell death is apoptosis. **30.** Important enzymes for DNA replication include helicases, DNA polymerase, and ligases. **31.** Interphase is a stage in a cell's life when it performs all its normal functions and, if necessary, prepares for cell division. The stages of interphase are G_1 , S , G_2 , and G_0 . A cell in G_0 is not preparing for cell division. **32.** This cell is likely in the G_1 phase of its life cycle. **33.** Mitosis is the essential step in cell division in which a single cell nucleus divides to produce two identical daughter cell nuclei. The four stages of mitosis are prophase, metaphase, anaphase, and telophase. **34.** If spindle fibers failed to form during mitosis, the cell would not be able to separate the chromosomes into two sets. If cytokinesis occurred, the result would be one cell with two sets of chromosomes and one cell with none. **PAGE 135** **35.** A growth factor is a natural substance, such as a peptide or hormone, that can stimulate the division of specific cell types. Representative growth factors include M-phase promoting factor (maturation-promoting factor), growth hormone, prolactin, fibroblast growth factor (FGF), nerve growth factor (NGF), epidermal growth factor (EGF), erythropoietin, thymosins and related compounds, and chalone. **PAGE 137** **36.** An illness characterized by mutations that disrupt normal controls and produce potentially malignant cells is termed cancer. **37.** Metastasis is the spread of cancer cells to distant tissues and organs, leading to the establishment of secondary tumors. **38.** Cellular differentiation is the development of specific cellular characteristics and functions that are different from those of the original cell. It results from genes in the cell being switched off, restricting the cell's potential functions.

Answers to Review Questions

PAGE 140

Level 1 Reviewing Facts and Terms

1. a. isotonic b. hypotonic c. hypertonic 2. b 3. e 4. d
5. a 6. d 7. b 8. d 9. e 10. c 11. (1) Cells are the

building blocks of all plants and animals. (2) Cells are produced by the division of preexisting cells. (3) Cells are the smallest units that perform all vital physiological functions. (4) Each cell maintains homeostasis at the cellular level. **12.** Four key functions of the glycocalyx include (1) lubrication and protection, (2) anchoring and locomotion, (3) specificity in binding, and (4) recognition.

13. Membrane proteins function as receptors, channels, carriers, enzymes, anchors, and identifiers. **14.** The major transport mechanisms are (1) diffusion, (2) carrier-mediated transport, and (3) vesicular transport. **15.** Factors that affect diffusion rate are

(1) distance, (2) steepness of the concentration gradient, (3) molecule size, (4) temperature, and (5) electrical forces.

16. Major functions of the ER are (1) synthesis of proteins, carbohydrates, and lipids; (2) storage of absorbed or synthesized molecules; (3) transport of materials; and (4) detoxification of drugs or toxins.

Level 2 Reviewing Concepts

17. a **18. c** **19. c** **20. c** **21. c** **22. d** **23. d** **24.** Helicases; the leading strand template DNA polymerase; the lagging strand template comprising the DNA polymerase and ligase enzymes. **25.** Prophase: chromatin condenses and chromosomes become visible; centrioles migrate to opposite poles of the cell and spindle fibers develop; and the nuclear membrane disintegrates. Metaphase: chromatids attach to spindle fibers and line up along the metaphase plate. Anaphase: chromatids separate and migrate toward opposite poles of the cell. Telophase: the nuclear membrane forms; chromosomes disappear as they uncoil back to chromatin; and nucleoli appear. **26. (a)** Apoptosis is the genetically controlled death of cells. **(b)** It is induced by the activation of specific “suicide genes” in the nucleus.

Level 3 Critical Thinking and Clinical Applications

27. It is receptor-mediated endocytosis. Iron ions are too big to pass through pores in the cell membrane. They bind to membrane receptors and become enclosed in endosomes called clathrin-coated vesicles. The endosomes fuse with lysosomes and finally, the iron ions are released into the cytoplasm. **28.** Since solution A has a higher solute concentration, the fluid level in it will increase through osmosis. This can be prevented by applying hydrostatic pressure on solution A equal to the osmotic pressure of the solution.

29. b **30.** The isolation of the internal contents of membrane-bound organelles allows them to manufacture or store secretions, enzymes, or toxins that could adversely affect the cytoplasm in general. Another benefit is the increased efficiency of having specialized enzyme systems concentrated in one place. For example, the concentration of enzymes necessary for energy production in the mitochondrion increases the efficiency of cellular respiration.

Answers to Clinical Case Wrap-up

PAGE 141 **1.** *V. cholerae*, the causal organism of cholera, is acquired through the intake of food and water. The best way to prevent infection is to drink clean water (bottled, boiled, or treated water) and to avoid eating uncooked foods. This is what Sachin should do on future trips. **2.** In most cases, cholera can be treated effectively and successfully by utilizing two general strategies. The first is to replace the lost fluid through oral rehydration therapy or intravenous fluid replacement. The second is to treat the causal *V. cholerae* infection through the use of antibiotics.

Answers to Figure-Based Questions

FIGURE 3-3 The three components that make up the cytoskeleton in all body cells are microfilaments, intermediate filaments, and microtubules.

FIGURE 3-9 The two reactants needed for energy production are oxygen and short carbon chains (such as the pyruvate molecule shown). The products from this reaction are carbon dioxide (CO_2), water (H_2O), and ATP.

FIGURE 3-11 In a dividing cell, DNA is tightly coiled and organized as chromosomes. In a nondividing cell, DNA is loosely coiled and organized as chromatin.

FIGURE 3-15 Small water-soluble molecules and ions diffuse through membrane channels. Lipid-soluble molecules diffuse directly through the plasma membrane.

FIGURE 3-17 In part b, the intracellular fluid is hypertonic to the extracellular fluid. In part c, the intracellular fluid is hypotonic to the extracellular fluid.

FIGURE 3-18 The concentration gradient determines the direction in which glucose molecules will be transported. Facilitated diffusion is a passive process, so glucose molecules will travel from high to low concentration.

FIGURE 3-19 Breaking the high-energy bond of ATP provides the energy for the sodium–potassium exchange pump.

Chapter 4

Answers to Checkpoints

PAGE 143 **1.** Histology is the study of tissues. **2.** The four major types of tissues that form all body structures are epithelial, connective, muscle, and nervous tissue. **PAGE 148** **3.** Epithelial tissue provides physical protection, controls permeability, provides sensation, and produces specialized secretions. **4.** Epithelial tissue is characterized by polarity, cellularity, attachment, avascularity, and regeneration. **5.** An epithelium whose cells have microvilli is probably involved in absorption or secretion. The microvilli greatly increase the cellular surface area available for these processes.

6. Epithelial cell junctions include tight junctions, gap junctions, spot desmosomes, and hemidesmosomes. **7.** Gap junctions allow small molecules and ions to pass from cell to cell. When connecting epithelial cells, they help coordinate such functions as the beating of cilia. In cardiac and smooth muscle tissues, they are essential for coordinating muscle cell contractions. **PAGE 154** **8.** The three cell shapes that are characteristic of epithelial cells are squamous (thin and flat), cuboidal (box shaped), and columnar (tall and slender). **9.** When classifying epithelial tissue, one with a single layer of cells is called simple, whereas one with multiple layers of cells is called stratified. **10.** No, this is not a sample from the skin surface. A simple squamous epithelium does not provide enough protection against infection, abrasion, or dehydration. The skin surface has a stratified squamous epithelium. **11.** All these regions are subject to mechanical trauma and abrasion—by food (pharynx and esophagus), by feces (anus), and by intercourse or childbirth (vagina).

12. The two primary types of glandular epithelia are endocrine glands and exocrine glands. **13.** Sebaceous glands exhibit holocrine secretion. **14.** An endocrine gland releases its secretions directly into the interstitial fluid. **PAGE 156**

15. Functions of connective tissues include (1) establishing a structural framework for the body; (2) transporting fluids and dissolved materials; (3) protecting delicate organs; (4) supporting, surrounding, and interconnecting other types of tissue; (5) storing energy reserves; and (6) defending the body from invading microorganisms. **16.** The three categories of connective tissues are connective tissue proper, fluid connective tissues, and supporting connective tissues. **PAGE 163** **17.** Cells found in connective tissue proper

are adipocytes, fibroblasts, fibrocytes, lymphocytes, macrophages, mast cells, melanocytes, mesenchymal cells, and microphages.

18. The reduced collagen production resulting from a lack of vitamin C in the diet would cause connective tissue to be weak and prone to damage. **19.** Mast cells and basophils produce the histamine, which antihistamines block. **20.** The type of connective tissue that contains triglycerides is adipose (fat) tissue. **21.** The three layers of fascia are superficial fascia (areolar and adipose tissue), deep fascia (dense regular connective tissue), and subserous fascia (areolar tissue). **PAGE 164** **22.** Blood and lymph each have a fluid matrix and are fluid connective tissues. **23.** The recirculation of fluid in the body is a continuous process from the cardiovascular system, through the interstitial fluid, to the lymph, and then back to the cardiovascular system. **PAGE 168** **24.** The two types of supporting connective tissue are cartilage and bone.

25. Bone heals faster than cartilage because, unlike cartilage, bone has a direct blood supply, which is necessary for proper and rapid healing to occur. **26.** The type of cartilage damaged in a herniated intervertebral disc is fibrocartilage. **PAGE 170** **27.** The four types of tissue membranes found in the body are the cutaneous membrane, mucous membranes, serous membranes, and synovial membranes. **28.** The pleural, peritoneal, and pericardial cavities are all lined by serous membranes. **29.** Mucous membranes typically line body passageways that open to the exterior.

PAGE 172 **30.** The three types of muscle tissue in the body are skeletal muscle, cardiac muscle, and smooth muscle. **31.** Muscle tissue that lacks striations is smooth muscle. Both cardiac and skeletal muscles are striated. **32.** Skeletal muscle is repaired by the division of myosatellite cells, which are stem cells that persist in adult skeletal muscle tissue. **PAGE 173** **33.** The cells are most likely neurons. **PAGE 174** **34.** The two phases in the response to tissue injury are inflammation and regeneration. **35.** The four common signs of inflammation are redness, heat (warmth), swelling, and pain. **36.** With advancing age, the speed and effectiveness of tissue repair decrease, the rate of energy consumption in general decreases, hormonal activity is altered, and other factors contribute to changes in structure and chemical composition. **37.** Longer life is associated with a longer period of potential exposure to chemicals and other environmental factors.

Answers to Review Questions

PAGE 178

Level 1 Reviewing Facts and Terms

1. (a) simple squamous epithelium (b) simple cuboidal epithelium (c) simple columnar epithelium (d) stratified squamous epithelium (e) stratified cuboidal epithelium (f) stratified columnar epithelium **2.** d **3.** c **4.** c **5.** b **6.** a **7.** c **8.** a **9.** c **10.** a **11.** d **12.** a **13.** e **14.** e **15.** b **16.** b **17.** Epithelial tissue (1) provides physical protection, (2) controls permeability, (3) provides sensations, and (4) produces specialized secretions. **18.** Endocrine glands secrete hormones onto the surface of the gland or directly into the surrounding fluid; exocrine glands secrete through ducts. **19.** Exocrine glandular epithelial cells release their secretions by (1) merocrine secretion, (2) apocrine secretion, or (3) holocrine secretion. **20.** Connective tissues contain (1) specialized cells, (2) extracellular protein fibers, and (3) a fluid ground substance. **21.** The four membranes in the body are (1) mucous membranes, (2) serous membranes, (3) the cutaneous membrane (skin), and (4) synovial membranes. **22.** Nervous tissue contains

(1) neurons, which propagate electrical impulses in the form of reversible changes in the membrane potential, and (2) neuroglia, which include several kinds of supporting cells and play a role in providing nutrients to neurons.

Level 2 Reviewing Concepts

23. The secretions of the salivary glands are merocrine secretions. Milk production in the mammary glands involves a combination of merocrine and apocrine secretions. **24.** Tight junctions block the passage of water or solutes between cells. In the digestive system, these junctions keep enzymes, acids, and wastes from damaging delicate underlying tissues. **25.** Cardiac muscle cells are shorter and more branched than skeletal muscle cells and they have less nuclei, and in cardiac muscle tissue, unlike skeletal muscle tissue, the cells are connected by intercalated discs. **26.** In the superficial layers of the skin, epithelial cells are strongly connected to each other due to the abundance of desmosomes. Therefore, when sunburn damages the skin, cells are usually lost in sheets rather than as a powder of individual cells. **27.** b **28.** c **29.** Both the superficial and the deep fascia belong to the connective tissue framework of the body. The location is different: the superficial fascia (or hypodermis) lies between the skin and the underlying organs. The deep fascia is bound to capsules, tendons, and ligaments, forming a strong fibrous internal framework. The superficial fascia consists of areolar and adipose tissue (loose connective tissue) whereas the deep fascia consists of dense connective tissue.

Level 3 Critical Thinking and Clinical Applications

30. It is the group of her elderly patients that has more chance of being affected by osteoporosis. With age, circulating sex hormones diminish. Often elderly people also become more inactive. A combination of these factors with a low dietary calcium level has a negative effect on bone strength. **31.** Skeletal muscle tissue would be made up of densely packed fibers running in the same direction, but since muscle fibers are composed of cells, they would have many nuclei and mitochondria. Skeletal muscle tissue also has an obvious banding pattern, or striations, due to the arrangement of the actin and myosin filaments within the cell. The student is probably looking at a slide of tendon (dense connective tissue). The small nuclei would be those of fibroblasts. **32.** The Pap test involves exfoliative cytology. It is a procedure in which cells are scraped from the cervix, the portion of the uterus that projects into the vagina, and are screened for cancer.

Answers to Clinical Case Wrap-Up

PAGE 179 **1.** The collagen fibers within the matrix of connective tissue are defective in Ehlers-Danlos syndrome. **2.** Connective tissues throughout Anne Marie's body are affected by Ehlers-Danlos syndrome. This includes structures and organs composed of dense regular connective tissue (tendons, ligaments, aponeuroses), dense irregular connective tissue (skin, organ capsules of liver, kidneys, and spleen), and reticular tissue (spleen, liver, lymph nodes) as well.

Answers to Figure-Based Questions

FIGURE 4-3 Only gap junctions allow the diffusion of ions and molecules between cells. Tight junctions, hemidesmosomes, and spot desmosomes do not.

FIGURE 4-6 Columnar describes cell shape. Simple describes the number of cell layers; here, simple means one layer.

FIGURE 4-8 Holocrine secretion destroys superficial gland cells. (Merocrine secretion uses exocytosis to release product from vesicles, and apocrine secretion sheds the apical cytoplasm to produce secretions.)

FIGURE 4-11 Adipose tissue provides padding, cushions shock, reduces heat loss, and stores energy. It is most commonly found deep to the skin of the sides, buttocks, and breasts.

FIGURE 4-14 White blood cells contain a nucleus. Red blood cells and platelets do not.

FIGURE 4-16 Chondrocytes (cartilage cells) are the only type of cell found in cartilage matrix. Chondrocytes are found within small chambers in the matrix called lacunae.

FIGURE 4-18 The epithelium that lines the peritoneal cavity is called the mesothelium.

FIGURE 4-19 Skeletal muscle tissue consists of multinucleate cells.

Chapter 5

Answers to Checkpoints

PAGE 186 1. The layers of the epidermis are the stratum basale, stratum spinosum, stratum granulosum, stratum lucidum, and stratum corneum. 2. Dandruff consists of cells from the stratum corneum. 3. This splinter is lodged in the stratum granulosum. 4. Wrinkles in the tips of the fingers (and toes) are due to the constriction of blood vessels in the underlying skin, which causes the skin to shrink. This effect is controlled by the autonomic nervous system, a division of the nervous system that acts outside our awareness. 5. Sanding the tips of the fingers will not permanently remove fingerprints. The ridges of the fingerprints are formed in layers of the skin that are constantly regenerated, so these ridges will eventually reappear. The pattern of the ridges is determined by the arrangement of tissue in the dermis, which is not affected by sanding. 6. Salivary glands and duodenal glands (glands of the duodenum) produce epidermal growth factor (EGF). 7. Epidermal growth factor (EGF) promotes the divisions of basal cells in the stratum basale and stratum spinosum, accelerates the production of keratin in differentiating keratinocytes, stimulates epidermal development and epidermal repair after injury, and stimulates synthetic activity and secretion by epithelial glands. **PAGE 188** 8. The dermis (a connective tissue layer) is located between the epidermis and the subcutaneous layer (hypodermis). 9. The capillaries and sensory nerve fibers that supply the epidermis are located in the papillary layer of the dermis. 10. The presence of elastic fibers and the flexibility and resilience of skin turgor allow the dermis to undergo repeated cycles of stretching and recoiling (returning to its original shape). **PAGE 189** 11. The tissue that connects the dermis to underlying tissues is the subcutaneous layer or hypodermis. 12. The subcutaneous layer is a layer of loose connective tissue (areolar tissue) and adipose tissue below (deep to) the dermis. The subcutaneous layer is not considered a part of the integument, but it is important in stabilizing the position of the skin in relation to underlying tissues. 13. Subcutaneous fat provides insulation to help reduce heat loss, serves as an energy reserve, and acts as a shock absorber for the body. **PAGE 191** 14. The two major pigments in the epidermis are melanin, which ranges in color from red-yellow (pheomelanin) to brown-black (eumelanin), and carotene, an orange-yellow pigment. 15. When exposed to the ultraviolet (UV) radiation in sunlight, melanocytes in the epidermis and dermis synthesize the pigment melanin, darkening the skin. 16. The skin, mucous

membranes, lips, nail beds, and whites of the eyes appear bluish, a condition known as cyanosis, in individuals who have decreased blood oxygen levels. **PAGE 193** 17. In the presence of ultraviolet radiation in sunlight, epidermal cells in the stratum spinosum and stratum basale convert a cholesterol-related steroid compound into cholecalciferol, or vitamin D₃. 18. Cholecalciferol (vitamin D₃) is needed to form strong bones and teeth. When the body surface is covered, UV light cannot penetrate to the stratum basale in the skin to begin vitamin D₃ production, resulting in fragile bones. **PAGE 196** 19. A typical hair is a keratinous strand produced by epithelial cells of the hair follicle. 20. The contraction of the arrector pili muscle pulls the hair follicle erect. The result is known as “goose bumps.” 21. Even though hair is a derivative of the epidermis, the hair follicles are in the dermis. Where the epidermis and deep dermis are destroyed, new hair will not grow. **PAGE 199** 22. Two types of exocrine glands found in the skin are sebaceous (oil) glands and sweat glands. 23. The functions of sebaceous secretions (called sebum) are to lubricate and protect the keratin of the hair shaft, lubricate and condition the surrounding skin, and inhibit the growth of bacteria. 24. Deodorants are used to mask the odor of apocrine sweat gland secretions, which contain several kinds of organic compounds. Some of these compounds have an odor, and others produce an odor when metabolized by skin bacteria.

25. Apocrine sweat glands enlarge and increase secretory activity in response to the increase in sex hormones that occurs at puberty. 26. Keratin is the substance that makes fingernails hard. 27. The area of thickened stratum corneum under the free edge of a nail is called the hyponychium. 28. Nail growth takes place at the nail root, an epidermal fold that is not visible from the surface. **PAGE 201** 29. The combination of fibrin clots, fibroblasts, and the extensive network of capillaries in tissue that is healing is called granulation tissue. 30. Skin can regenerate effectively even after considerable damage because stem cells persist in both the epithelial and connective tissue components of skin. When injury occurs, cells of the stratum basale replace epithelial cells, and mesenchymal cells replace cells lost from the dermis. **PAGE 203** 31. As a person ages, the blood supply to the dermis decreases and eccrine sweat glands become less active. These changes make it more difficult for older individuals to cool themselves in hot weather. 32. With advancing age, melanocyte activity decreases, leading to gray or white hair.

Answers to Review Questions

PAGE 206

Level 1 Reviewing Facts and Terms

1. (a) epidermis (b) dermis (c) papillary layer (d) reticular layer (e) subcutaneous layer (hypodermis) 2. a 3. c 4. b 5. d 6. d 7. b 8. b 9. d 10. a 11. c 12. a 13. c 14. c 15. Epidermal cell division occurs in the stratum basale. 16. The tactile corpuscles or Meissner corpuscles in the dermal papillae are sensitive to a light touch. 17. Epidermal growth factor promotes the divisions of basal cells in the stratum basale and stratum spinosum, accelerates the production of keratin in differentiating epidermal cells, stimulates both epidermal development and epidermal repair after injury, and stimulates secretory product synthesis and secretion by epithelial glands. 18. The dermis is made up of (1) the papillary layer, which consists of areolar connective tissue and contains capillaries and sensory nerve fibers and receptors, and (2) the reticular layer, which consists of dense irregular connective tissue and bundles of collagen fibers. Both layers contain networks of blood vessels, lymphatic vessels, and nerve fibers.

19. (1) Fluid and electrolyte balance is lost because the skin is no longer an effective barrier, (2) thermoregulation requires more energy due to increased evaporation, and (3) protection from infection is disturbed, potentially resulting in sepsis and death.

Level 2 Reviewing Concepts

20. Thin skin contains four layers of keratinocytes, whereas thick skin contains five layers. **21.** The integument is the first barrier to substances entering the body. This method of delivering drugs requires the substance to move across the epidermal plasma membranes. The lipid bilayer of the plasma membranes creates a barrier that prevents water from rapidly entering or leaving the cells. Fat-soluble (lipophilic) substances, such as oil containing a dissolved drug, can easily pass through this barrier to underlying connective tissue and enter the circulation. Water-soluble drugs are lipophobic and thus do not readily penetrate the integument. **22.** In a first-degree burn, only the surface of the epidermis is damaged. The skin reddens and can be painful. In a second-degree burn, the entire epidermis and some of the dermis are damaged. Hair follicles and glands are usually not affected, but blistering, pain, and swelling occur. Third-degree burns destroy the epidermis and dermis, extending into the subcutaneous layer. Despite swelling, these burns are less painful than second-degree burns, because sensory nerves are destroyed. **23.** Incisions along tension lines—which represent the orientation of dermal collagen and elastin fibers—are more likely to remain closed, and thus heal more quickly, than incisions that cut across tension lines. **24. c** **25. c** **26. d**

Level 3 Critical Thinking and Clinical Applications

27. a **28.** Lisa has vitiligo. The white patches on her skin are the result of the loss of melanocytes in those areas. This condition develops when the body's immune defenses malfunction and antibodies attack normal melanocytes. **29. (a)** Ultraviolet radiation in sunlight converts a cholesterol-related steroid compound into vitamin D₃, or cholecalciferol. This compound is then converted to the hormone calcitriol, which is essential for absorbing the calcium and phosphate ions by the small intestine that is necessary for normal bone maintenance and growth. **(b)** The child can drink more milk. Milk is routinely fortified with cholecalciferol, normally identified as "vitamin D," which is easily absorbed by the intestines. **30.** Sweating from eccrine sweat glands is precisely regulated, and one influencing factor is emotional state. Presumably, a person who is lying is nervous and sweats profusely; the lie detector machine detects a change in electrical skin conductance caused by this sweating. **31.** The patient contracted a third-degree or full-thickness burn. Despite extensive damage, this type of burn is less painful than lighter burn types because of the destruction of the sensory nerves in the burn area. A burn like this will not heal by itself but requires skin grafting. This patient will probably need a full-thickness graft, involving epidermis and both layers of the dermis.

Answers to Clinical Case Wrap-Up

PAGE 207 **1.** Ichthyosis affects keratinization, also called cornification. This disorder causes abnormal function of keratinocytes, the most numerous cells of the epidermis. Dysfunction begins in the stratum granulosum and continues through the stratum corneum. Keratinocytes in the granulosum layer make defective keratohyalin, which does a poor job of linking keratin fibers into the waterproof

web desired for protection of the skin. As dying keratinocytes are pushed up, they bring this fragmented web to the surface, where it dries, peels, and scales. **2.** Sweat glands are connected to the epidermal surface through ducts. In ichthyosis, the thick scales block the sweat pores. Grandpa can't easily secrete sweat onto his body surface to cool his body temperature through evaporation. The thermoregulatory function of his integument is impaired, so he must guard against overheating.

Answers to Figure-Based Questions

FIGURE 5-1 Sebaceous glands and sweat glands are found in the skin.

FIGURE 5-6 The subpapillary plexus supplies blood to the capillary loops that follow the epidermis–dermis boundary.

FIGURE 5-8 Melanocytes are found in the stratum basale.

FIGURE 5-10 Sunlight and food are the body's sources of vitamin D₃.

FIGURE 5-13 A sebaceous gland discharges its secretion into a hair follicle. A sebaceous follicle discharges its secretion directly onto the epidermis.

Chapter 6

Answers to Checkpoints

PAGE 210 **1.** Major functions of the skeletal system are support, storage of minerals and lipids, blood cell production, protection, and leverage. **PAGE 211** **2.** The different broad categories for classifying bones according to shape are sutural bones, irregular bones, short bones, flat bones, long bones, and sesamoid bones. **3.** Bone markings (surface features) are characteristics of a bone's surface that have specific functions, such as joint formation, muscle attachment, or the passage of nerves and blood vessels. **PAGE 215** **4.** Mature bone cells are known as osteocytes, bone-building cells are called osteoblasts, and osteoclasts are bone-resorbing cells. **5.** If the ratio of collagen to hydroxyapatite in a bone increased, the bone would become less strong (as well as more flexible). **6.** Because osteoclasts break down or demineralize bone, the bone would have a decreased mineral content (less mass); as a result, it would also be weaker. **PAGE 218** **7.** Compact bone consists of osteons (Haversian systems) with little space between them. Compact bone lies over spongy bone and makes up most of the diaphysis. It functions to protect, support, and resist stress. Spongy bone consists of trabeculae with numerous red marrow-filled spaces. Spongy bone makes up most of the structure of short, flat, and irregular bones and is also found at the epiphyses of long bones. Spongy bone functions in storing marrow and providing some support. **8.** The presence of lamellae that are not arranged in osteons is indicative of spongy bone, which is located in an epiphysis. **PAGE 222** **9.** In endochondral ossification, cells of the inner layer of the perichondrium differentiate into osteoblasts, and a cartilage model is gradually replaced by bone. **10.** During intramembranous ossification, fibrous connective tissue is replaced by bone. **11.** Long bones of the body, such as the femur, have an epiphyseal cartilage, a plate of cartilage that separates the epiphysis from the diaphysis so long as the bone is still growing lengthwise. An x-ray would indicate whether the epiphyseal cartilage is still present. If it is, growth is still occurring. If it is not, the bone has reached its adult length and, thus, the person has reached full height. **PAGE 224** **12.** Bone remodeling refers to the process whereby old bone is continuously being destroyed by osteoclasts while new bone is being constructed by osteoblasts.

13. The biochemistry of some heavy-metal ions, such as strontium, cobalt, uranium, and plutonium, is very similar to that of calcium. Osteoblasts cannot differentiate these heavy-metal ions from normal calcium ions, so the heavy-metal ions become incorporated into the bone matrix. Over time, these dangerous ions can be released into the bloodstream during normal bone remodeling. **PAGE 226** **14.** The larger arm muscles of the weightlifter would apply more mechanical stress to the bones of the upper limbs. In response to that stress, the bones would grow thicker. **15.** Growth continues throughout childhood. At puberty, a growth spurt takes place and is followed by the closure of the epiphyseal cartilages. The later puberty begins, the taller the child will be when the growth spurt begins, so the taller the person will be when growth is completed. **16.** Increased levels of growth hormone prior to puberty will result in excessive bone growth, making the child taller. **PAGE 228** **17.** Parathyroid hormone (PTH) indirectly stimulates osteoclasts to release calcium ions from bone and enhances calcitriol's effect on the intestinal absorption of calcium. Increased PTH secretion would result in an increase in the level of calcium ions in the blood. **18.** The bones of children who have rickets are poorly mineralized and as a result are quite flexible. Under the weight of the body, the leg bones bend. The instability makes walking difficult and can lead to other problems of the legs and feet. **PAGE 229** **19.** Immediately following a fracture, extensive bleeding occurs at the injury site. After several hours, a large blood clot called a fracture hematoma develops. Next, an internal callus forms as a network of spongy bone unites the inner edges, and an external callus of cartilage and bone stabilizes the outer edges. The cartilaginous external callus is eventually replaced by bone, and the struts of new spongy bone now unite the broken ends. With time, the swelling that initially marks the location of the fracture is remodeled, new compact bone is formed, and there is little evidence that a break occurred. **20.** An external callus forms early in the healing process when cells from the endosteum and periosteum migrate to the area of the fracture. These cells form an enlarged collar (external callus) that encircles the bone in the area of the fracture. **PAGE 232** **21.** Osteopenia is inadequate ossification and is common during the aging process. It results from decreasing osteoblast activity accompanied by normal osteoclast activity. **22.** In females, the sex hormone known as estrogen plays an important role in moving calcium into bones. After menopause, the level of estrogen decreases dramatically. As a result, older females have difficulty replacing the calcium in bones that is being lost due to normal aging. In males, the level of testosterone does not decrease until much later in life.

Answers to Review Questions

PAGE 234

Level 1 Reviewing Facts and Terms

1. a **2.** b **3.** b **4.** a **5.** d **6.** a **7.** (a) long bone (b) flat bone (c) sutural bone (d) irregular bone (e) short bones (f) sesamoid bone **8.** d **9.** c **10.** b **11.** (1) support, (2) storage of minerals and lipids, (3) blood cell production, (4) protection, and (5) leverage **12.** Diploë is the layer of spongy bone between the layers of compact bone in the cranium. **13.** A sinus is a chamber within a bone and is normally filled with air. **14.** The periosteum has a fibrous and a cellular layer. It contains collagen fibers. The endosteum is an incomplete cellular layer containing osteoblasts, osteogenic cells, and osteoclasts. **15.** calcium, phosphate, carbonate, magnesium **16.** (a) calcium salts, phosphate salts, and vitamins A, C, and D₃ (b) calcitriol,

growth hormone, thyroxine, estrogen (in females) or testosterone (in males), parathyroid hormone, and calcitonin **17.** The three organs or tissues are the bones, the intestines of the digestive tract, and the kidneys. **18.** Bone injuries are usually very painful because bones are richly innervated by sensory nerves that enter the compact bone through small perforating canals and innervate the endosteum, medullary cavity, and epiphyses.

Level 2 Reviewing Concepts

19. Blood is carried to and from an osteon by a capillary and a venule that run in the osteon's central canal. **20.** Dermal bones are formed in the deeper layers of the dermis through intramembranous ossification. The final result is that a diploë is formed, consisting of a central layer of spongy bone covered on both sides by compact bone. **21.** Some forms of cancer lead to the development of osteoporosis as a secondary effect due to the release of the osteoclast-activating factor. This chemical induces both an increase in the number and the activity of osteoclasts, leading to bone osteolysis. **22.** In pregnant women, the increase in calcitonin secretion is suspected to be responsible for transferring maternal calcium to the fetus and also for preserving and recovering bone mineral density in the mother. **23.** There are many long bones in the hand, each of which has an epiphyseal cartilage (plate). Measuring the width of these plates will provide clues to the hormonal control of growth in the child. **24.** In a greenstick fracture, only one side of the shaft of a long bone is broken, while the other side is bent. Such fractures occur commonly in children because their long bones have not yet fully ossified. **25.** b **26.** Bone markings give clues as to the size, age, sex, and general appearance of an individual.

Level 3 Critical Thinking and Clinical Applications

27. The fracture might have damaged the epiphyseal cartilage in Reba's right leg. Even though the bone healed properly, the damaged leg did not produce as much cartilage as did the undamaged leg. The result would be a shorter bone on the side of the injury. **28.** a **29.** a **30.** Astronauts live in an environment without gravity. In that weightless environment, their bones are not subjected to ordinary stresses and might become thin and brittle fast. The loss of calcium salts associated with bone density loss is a serious health hazard. A disturbance of the calcium ion balance can damage vital physiological processes. When normal weight loading is resumed, bones can be rebuilt, but it takes longer to rebuild than to lose bone density.

Answers to Clinical Case Wrap-Up

PAGE 235 **1.** The compact bone in Alex's tibia is composed of osteons that have plenty of calcified matrix (for hardness) but few "supporting beams" of collagen. The spongy bone of his epiphyses is likewise missing collagen reinforcement in the trabeculae. Therefore, the bony architecture of Alex's tibia is intrinsically weak. The bone won't be able to bend with forces placed on it during daily activities, especially in sports, and will be prone to snap. **2.** Alex should not continue playing soccer, and he should avoid contact sports. As this incident shows, Alex is at much higher risk for fractures than any other soccer player on the field. He should be encouraged to pursue swimming, music, writing, art, or other stimulating, yet less physical, activities.

Answers to Figure-Based Questions

FIGURE 6-3 In long bones, spongy bone is found in the epiphyses. In flat bones, spongy bone is found between two layers of compact bone.

FIGURE 6-5 An osteogenic cell divides to produce osteoblasts. Osteoblasts become osteocytes when they are surrounded by bone matrix.

FIGURE 6-7 Lamellae are organized concentrically around an osteon, interstitially between osteons, and circumferentially around the entire bone.

FIGURE 6-10 The periosteum covers the superficial layer of compact bone and is made up of the fibrous and cellular layers.

FIGURE 6-16a The parathyroid gland secretes parathyroid hormone when the blood calcium level is too low.

Chapter 7

Answers to Checkpoints

PAGE 237 1. The axial skeleton includes the skull (8 cranial bones and 14 facial bones), the bones associated with the skull (6 auditory ossicles and the hyoid bone), the thoracic cage (the sternum and 24 ribs), and the vertebral column (24 vertebrae, the sacrum, and the coccyx). 2. The axial skeleton serves as a framework that supports and protects organs, provides an extensive surface area for muscle attachment, and stabilizes and positions parts of the appendicular skeleton that support the limbs. **PAGE 253** 3. The foramen magnum is located in the base of the occipital bone. 4. Tomás has fractured his right parietal bone. 5. The sphenoid contains the sella turcica, which in turn contains the pituitary gland. 6. The 14 facial bones are the 2 inferior nasal conchae, 2 lacrimal bones, 1 mandible, 2 maxillae (maxillary bones), 2 nasal bones, 2 palatine bones, 1 vomer, and 2 zygomatic bones. 7. The mental foramen is found in the mandible. Structures passing through this opening include the mental nerve, which carries sensory information to the brain, and mental vessels, which supply the chin and lips. 8. The optic canal is found in the sphenoid. The optic nerve and ophthalmic artery pass through this structure. 9. The foramina in the ethmoid are the olfactory foramina. **PAGE 254** 10. The bones forming the orbital complex are the frontal, sphenoid, zygomatic, palatine, maxilla, lacrimal, and ethmoid. 11. The bones forming the nasal complex are the frontal, ethmoid, nasal, maxilla, palatine, and sphenoid. 12. The sphenoid, ethmoid, frontal, and paired palatine and maxillary bones contain the paranasal sinuses. **PAGE 255** 13. A fontanelle is a relatively soft, flexible, fibrous region between two flat bones in the developing skull. The major fontanelles are the anterior fontanelle, posterior fontanelle, sphenoidal fontanelles, and mastoid fontanelles. 14. Because they are not ossified at birth, fontanelles permit the skull to change shape during childbirth, and they allow for enlargement of the brain during infancy and early childhood. **PAGE 257** 15. The secondary curves of the spine allow us to balance our body weight on our lower limbs with minimal muscular effort. Without the secondary curves, we would not be able to stand upright for extended periods. 16. The adult vertebral column consists of 26 bones: the vertebrae (24), the sacrum (1), and the coccyx. **PAGE 265** 17. The adult vertebral column has fewer vertebrae than a newborn because, in an adult, the five sacral vertebrae fuse to form a single sacrum, and the four coccygeal vertebrae fuse to form a single coccyx. 18. The axis is fractured. The dens is a tooth-like process projecting upward from the body of the axis, or second cervical vertebra, which is located in the neck (cervical region). 19. The presence of transverse foramina indicates that this vertebra is from the cervical region of the vertebral column. These foramina are passageways for important blood vessels that supply the brain. 20. The bodies of the lumbar vertebrae

are larger because they must support a great deal more weight than do vertebrae that are more superior in the spinal column. The larger vertebral bodies allow the weight to be distributed over a larger area. **PAGE 267** 21. False ribs (ribs 8–12) are the five lower ribs on either side that do not articulate with the sternum directly. 22. Improper compression of the chest during CPR can—and commonly does—result in a fracture of the xiphoid process of the sternum or the ribs. 23. True ribs (ribs 1–7) attach directly to the sternum by separate costal cartilages; floating ribs (ribs 11 and 12) are the two lower ribs on either side that are not attached anteriorly to the sternum.

Answers to Review Questions

PAGE 269

Level 1 Reviewing Facts and Terms

1. (a) occipital bone (b) parietal bone (c) frontal bone (d) temporal bone (e) sphenoid (f) ethmoid (g) vomer (h) mandible (i) lacrimal bone (j) nasal bone (k) zygomatic bone (l) maxilla 2. a 3. b 4. c 5. b 6. a 7. (a) cervical (b) thoracic (c) lumbar 8. a 9. b 10. d 11. (1) parietals, (2) temporals, (3) zygomatics, (4) lacrimals, (5) nasals, (6) maxillae, (7) palatines, (8) inferior nasal conchae 12. (1) sphenoid; (2) frontal bone; (3) ethmoid; (4) lacrimal bone; (5) maxilla; (6) palatine bone; (7) zygomatic bone 13. The hard palate is made up of the paired maxillary palatine processes connected to the horizontal parts of the paired palatine bones. 14. The fibrocartilage discs between adjacent vertebrae make the vertebral column more flexible.

Level 2 Reviewing Concepts

15. Together the lacrimal bones and the maxillae form the nasolacrimal canals. These canals open into the lower part of the nasal cavity. They provide protection for the lacrimal sacs and the lacrimal ducts, which carry tears from the orbits to the nasal cavity. 16. The two superior nasal conchae and the two middle nasal conchae are projections that are part of the ethmoidal labyrinth. The two inferior nasal conchae articulate with the maxillae. 17. The ribs raise and lower to increase and decrease the volume of the thoracic cage. When they rise, the thoracic cage expands and we breathe in. When the ribs are lowered to their original position, the volume of the thoracic cage decreases and we breathe out. 18. Keeping the back straight keeps the weight aligned along the axis of the vertebral column, where it can be transferred to the lower limbs. Bending the back would strain the muscles and ligaments of the back, increasing the risk of injury. 19. c 20. The paranasal sinuses lighten the skull bones. They are coated by an extensive amount of mucous epithelium through which mucus is released into the nasal cavities. 21. a 22. b 23. d

Level 3 Critical Thinking and Clinical Applications

24. d 25. The large bones of a child's cranium are not yet fused; they are connected by fontanelles, areas of fibrous tissue. By examining the bones, the archaeologist could readily see if sutures had formed. By knowing approximately how long it takes for the various fontanelles to close and by determining their sizes, she could estimate the age of the person at death. 26. Craniostenosis is the premature closure of cranial fontanelles. In trying to respond to the growth of the brain, the rest of the skull changes shape. This can lead to either a long and narrow or a very broad skull, depending on which suture closes early. When all cranial sutures close early, the brain cannot develop. Surgery is then inevitable to prevent brain damage.

Answers to Clinical Case Wrap-Up

PAGE 270 1. The seven bones that make up the orbital complex are the frontal bone (forming the roof), the zygomatic bone (forming the lateral wall), the maxilla (forming most of the floor), the lacrimal bone, the ethmoidal labyrinth, the sphenoid, and the palatine bone (forming the thin medial wall and floor). 2. The four paranasal sinuses surrounding the orbital complex are the frontal, maxillary, and sphenoidal sinuses and ethmoidal cells.

Answers to Figure-Based Questions

FIGURE 7-3 The skull contains four major sutures: the sagittal suture, the lambdoid suture, the squamous suture, and the coronal suture.

FIGURE 7-16 The infant skull has six fontanelles: sphenoidal (paired), mastoid (paired), anterior, and posterior. As the skull develops, bones ossify and fuse. In an adult skull, all of the bones are complete and fused, so there aren't any fontanelles on the adult skull.

FIGURE 7-17 The thoracic and the sacral regions of the spine form primary curves.

FIGURE 7-23 The last two pairs of ribs (11 and 12) are the floating ribs and do not attach to the sternum. The other false ribs are indirectly attached to the sternum by costal cartilage.

Chapter 8

Answers to Checkpoints

PAGE 275 1. Each of the two pectoral girdles consists of a clavicle (collarbone) and a scapula (shoulder blade). Each arm articulates with the trunk at the pectoral girdle. 2. The clavicle attaches the scapula to the sternum and restricts the scapula's range of motion (mobility). When the clavicle is broken, the scapula has a greater than normal range of motion and is less stable. 3. The head of the humerus articulates with the scapula at the glenoid cavity. **PAGE 280** 4. The bones of an upper limb are the humerus, ulna, radius, carpal (wrist) bones (scaphoid, lunate, triquetrum, pisiform, trapezium, trapezoid, capitate, and hamate), 5 metacarpals (palm bones), and 14 phalanges (fingers). 5. The two rounded projections on either side of the elbow are the lateral and medial epicondyles of the humerus. 6. The radius is lateral to the ulna while in the anatomical position, or the ulna is medial to the radius while in the anatomical position. 7. The first distal phalanx is located at the tip of the pollex (thumb), so Ricardo's thumb is broken. **PAGE 282** 8. The pelvic girdle is composed of the paired hip bones, also known as the coxal bones or pelvic bones. 9. The three bones that make up a hip bone are the ilium, ischium, and pubis. 10. When seated, the body weight is supported by the ischial tuberosities. **PAGE 288** 11. The bones of the lower limb are the femur (thigh), patella (kneecap), tibia and fibula (leg), tarsal (ankle) bones (talus, calcaneus, cuboid, navicular, medial cuneiform, intermediate cuneiform, and lateral cuneiform), 5 metatarsals, and 14 phalanges. 12. The fibula is not part of the knee joint and does not bear weight, but it is an important point of attachment for many leg muscles. When the fibula is fractured, these muscles cannot function properly to move the leg, so walking is difficult and painful. The fibula also helps stabilize the ankle joint. 13. Joey has most likely fractured the calcaneus (heel bone). 14. The talus transfers the weight of the body from the tibia toward the toes. 15. In general, the bones of males tend to be heavier than those of females, and bone markings are more prominent in males than in females. 16. Bones can reveal information about a person's sex, age, muscular development, nutritional state, handedness, and occupation, plus other information

relative to the medical history. 17. The female pelvis is adapted for supporting the weight of the developing fetus and enabling its passage through the pelvic outlet during delivery. Compared to males, such adaptations of the female pelvis include an enlarged pelvic outlet, a sacrum and coccyx with less curvature, a pelvic inlet that is wider and more circular, a relatively broad shape, ilia that project farther laterally, and an inferior angle between the pubic bones that is greater than 100 degrees (as opposed to 90 degrees or less for males).

Answers to Review Questions

PAGE 291

Level 1 Reviewing Facts and Terms

1. (a) anterior view (b) lateral view (c) posterior view (d) acromion (e) coracoid process (f) spine (g) glenoid cavity 2. e 3. (a) sacrum (b) coccyx (c) ilium (d) pubis (e) ischium (f) hip bone 4. b 5. c 6. d 7. b 8. radial groove 9. pubic bones and a pad of fibrocartilage 10. (1) scaphoid; (2) lunate; (3) triquetrum; (4) pisiform; (5) trapezium; (6) trapezoid; (7) capitate; (8) hamate

Level 2 Reviewing Concepts

11. a 12. c 13. e 14. b 15. d 16. e 17. b 18. The true pelvis is the space enclosed by the bones of the pelvic girdle beneath the pelvic brim. The false pelvis is the space surrounded by the broad, bladelike portions of each ilium superior to the pelvic brim. 19. The fusion of the epiphyseal cartilages of the long bones permits the determination of an approximate age; the fusion of the epiphyses in the pectoral and pelvic girdles allows for more accurate age estimates. 20. c 21. e 22. A shoulder girdle consists of a clavicle and a scapula. The clavicle articulates with the manubrium of the sternum, and this is the only direct connection between the shoulder girdle and the axial skeleton. The scapula is connected to the thoracic cage only by skeletal muscles. This arrangement makes the shoulders very mobile but not very strong. 23. e

Level 3 Critical Thinking and Clinical Applications

24. In osteoporosis, a decrease in the calcium content of the bones leads to bones that are weak and brittle. Hip fractures involve the femur, not the hip bones. Because the hip joint must help support the body's weight, any weakening of the femoral bones may result in their breaking under the weight of the body. The shoulder, by contrast, is not a load-bearing joint and is not subject to the same great stresses or strong muscle contractions as the hip joint. As a result, it is less likely to become broken. 25. The surgical neck lies between the round head and the narrow shaft of the humerus. It derives its name from the fact that fractures very frequently occur at this site. 26. Several characteristics are important in determining a person's sex from the pelvis, including its general appearance, shape of the pelvic inlet, depth of the iliac fossa, characteristics of the ilium, angle inferior to the pubic symphysis, position of the acetabulum, shape of the obturator foramen, and characteristics of the ischium. The person's age can be estimated by the bone's size, degree of mineralization (mineral content), and various markings. The person's general appearance can be reconstructed from the markings where muscles attach to the bones, which can indicate the size and shape of the muscles and thus the person's general body contours.

Answers to Clinical Case Wrap-Up

PAGE 292 1. The clavicle is a bone that forms part of the pectoral girdle and connects the arm with the central trunk of the body via

connections to the acromion and the sternum, respectively, and it is necessary to allow for the complete movement of the shoulder and arm. If the clavicle does not heal properly after a fracture, then a person is likely to lose some range of movement of the arm. **2.** The nerves underlying the clavicle are nerves that carry motor and sensory signals to and from the arm. Damage to these nerves by a clavicular fracture is therefore likely to affect movement and sensation in the arm.

Answers to Figure-Based Questions

FIGURE 8-1 The appendicular skeleton is composed of the pectoral girdles (clavicles and scapulae), upper limbs (humeri, radii, ulnae, carpal bones, metacarpals, and phalanges), pelvic girdle (hip bones), and lower limbs (femurs, patellae, tibiae, fibulas, tarsal bones, metatarsals, and phalanges).

FIGURE 8-6 Metacarpal IV articulates with the hamate and capitate.

FIGURE 8-8 The opening formed by the pubis and the ischium is the obturator foramen.

FIGURE 8-12 The fibula does not articulate with the femur. The fibula does articulate with the tibia.

Chapter 9

Answers to Checkpoints

PAGE 296 **1.** The three types of joints as classified by range of motion are (1) an immovable joint or synarthrosis, (2) a slightly movable joint or amphiarthrosis, and (3) a freely movable joint or diarthrosis. A synarthrosis can be fibrous or cartilaginous, depending on the nature of the connection, or it can be a bony fusion, which develops over time. An amphiarthrosis is either fibrous or cartilaginous, depending on the nature of the connection. A diarthrosis is a synovial joint, which permits the greatest range of motion. **2.** Both synarthrotic joints (except synostoses) and amphiarthrotic joints consist of bony regions separated by fibrocartilage or cartilaginous connective tissue. **3.** These are fibrous joints known as sutures. **PAGE 298** **4.** Components of a synovial joint include a joint capsule (articular capsule), articular cartilages, synovial fluid, and various accessory structures (menisci, fat pads, ligaments, tendons, and bursae). Synovial joints are freely movable joints that have a joint (synovial) cavity, which is the space between the articulating surfaces of two bones in a joint. Articular cartilages resembling hyaline cartilage cover the articulating bone surfaces. The fibrous joint capsule surrounds the joint, and a synovial membrane, which secretes synovial fluid, lines the walls of the joint cavity. Within the cavity, synovial fluid lubricates, distributes nutrients, and absorbs shocks. Menisci are pads of fibrocartilage that allow for variation in the shapes of the articulating surfaces. Fat pads protect the cartilages. Ligaments are cords of fibrous tissue that support, strengthen, and reinforce the joint. Tendons passing across or around the joint limit the range of motion and provide mechanical support. Bursae are synovial fluid-filled pockets that reduce friction and absorb shocks. **5.** Because articular cartilages are avascular (lack a blood supply), they rely on synovial fluid to supply nutrients and eliminate wastes. Impairing the circulation of synovial fluid would have the same effect as impairing a tissue's blood supply: Nutrients would not be delivered to meet the tissue's needs, and wastes would accumulate. Tissue damage or death could ultimately result.

6. A dislocation is a complete loss of contact between the articulating surfaces within a joint. **PAGE 304** **7.** Based on the shapes of the articulating surfaces, synovial joints are classified as plane (gliding), hinge, pivot, condylar (ellipsoid), saddle, and ball-and-socket joints. **8.** When doing jumping jacks, a person moves their lower limbs

away from the body's midline; this movement is abduction. When the lower limbs are brought back together, the movement is adduction. **9.** Flexion and extension are the movements associated with hinge joints. **PAGE 305** **10.** The type of joint that only permits slight movements is an amphiarthrosis. **11.** Intervertebral discs are not found between the first and second cervical vertebrae, between sacral vertebrae in the sacrum, or between coccygeal vertebrae in the coccyx. An intervertebral disc between the first and second cervical vertebrae would prohibit rotation. The vertebrae in the sacrum and coccyx are fused to provide a firm attachment for muscles and ligaments. **12.** The vertebral movement involved in (a) bending forward is flexion. The movement involved in (b) bending to the side is lateral flexion. The movement involved in (c) moving the head to signify "no" is rotation. **PAGE 309** **13.** Kai has most likely damaged his annular ligament. **14.** Damage to the menisci of the knee joint decreases the joint's stability, so the person would have a difficult time locking the knee in place while standing and would have to use muscle contractions to stabilize the joint. If the person had to stand for a long time, the muscles would fatigue and the knee would "give out." It is also likely that the person would feel pain. **15.** Like members of the clergy, carpet layers and roofers kneel a lot (and they also slide along on their knees), causing inflammation of the bursae in the knee joint. **16.** The bones involved with the knee joint are the femur, tibia, and patella. The fibula is not part of the knee joint. **PAGE 313** **17.** Ligaments and muscles provide most of the stability for the shoulder joint. **18.** The subscapular bursa is located in the shoulder joint, so the tennis player would be more likely to develop inflammation of this structure (bursitis). The condition is associated with repetitive motion that occurs at the shoulder, such as swinging a tennis racket. The jogger would be more at risk for injuries to the knee joint. **19.** A shoulder separation is an injury involving partial or complete dislocation of the acromioclavicular joint. **20.** The bones making up the shoulder joint are the humerus and scapula. **21.** The iliofemoral, pubofemoral, and ischiofemoral ligaments are at the hip joint. **PAGE 314** **22.** Rheumatism is a general term describing any painful condition of the bones, muscles, and joints (musculoskeletal system). One of several forms of rheumatism is arthritis. **23.** Arthritis applies to all the rheumatic diseases that affect synovial joints. Of the many different types of arthritis, osteoarthritis is the most common. **24.** Osteoblast activity must equal osteoclast activity or else the integrity of bone structure is compromised. For example, if osteoclast activity outpaces osteoblast activity, the result is thin, brittle bones. **25.** The skeletal system provides structural support for all body systems and stores energy, calcium, and phosphate. The integumentary system synthesizes vitamin D₃, which is essential for calcium and phosphorus absorption. Calcium and phosphorus are needed for bone growth and maintenance.

Answers to Review Questions

PAGE 317

Level 1 Reviewing Facts and Terms

1. (a) joint capsule (b) synovial membrane (c) articular cartilage (d) joint cavity (contains synovial fluid) **2.** b **3.** b **4.** c **5.** d **6.** d **7.** c **8.** b **9.** c **10.** c **11.** b **12.** a **13.** d **14.** a **15.** b **16.** b **17.** a **18.** b **19.** b

Level 2 Reviewing Concepts

20. b **21.** c **22.** The acetabular labrum is a projecting rim of rubbery fibrocartilage. It increases the depth of the hip joint cavity. It also helps to keep the synovial fluid in. **23.** Twisting an extended weight-bearing knee frequently leads to the injury of the anterior

cruciate ligament. **24.** In joints affected by gouty arthritis, crystals of uric acid form within the synovial fluid. This hampers movement. **25.** Inversion is a twisting movement of the foot that turns the sole inward, elevating the medial edge of the sole. Eversion is the opposite movement. **26.** Height decreases during adulthood in part as a result of osteoporosis in the vertebrae and in part as a result of the decrease in water content of the nucleus pulposus region of intervertebral discs. **27.** The muscles forming the rotator cuff are the (1) supraspinatus, (2) infraspinatus, (3) teres minor, and (4) subscapularis (SITS). The rotator cuff supports the shoulder joint and limits its range of motion.

Level 3 Critical Thinking and Clinical Applications

28. The upward, twisting pull on the elbow joint in pronation could have caused a partial dislocation of the radial head from the annular ligament known as nursemaid's elbow. **29.** Cartilage does not contain blood vessels, so the chondrocytes rely on diffusion to gain nutrients and eliminate wastes. The synovial fluid is very important in supplying nutrients to the articular cartilages that it bathes and in removing wastes. If the circulation of the synovial fluid is impaired or stopped, the cells will not get enough nutrients or be able to get rid of their waste products. This combination of factors can lead to the death of the chondrocytes and the breakdown of the cartilage. **30.** Shoulder dislocations would occur more frequently than hip dislocations because the shoulder is a more mobile joint. Because the shoulder joint is not bound tightly by ligaments or other structures, it is easier to dislocate when excessive forces are applied. By contrast, the hip joint, although mobile, is less easily dislocated because it is stabilized by four heavy ligaments, and the bones fit together snugly in the joint. Additionally, the synovial capsule of the hip joint is larger than that of the shoulder, and its range of motion is decreased.

Answers to Clinical Case Wrap-Up

PAGE 318 **1.** Only diarthroses, or synovial joints, are affected by juvenile rheumatoid arthritis. This is a disease of the synovial lining, so it does not affect joints that have no synovial membrane. **2.** Normal synovial membranes are thin, delicate, and smooth. The inflamed synovial membrane in a joint affected by rheumatoid arthritis would look thickened, red, excessively fluid filled, swollen, and overgrown.

Answers to Figure-Based Questions

FIGURE 9-1 Articular cartilage covers the bony surfaces of a synovial joint. The articular cartilage on each bony surface is separated by a thin layer of synovial fluid.

FIGURE 9-3 Angular movements include flexion/extension/hyperextension, abduction/adduction, and circumduction.

FIGURE 9-6 The annulus fibrosus provides the tough outer layer of fibrocartilage, and the nucleus pulposus provides the soft inner core for resiliency and shock absorption.

FIGURE 9-9 The acromioclavicular ligament connects the scapula (specifically, the acromion of the scapula) and the clavicle.

Chapter 10

Answers to Checkpoints

PAGE 321 **1.** The three types of muscle tissue are skeletal muscle, cardiac muscle, and smooth muscle. Skeletal muscle tissue moves the body by pulling on bones; cardiac muscle tissue pumps blood through the cardiovascular system; smooth muscle tissue pushes fluids and solids along the digestive tract and other internal organs, and it regulates the diameters of small arteries. **2.** Muscle

tissues share the common properties of excitability (the ability to receive and respond to a stimulus), contractility (the ability of a muscle cell to shorten when it is stimulated), extensibility (stretching movement of a muscle), and elasticity (the ability of a muscle to recoil to its resting length). **3.** Skeletal muscles produce skeletal movement, maintain posture and body position, support soft tissues, guard body entrances and exits, maintain body temperature, and store nutrients. **4.** The epimysium is a dense layer of collagen fibers that surrounds the entire muscle; the perimysium divides the skeletal muscle into a series of compartments, each containing a bundle of muscle fibers called a fascicle; and the endomysium surrounds individual skeletal muscle cells (muscle fibers). The collagen fibers of the epimysium, perimysium, and endomysium come together to form either bundles known as tendons, or broad sheets called aponeuroses. Tendons and aponeuroses generally attach skeletal muscles to bones. **5.** Because tendons attach muscles to bones, severing the tendon would disconnect the muscle from the bone, and so the muscle could not move a body part. **PAGE 330** **6.** Sarcomeres, the smallest contractile units of a striated muscle cell, are segments of myofibrils. Each sarcomere has a dark A band and light I bands. The A band contains the M line, the H band, and the zone of overlap. Each I band contains thin filaments, but not thick filaments. Z lines bisect the I bands and mark the boundaries between adjacent sarcomeres.

7. Skeletal muscle fibers appear striated when viewed through a light microscope because the Z lines and thick filaments of the myofibrils within the muscle fibers are aligned. **8.** You would expect the greatest concentration of calcium ions in a resting skeletal muscle fiber to be in the terminal cisternae of the sarcoplasmic reticulum. **PAGE 339** **9.** The neuromuscular junction is the synapse between a motor neuron and a skeletal muscle cell (fiber). This connection enables communication between the nervous system and a skeletal muscle fiber. **10.** Acetylcholine (ACh) release from the axon terminal is necessary for skeletal muscle contraction because it serves as the first step in the process that leads to the formation of cross-bridges in the sarcomeres. A muscle's ability to contract depends on the formation of cross-bridges between the myosin heads and actin myofilaments. A drug that blocks ACh release would interfere with this cross-bridge formation and prevent muscle contraction. **11.** If the sarcolemma of a resting skeletal muscle suddenly became permeable to Ca^{2+} , the cytosolic concentration of Ca^{2+} would increase, and the muscle would contract. In addition, because the amount of calcium ions in the cytosol must decrease for relaxation to occur, the increased permeability of the sarcolemma to Ca^{2+} might prevent the muscle from relaxing completely. **12.** Without acetylcholinesterase (AChE), the motor end plate would be stimulated continuously by acetylcholine, locking the muscle in a state of contraction. **PAGE 342** **13.** A muscle's ability to contract depends on the formation of cross-bridges between the myosin and actin myofilaments in the muscle. In a muscle that is overstretched, the myofilaments would overlap very little, so very few cross-bridges between myosin and actin could form and, thus, the contraction would be weak. If the myofilaments did not overlap at all, then no cross-bridges would form and the muscle could not contract.

PAGE 347 **14.** Yes, a skeletal muscle can contract without shortening. The muscle can shorten (isotonic concentric contraction), elongate (isotonic eccentric contraction), or remain the same length (isometric contraction), depending on the relationship between the load (resistance) and the tension produced by actin-myosin interactions. **PAGE 351** **15.** Muscle fibers synthesize ATP continuously by utilizing creatine phosphate (CP) and metabolizing

glycogen and fatty acids. Most cells generate ATP only through aerobic metabolism in the mitochondria and through glycolysis in the cytosol. **16.** Oxygen debt is the amount of oxygen required to restore normal, pre-exertion conditions in muscle tissue. **PAGE 355**

17. The three types of skeletal muscle fibers are (1) fast fibers (also called white muscle fibers, fast-twitch glycolytic fibers, Type II-B fibers, and fast fatigue fibers); (2) slow fibers (also called red muscle fibers, slow-twitch oxidative fibers, Type I fibers, and slow oxidative fibers); and (3) intermediate fibers (also called fast-twitch oxidative fibers, Type II-A fibers, and fast resistant fibers). **18.** Muscle fatigue is a muscle's reduced ability to contract due to low pH (hydrogen ion buildup), low ATP levels, or other problems. **19.** General age-related effects on skeletal muscles include decreased skeletal muscle fiber diameters, diminished muscle elasticity, decreased tolerance for exercise, and a decreased ability to recover from muscular injuries. **20.** A sprinter requires large amounts of energy for a short burst of activity. To supply this energy, the sprinter's muscles rely on anaerobic metabolism. Anaerobic metabolism is less efficient in producing energy than aerobic metabolism, and the process also produces acidic wastes; this combination contributes to muscle fatigue. Conversely, marathon runners derive most of their energy from aerobic metabolism, which is more efficient and produces fewer wastes than anaerobic metabolism does.

21. Activities that require short periods of strenuous activity produce a greater oxygen debt, because such activities rely heavily on energy production by anaerobic metabolism. Because lifting weights is more strenuous over the short term than swimming laps, which is an aerobic activity, weightlifting would likely produce a greater oxygen debt than would swimming laps. **22.** People who excel at endurance activities have a high percentage of slow fibers. Slow fibers are physiologically better adapted to this type of activity than are fast fibers, which are less vascular and fatigue faster. **PAGE 356**

23. Compared to skeletal muscle tissue, cardiac muscle tissue (1) has relatively small cells; (2) has cells with a centrally located nucleus (some may contain two or more nuclei); (3) has T tubules that are short and broad and do not form triads; (4) has an SR that lacks terminal cisternae and has tubules that contact the plasma membrane as well as the T tubules; (5) has cells that are nearly totally dependent on aerobic metabolism as an energy source; and (6) contains intercalated discs that assist in stabilizing tissue structure and spreading action potentials. **24.** Cardiac muscle cells are joined by gap junctions, which allow ions and small molecules to flow directly between cells. As a result, action potentials generated in one cell spread rapidly to adjacent cells. Thus, all the cells contract simultaneously, as if they were a single unit (a syncytium). **PAGE 359**

25. Smooth muscle cells lack sarcomeres, and thus smooth muscle tissue is nonstriated. Additionally, the thin filaments are anchored to dense bodies. **26.** Skeletal muscle contractions are least affected by changes in extracellular Ca^{2+} concentrations. In skeletal muscle, most of the calcium ions come from the sarcoplasmic reticulum. Most of the calcium ions that trigger a contraction in cardiac and smooth muscles come from the extracellular fluid. **27.** The looser organization of actin and myosin filaments in smooth muscle allows smooth muscle to contract over a wider range of resting lengths than skeletal muscle.

Answers to Review Questions

PAGE 362

Level 1 Reviewing Facts and Terms

1. (a) sarcolemma (b) sarcoplasm (c) mitochondria (d) myofibril (e) thin filament (f) thick filament (g) sarcoplasmic reticulum

(h) T tubules 2. d 3. a 4. c 5. d 6. a 7. d 8. c

9. (1) skeletal muscle; (2) cardiac muscle; (3) smooth muscle

10. (1) epimysium: surrounds entire muscle; (2) perimysium: surrounds bundles of muscle fibers (fascicles); (3) endomysium: surrounds individual skeletal muscle fibers (cells) 11. a 12. The transverse (T) tubules propagate action potentials into the interior of the cell. 13. (1) exposure of active sites; (2) attachment of cross-bridges; (3) pivoting of myosin heads (power stroke); (4) detachment of cross-bridges; (5) reactivation of myosin heads (recocking myosin head) 14. Both the frequency of motor unit stimulation and the number of motor units involved affect the amount of tension produced when a skeletal muscle contracts. 15. Recruitment is the smooth but steady increase in muscular tension produced by increasing the number of active motor units. 16. White muscles contain fast muscle fibers while red muscles mainly contain slow muscle fibers. 17. Transmission of contractile forces between smooth muscle cells occurs at dense bodies.

Level 2 Reviewing Concepts

18. b 19. a 20. a 21. e 22. In an initial latent period (after the stimulus arrives and before tension begins to increase), an action potential generated in the muscle fiber triggers the release of calcium ions from the SR. In the contraction phase, calcium ions bind to troponin (cross-bridges form) and tension begins to increase. In the relaxation phase, tension decreases because cross-bridges have detached and because calcium ion levels have decreased; the active sites are once again covered by the troponin-tropomyosin complex.

23. Hormones are effective in adjusting metabolic activity in skeletal muscle fibers. (1) Growth hormone and (2) testosterone stimulate the production of the contractile proteins myosin and actin, resulting in muscle enlargement, (3) thyroid hormones increase the rate of energy consumption in resting and active skeletal muscles, and (4) in emergency situations, epinephrine increases the force of muscle contraction and the duration of stimulation. 24. Skeletal muscles fatigue much more rapidly than cardiac muscle. Cardiac muscle cells have a longer refractory period. Their contractions last about ten times longer than those of skeletal muscle cells.

25. If atracurium blocked the binding of ACh to its receptors at the motor end plates of neuromuscular junctions, the muscle's ability to contract would be inhibited. 26. In rigor mortis, the membranes of the dead cells are no longer selectively permeable; the SR is no longer able to retain calcium ions. As calcium ions enter the cytosol, a sustained contraction develops, making the body extremely stiff. Contraction persists because the dead muscle cells can no longer make the ATP required for cross-bridge detachment from the active sites. Rigor mortis begins a few hours after death and ends after 1 to 6 days, or when decomposition begins. Decomposition begins when the lysosomal enzymes released by autolysis break down the myofilaments. 27. b

Level 3 Critical Thinking and Clinical Applications

28. Because organophosphates block the action of acetylcholinesterase (AChE), ACh released into the synaptic cleft would not be removed. It would continue to stimulate the motor end plate, causing a state of persistent contraction (spastic paralysis). If the muscles of respiration were affected (which is likely), Ivan would die of suffocation. Prior to death, the most obvious sign would be uncontrolled tetanic contractions of skeletal muscles. 29. CK is the enzyme creatine kinase. It functions in the anaerobic reaction that transfers phosphate from creatine phosphate to ADP in muscle cells. The presence of cardiac troponin, a form found only in cardiac muscle cells, provides direct evidence that cardiac muscle cells have been severely damaged.

30. A good warm-up is important to stimulate blood circulation in the muscles and to increase muscle temperature. Glucose is the preferred energy source, so she should consume a lot of carbohydrates before the event and glucose-rich sports drinks during the event.

Answers to Clinical Case Wrap-Up

PAGE 363 1. A drug that inhibits acetylcholinesterase (AChE) is inhibiting the enzyme that breaks down the neurotransmitter acetylcholine (ACh). As a result, ACh is present longer in the neuromuscular junction (NMJ). Because a patient with myasthenia gravis does not have enough functioning ACh receptors, a greater amount of ACh is better for strength of muscular response. In short, by inhibiting the breakdown of ACh, the drug strengthens the patient's muscular response. **2.** Myasthenia gravis affects voluntary, skeletal muscle at the neuromuscular junction (NMJ). Cardiac muscle tissue contracts without neural stimulation, a property known as automaticity. There is no neural stimulation, no NMJ, no ACh neurotransmitter or receptor required for cardiac muscle contraction. For these reasons, myasthenia gravis would not affect cardiac muscle.

Answers to Figure-Based Questions

FIGURE 10-3 The terminal cisternae are part of the sarcoplasmic reticulum.

FIGURE 10-6 A skeletal muscle is surrounded by epimysium. A muscle fascicle is surrounded by perimysium. A muscle fiber is surrounded by endomysium. A myofibril is surrounded by sarcoplasmic reticulum.

FIGURE 10-14 If the zone of overlap is decreased, the sarcomere length is increased.

FIGURE 10-21 Slow skeletal muscle fibers contain more mitochondria than fast fibers.

Chapter 11

Answers to Checkpoints

PAGE 367 1. Based on the patterns of fascicle arrangement, the four types of skeletal muscles are parallel muscles, convergent muscles, pennate muscles, and circular muscles. **2.** Contraction of a pennate muscle generates more tension than would contraction of a parallel muscle of the same size because a pennate muscle contains more muscle fibers, and thus more myofibrils and sarcomeres, than does a parallel muscle of the same size. **3.** The anal opening between the large intestine and the exterior would be guarded by a circular muscle, or sphincter. The concentric circles of muscle fibers found in sphincters are ideally suited for opening and closing passageways and for acting as valves in the body. **4.** A lever is a rigid structure—such as a board, a pry bar, or a bone—that moves on a fixed joint called a fulcrum. There are three classes of levers: In a first-class lever, the fulcrum lies between the applied force and load; in a second-class lever, the load lies between the applied force and fulcrum; and in a third-class lever, the applied force or pull exerted is between the fulcrum and the load. Third-class levers are the most common type in the body. **5.** The joint between the occipital bone and the first cervical vertebra is part of a first-class lever system. The joint between the two bones (the fulcrum) lies between the skull (which provides the load) and the neck muscles (which provide the applied force). **PAGE 369 6.** The origin of a muscle is the end that is less movable. Because the gracilis moves the tibia, the origin of this muscle must be on the pelvis (pubis and ischium). **7.** Muscles A and B are antagonists to each other, because they perform opposite actions. **8.** A synergist is a muscle that helps a larger

prime mover (or agonist—a muscle that is responsible for a specific movement) perform its actions more efficiently.

PAGE 374 9. Names of skeletal muscles are based on several factors, including region of the body; position, direction, or fascicle arrangement; origin and insertion; shape and size; and action.

10. The name flexor carpi radialis longus tells you that this muscle is a long muscle (longus) that lies next to the radius (radialis) and flexes (flexor) the wrist (carpi). **PAGE 375 11.** Axial muscles arise on the axial skeleton. They position the head and vertebral column,

move the rib cage, and form the pelvic floor. **12.** Appendicular muscles stabilize or move structures of the appendicular skeleton. These muscles move and support the pectoral (shoulder) girdles and the upper and lower limbs. **PAGE 390 13.** Contracting the masseter elevates the mandible, and relaxing this muscle depresses the mandible. They would probably be chewing something.

14. The buccinator, which positions the mouth for blowing, is well developed in a trumpet player. **15.** Swallowing involves contractions of the palatal muscles, which elevate the soft palate as well as portions of the superior pharyngeal wall. Elevation of the superior portion of the pharynx enlarges the opening to the auditory tube,

permitting airflow to the middle ear and the inside of the eardrum. Making this opening larger by swallowing facilitates airflow into or out of the middle ear cavity. **16.** Damage to the intercostal muscles would interfere with breathing. **17.** A hit in the rectus abdominis would cause that muscle to contract forcefully, resulting in flexion of the vertebral column. In other words, you would “double over.” **18.** The sore muscles in Joe's back are most likely the erector spinae, especially the longissimus and the iliocostalis of the lumbar region. These muscles would have to contract with more tension than normal to counterbalance the increased anterior weight when carrying heavy boxes. **PAGE 411 19.** A person shrugging their shoulders is contracting their levator scapulae.

20. The muscles involved in a rotator cuff injury are the supraspinatus, infraspinatus, teres minor, and subscapularis (SITS).

21. Injury to the flexor carpi ulnaris would impair wrist flexion and adduction. **22.** Injury to the obturator would impair one's ability to laterally rotate the hip. **23.** A pulled hamstring refers to a strain affecting one or more of the three muscles that collectively flex the knee: the biceps femoris, semitendinosus, and semimembranosus. **24.** A torn calcaneal tendon would make plantar flexion difficult because this tendon attaches the soleus and gastrocnemius to the calcaneus (heel bone). **25.** The muscular system generates heat that maintains normal body temperature. **26.** Exercise affects the cardiovascular system by increasing heart rate and dilating blood vessels. With exercise, the rate and depth of breathing increase, and sweat gland secretion increases. The physiological effects that result from exercise are directed and coordinated by the nervous and endocrine systems.

20. The muscles involved in a rotator cuff injury are the supraspinatus, infraspinatus, teres minor, and subscapularis (SITS).

21. Injury to the flexor carpi ulnaris would impair wrist flexion and adduction. **22.** Injury to the obturator would impair one's ability to laterally rotate the hip. **23.** A pulled hamstring refers to a strain affecting one or more of the three muscles that collectively flex the knee: the biceps femoris, semitendinosus, and semimembranosus. **24.** A torn calcaneal tendon would make plantar flexion difficult because this tendon attaches the soleus and gastrocnemius to the calcaneus (heel bone). **25.** The muscular system generates heat that maintains normal body temperature. **26.** Exercise affects the cardiovascular system by increasing heart rate and dilating blood vessels. With exercise, the rate and depth of breathing increase, and sweat gland secretion increases. The physiological effects that result from exercise are directed and coordinated by the nervous and endocrine systems.

Answers to Review Questions

PAGE 414

Level 1 Reviewing Facts and Terms

1. (a) deltoid (multipennate) **(b)** extensor digitorum (unipennate) **(c)** rectus femoris (bipennate) **2. (a)** supraspinatus **(b)** infraspinatus **(c)** teres minor **3. c 4. a 5. d 6. b 7. a 8. b 9. a 10. c 11. b 12. a 13. a 14.** The possible actions are flexion, extension, adduction, abduction, medial rotation, and lateral rotation. **15.** An aponeurosis is a collagenous sheet connecting two muscles. The epicranial aponeurosis and the linea alba are examples. **16.** The axial musculature includes (1) muscles of the head and neck, (2) muscles of the vertebral column, (3) oblique and

rectus muscles, and (4) muscles of the pelvic floor. **17.** The muscles of the pelvic floor (1) support the organs of the pelvic cavity, (2) flex joints of the sacrum and coccyx, and (3) control movement of materials through the urethra and anus. **18.** The supraspinatus, infraspinatus, and teres minor originate on the posterior body of the scapula, and the subscapularis originates on the anterior body of the scapula. All four muscles insert on the humerus.

19. The five muscles that form the adductor group of the lower limb are the (1) pectineus, (2) adductor brevis, (3) adductor longus, (4) adductor magnus, and (5) gracilis.

Level 2 Reviewing Concepts

20. c **21. a** **22.** retinaculum **23.** pitcher's arm **24.** The vertebral column does not have a massive series of anterior flexors because many of the large trunk muscles flex the vertebral column when they contract. In addition, most of the body weight lies anterior to the vertebral column, and gravity tends to flex the intervertebral joints. **25.** In a convergent muscle, the direction of pull can be changed by stimulating only one group of muscle cells at any one time. When all the fibers contract at once, they do not pull as hard on the tendon as would a parallel muscle of the same size, because the muscle fibers on opposite sides of the tendon are pulling in different directions rather than working together. **26.** The trapezius and rhomboid muscles act as fixators by stabilizing and preventing movement of the scapula during flexion at the elbow by the biceps brachii. **27.** Lifting heavy objects becomes easier as the elbow approaches a 90° angle. As you increase the angle at or near full extension, tension production decreases, so movement becomes more difficult. **28.** When the hamstrings are injured, flexion at the knee and extension at the hip are affected.

Level 3 Critical Thinking and Clinical Applications

29. The passage of the esophagus creates a weak spot in the diaphragm. Abdominal organs sometimes protrude through this esophageal hiatus, a condition called a hiatal hernia. This frequently leads to the increased entry of gastric acid into the esophagus causing heartburn, a burning pain sensation behind the sternum.

30. c **31.** Although the pectoralis is located across the chest, it inserts on the greater tubercle of the humerus, the bone of the arm. When this muscle contracts, it contributes to flexion, adduction, and medial rotation of the humerus at the shoulder joint. All of these arm movements would be impaired if the muscle were damaged.

Answers to Clinical Case Wrap-Up

PAGE 415 **1.** The downward-facing dog pose engages muscles throughout the body: extensors of the neck and vertebral column (erector spinae group), hip flexors (iliopsoas group and tensor fasciae latae), extensors of the knee (quadriceps femoris group), ankle flexors (tibialis anterior), extensors of the shoulder (latissimus dorsi and teres major), extensors of the elbow (triceps brachii) and wrist (extensor carpi group), and abductors of the fingers (abductor pollicis brevis and interossei). **2.** The muscles of the "core" support good posture. These include the abdominal muscles (rectus abdominis, external and internal obliques, transversus abdominis); muscles of the pelvic floor; the erector spinae group, especially the longissimus thoracis; and the diaphragm, a muscle that is often overlooked when considering skeletal muscles.

Answers to Figure-Based Questions

FIGURE 11-5 The term levator anguli oris means "to raise the corner of the mouth." This is one of the muscles that assists with smiling.

FIGURE 11-6 From the lateral or the medial surface you can see five of the six eye muscles. From the lateral surface, you cannot see

the medial rectus and from the medial surface you cannot see the lateral rectus.

FIGURE 11-10 The digastric, geniohyoid, omohyoid, sternohyoid, stylohyoid, and thyrohyoid all insert on the hyoid bone. The mylohyoid inserts on the hyoid bone by a band of connective tissue.

FIGURE 11-17 The triceps brachii has three heads, and each head has a different origin. The lateral head's origin is on the superior lateral surface of the humerus. The long head's origin is on the scapula. The medial head's origin is on the posterior surface of the humerus.

FIGURE 11-19 The adductor pollicis and abductor pollicis brevis are an agonist–antagonist pair.

FIGURE 11-21 The vastus intermedius is not visible from the superficial anterior view of the thigh. This muscle and the vastus lateralis, vastus medialis, and rectus femoris make up the quadriceps femoris.

Chapter 12

Answers to Checkpoints

PAGE 420 **1.** The two anatomical divisions of the nervous system are the central nervous system (CNS), consisting of the brain and spinal cord, and the peripheral nervous system (PNS), consisting of all nervous tissue outside the CNS. The subdivisions of the PNS are the somatic nervous system (SNS) and the autonomic nervous system (ANS). The ANS includes the sympathetic and parasympathetic divisions and the enteric nervous system (ENS). **2.** The two functional divisions of the peripheral nervous system are the afferent division, which brings sensory information to the CNS from receptors in peripheral tissues and organs, and the efferent division, which carries motor commands from the CNS to muscles, glands, and adipose tissue. **3.** The two components of the efferent division of the PNS and their effectors are the somatic nervous system (SNS) and the autonomic nervous system (ANS). The SNS effectors are skeletal muscles, and the ANS effectors include smooth and cardiac muscle, glands, and adipose tissue. **4.** Damage to the afferent division of the PNS, which is composed of nerves that carry sensory information to the brain and spinal cord, would interfere with a person's ability to experience a variety of sensory stimuli. **PAGE 423**

5. The structural components of a typical neuron include a cell body or soma (which contains the nucleus and perikaryon), dendrites (some with dendritic spines), an axon, telodendria, Nissl bodies, neurofilaments, intermediate neurotubules, neurofibrils, axoplasm, axolemma, initial segment, axon hillock, and collaterals. **6.** According to structure, neurons are classified as anaxonic, bipolar, unipolar, or multipolar. **7.** According to function, neurons are classified as sensory neurons, motor neurons, or interneurons. **8.** Because most sensory neurons of the PNS are unipolar, these neurons most likely function as sensory neurons. **PAGE 429**

9. Central nervous system neuroglia include astrocytes, ependymal cells, oligodendrocytes, and microglia. **10.** Peripheral nervous system neuroglia include satellite cells and Schwann cells (neurolemmocytes). **11.** The small phagocytic cells called microglia occur in increased numbers in infected (and damaged) areas of the CNS. **PAGE 437** **12.** The resting membrane potential is the membrane potential of a normal, unstimulated cell. **13.** If the voltage-gated sodium ion channels in the plasma membrane of a neuron could not open, sodium ions could not flood into the neuron and it would not be able to depolarize. **14.** If the extracellular concentration of potassium ions decreased, more potassium would leave the cell, and the membrane potential would become more

negative. This condition is called hyperpolarization. **PAGE 444**

15. An action potential is a propagated change in the membrane potential of excitable cells, initiated by a change in the membrane permeability to sodium ions. **16.** The four steps involved in the generation of action potentials are (1) depolarization to threshold; (2) activation of voltage-gated sodium ion channels and rapid depolarization; (3) inactivation of voltage-gated sodium ion channels and activation of voltage-gated potassium ion channels; and (4) closing of voltage-gated potassium ion channels and return to normal permeability. **17.** The presence of myelin greatly increases the propagation speed of action potentials. **18.** Action potentials travel along myelinated axons (by saltatory propagation) at much higher speeds than along unmyelinated axons. The axon with a propagation speed of 50 meters per second must be the myelinated axon. Typical propagation speeds for unmyelinated axons are about 1 m/sec. **PAGE 448**

19. The general structural components of a synapse, the site where a neuron communicates with another cell, are a presynaptic cell and a postsynaptic cell, whose plasma membranes are separated by a narrow synaptic cleft. **20.** If a synapse involves direct physical contact between cells, it is termed electrical; if the synapse involves a neurotransmitter, it is termed chemical. **21.** If the voltage-gated calcium ion channels at a cholinergic synapse were blocked, Ca^{2+} could not enter the axon terminal and trigger the release of ACh into the synapse, so no communication would take place across the synapse. **22.** Because of synaptic delay, the pathway with fewer neurons (in this case, three) will transmit impulses more rapidly. **PAGE 452**

23. Both neurotransmitters and neuromodulators are substances that are released by one neuron and affect another neuron. A neurotransmitter alters the membrane potential of the other neuron, whereas a neuromodulator alters the other neuron's response to specific neurotransmitters. **24.** Neurotransmitters and neuromodulators are (1) compounds that have a direct effect on membrane potential, or (2) compounds that have an indirect effect on membrane potential through G proteins, or (3) lipid-soluble gases that have an indirect effect on membrane potential through intracellular enzymes. **PAGE 456**

25. No action potential will be generated. **26.** Yes, an action potential will be generated. **27.** Temporal summation would occur if the two EPSPs happened at the same time.

Answers to Review Questions

PAGE 458

Level 1 Reviewing Facts and Terms

1. (a) dendrite (b) nucleolus (c) nucleus (d) axon hillock (e) initial segment (f) axolemma (g) axon (h) telodendria (i) axon terminals **2.** c **3.** a **4.** c **5.** c **6.** a **7.** b **8.** b

9. (a) the CNS: brain and spinal cord (b) the PNS: all the nervous tissue outside the CNS and ENS divided between the efferent division (which consists of the somatic nervous system and the autonomic nervous system) and the afferent division (which consists of receptors and sensory neurons) (c) the ENS: network of neurons and nerve networks in the walls of the digestive tract

10. Diphtheria and multiple sclerosis are demyelinating diseases. **11.** (1) Special sensory receptors: monitor smell, taste, vision, balance, and hearing; (2) visceral sensory receptors: monitor internal organs; (3) somatic sensory receptors: monitor skeletal muscles, joints, and skin surface

Level 2 Reviewing Concepts

12. b **13.** A multipolar neuron has a distinct axon, whereas an anaxonic neuron has dendrites but no obvious axons.

14. Interoceptors are sensory receptors that monitor the internal body systems, registering stretch, deep pressure, and pain. Proprioceptors are sensory receptors that monitor the position and movement of skeletal muscles and joints. **15.** Chemically gated (ligand-gated) ion channels open or close when they bind specific extracellular chemicals (ligands). Voltage-gated ion channels open or close in response to changes in the membrane potential. Mechanically gated ion channels open or close in response to physical distortion of the membrane surface. **16.** During the absolute refractory period, the plasma membrane cannot respond to further stimulation; whereas during the relative refractory period, the plasma membrane can respond only to a larger-than-normal stimulus. **17.** When a peripheral nerve is lacerated, the distal stump disintegrates. Axons and myelin fall apart in fragments. The Schwann cells form a cord and grow into the cut to unite the stumps. Macrophages engulf the cut and remove the debris. The proximal part of the axon sends a bud into the network of Schwann cells and keeps growing until it reaches the distal stump and becomes enclosed by Schwann cells. **18.** In saltatory propagation, which occurs in myelinated axons, only the nodes along the axon can respond to a depolarizing stimulus. In continuous propagation, which occurs in unmyelinated axons, an action potential appears to move across the membrane surface in a series of tiny steps. **19.** Electrical synapse: There is direct physical contact between cells. The cell membranes are locked together at gap junctions. Membrane pores permit ions to pass between the cells. Chemical synapse: There is a narrow synaptic cleft between cells. One neuron sends chemical signals to another cell using neurotransmitters. **20.** (1) The action potential arrives at the axon terminal, depolarizing it; (2) extracellular calcium enters the axon terminal, triggering the exocytosis of ACh; (3) ACh binds to the postsynaptic membrane and depolarizes the next neuron in the chain; (4) ACh is removed by AChE. **21.** In presynaptic inhibition, GABA is released and that decreases postsynaptic effect. In presynaptic facilitation, serotonin is released and that increases postsynaptic effect.

Level 3 Critical Thinking and Clinical Applications

22. Manny's kidney condition is causing the retention of potassium ions. As a result, the K^+ concentration of the extracellular fluid is higher than normal. Under these conditions, less potassium diffuses from heart muscle cells than normal, resulting in a resting membrane potential that is less negative (more positive). This change in the resting membrane potential moves the membrane potential closer to threshold, so it is easier to stimulate the muscle. The ease of stimulation accounts for the increased number of contractions evident in the rapid heart rate. **23.** To reach threshold, the postsynaptic membrane must receive enough neurotransmitter to produce an EPSP of +20 mV (+10 mV to reach threshold and +10 mV to cancel the IPSPs produced by the 5 inhibitory neurons). Each neuron releases enough neurotransmitter to produce a change of +2 mV, so at least 10 of the 15 excitatory neurons must be stimulated to produce this effect by spatial summation. **24.** When the rabies virus enters a body part, the virus particles quickly enter axon terminals and peripheral axons. They are then transported in retrograde flow from the axon terminals toward cell bodies in the CNS. The virus particles travel the length of the axons on neurotubules in the axoplasm, carried by dynein, a protein molecular motor. The further from the brain the virus enters the body, the longer it takes for symptoms to develop. **25.** The absolute refractory period limits the number of action potentials that can travel along an axon in a given unit of

time. During the absolute refractory period, the membrane cannot conduct an action potential, so a new depolarization event cannot occur until after the absolute refractory period has passed. If the absolute refractory period for a particular axon is 0.001 sec, then the maximum frequency of action potentials propagated by this axon would be 1000/sec.

Answers to Clinical Case Wrap-Up

PAGE 459 1. The polio virus attacks the motor neurons located in the spinal cord. 2. Guillain-Barré syndrome is an autoimmune disorder that attacks the myelin covering of peripheral nerves in adults. This causes both sensory and motor signs and symptoms because peripheral nerves are mixed nerves.

Answers to Figure-Based Questions

FIGURE 12-2 The axon hillock is a region between the cell body and the axon of a neuron.

FIGURE 12-4 Oligodendrocytes myelinate CNS axons and Schwann cells myelinate PNS axons.

FIGURE 12-16 Choline undergoes reuptake by the axon terminal. The acetate part of acetylcholine does not undergo reuptake.

Chapter 13

Answers to Checkpoints

PAGE 463 1. The central nervous system (CNS) is made up of the brain and spinal cord, while cranial nerves and spinal nerves make up the peripheral nervous system (PNS). 2. A spinal reflex is a rapid, automatic response triggered by specific stimuli that is controlled in the spinal cord. **PAGE 468** 3. The three spinal meninges are the dura mater, arachnoid mater, and pia mater. 4. Damage to the anterior root of a spinal nerve, which contains both visceral and somatic motor fibers, would interfere with motor function. 5. The cerebrospinal fluid that surrounds the spinal cord is located in the subarachnoid space, which lies between the epithelium of the arachnoid mater and the pia mater. **PAGE 470** 6. Sensory nuclei receive and relay sensory information from peripheral receptors. Motor nuclei issue motor commands to peripheral effectors. 7. The polio virus-infected neurons would be in the anterior horns of the spinal cord, where the cell bodies of somatic motor neurons are located. 8. A disease that damages myelin sheaths would affect the columns in the white matter of the spinal cord, because the columns are composed of bundles of myelinated axons. **PAGE 480** 9. The major nerve plexuses are the cervical, brachial, lumbar, and sacral. 10. An anesthetic that blocks the function of the posterior rami of the cervical spinal nerves would affect the skin and muscles of the back of the neck and of the shoulders. 11. Damage to the cervical plexus—or more specifically to the left and right phrenic nerves, which originate in this plexus and innervate the diaphragm—would greatly interfere with the ability to breathe and might even be fatal. 12. Compression of the sciatic nerve produces the sensation that the leg has “fallen asleep.” **PAGE 481** 13. A neuronal pool is a functional group of organized interneurons within the CNS. 14. The five neuronal pool circuit patterns are divergence, convergence, serial processing, parallel processing, and reverberation. **PAGE 485** 15. A reflex is a rapid, automatic response to a specific stimulus. It is an important mechanism for maintaining homeostasis. 16. The minimum number of neurons required for a reflex arc is two. One must be a sensory neuron that brings impulses to the CNS, and the other a motor neuron that

transmits a response to the effector. 17. The suck reflex is an innate reflex. **PAGE 488** 18. All polysynaptic reflexes involve pools of interneurons, are intersegmental in distribution, and involve reciprocal inhibition, reverberating circuits, and the cooperation of several reflexes. 19. When intrafusal fibers are stimulated by gamma motor neurons, the muscle spindles become more sensitive. As a result, little if any stretching stimulus would be needed to stimulate the contraction of the quadriceps muscles in the patellar reflex. For this reason, the reflex response would appear more quickly. 20. This response is the tendon reflex. 21. During a withdrawal reflex, the limb on the opposite side is extended. This response is called a crossed extensor reflex. **PAGE 489** 22. Reinforcement is an enhancement of spinal reflexes. It occurs when the postsynaptic neuron enters a state of generalized facilitation caused by chronically active excitatory synapses. 23. A Babinski reflex is abnormal in adults. It indicates possible damage to descending tracts in the spinal cord.

Answers to Review Questions

PAGE 491

Level 1 Reviewing Facts and Terms

1. (a) white matter (b) anterior root (c) posterior root (d) pia mater (e) arachnoid mater (f) gray matter (g) spinal nerve (h) posterior root ganglion (i) dura mater 2. b 3. b 4. b 5. b 6. c 7. d 8. b 9. b 10. d 11. a 12. b 13. c 14. a 15. (a) 1 (b) 3 (c) 4 (d) 2 (e) 7 (f) 5 (g) 6 (h) 8

Level 2 Reviewing Concepts

16. The vertebral column continues to grow, extending beyond the spinal cord. The end of the spinal cord is visible as the conus medullaris near L₁, and the cauda equina extends the remainder of the vertebral column. 17. (1) arrival of stimulus and activation of receptor; (2) activation of sensory neuron; (3) information processing; (4) activation of a motor neuron; (5) response by an effector (muscle, gland, or adipose tissue) 18. b 19. In spinal anesthesia, a single dose of local anesthetic is injected into the subarachnoid space of the spinal cord. The movement of the cerebrospinal fluid distributes the anesthetic along the spinal cord. The effects include temporary muscle paralysis and sensory loss. 20. The cell bodies of spinal sensory neurons are located in the spinal ganglia of the posterior roots. Damage to these roots would result in the loss of sensory information. 21. Cerebrospinal fluid fills the subarachnoid space between the arachnoid mater and the pia mater. CSF acts as a shock absorber and a diffusion medium for dissolved gases, nutrients, chemicals, and wastes. 22. (1) involvement of pools of interneurons; (2) intersegmental distribution; (3) involvement of reciprocal inhibition; (4) motor response prolonged by reverberating circuits; (5) cooperation of reflexes to produce a coordinated, controlled response 23. Transection of the spinal cord at segment C₇ would most likely result in paralysis from the neck down. Transection at segment T₁₀ would produce paralysis and eliminate sensory input in the lower half of the body only. 24. b 25. b 26. d 27. If a reflex fails to appear when it is tested using the reinforcement procedure, the likelihood of nerve or CNS damage is increased.

Level 3 Critical Thinking and Clinical Applications

28. The median nerve is involved. 29. The gynecologist proposes epidural anesthesia. 30. The individual would still exhibit a defecation (bowel) and urination (urinary bladder) reflex because these spinal reflexes are processed at the level of the spinal cord. Efferent

impulses from the organs would stimulate specific interneurons in the sacral region that synapse with the motor neurons controlling the sphincters, thus bringing about emptying when the organs began to fill. (This is the same situation that exists in a newborn infant who has not yet fully developed the descending tracts required for conscious control.) However, an individual with the spinal cord transection at L_1 would lose voluntary control of the bowel and bladder because these functions rely on impulses carried by motor neurons in the brain that must travel down the cord and synapse with the interneurons and motor neurons involved in the reflex. **31.** Jane's condition is called shingles. The virus that causes chickenpox also causes shingles. This herpesvirus often remains dormant in neurons of the anterior horns of the spinal cord. Sometimes the virus reactivates and attacks neurons within the posterior roots of spinal nerves and sensory ganglia of cranial nerves.

Answers to Clinical Case Wrap-Up

PAGE 492 **1.** No. Recovery of motor activity or sensation is not expected inferior to the level of Grady's complete injury at T_{11} . Central nervous tissue (brain and spinal cord) has very limited healing ability. **2.** Grady would exhibit Babinski reflexes with toes going up (dorsiflexed), which is abnormal in adults (but not in infants). The descending motor pathways to the feet have been completely disrupted at T_{11} .

Answers to Figure-Based Questions

FIGURE 13-3 The area between the arachnoid mater and the pia mater is the subarachnoid space.

FIGURE 13-5 Somatic motor nuclei are located in the anterior horn.

FIGURE 13-9 The axillary, radial, and ulnar nerves branch from the brachial plexus.

FIGURE 13-15 Reflexes can be classified by development (innate or acquired), response (somatic or visceral), circuit complexity (monosynaptic or polysynaptic), and processing site (spinal or cranial).

Chapter 14

Answers to Checkpoints

PAGE 497 **1.** The four major regions of the brain are the cerebrum, cerebellum, diencephalon, and brainstem. **2.** The brainstem is made up of the midbrain, pons, and medulla oblongata. **3.** The rhombencephalon or hindbrain develops into the cerebellum, pons, and medulla oblongata. **PAGE 502** **4.** The layers of the cranial meninges are the outer dura mater, the middle arachnoid mater, and the inner pia mater. **5.** If the normal circulation or resorption of cerebrospinal fluid (CSF) became blocked, CSF would continue to be produced at the choroid plexus in each ventricle, but the fluid would remain there, causing the ventricles to swell—a condition known as hydrocephalus. **6.** If the rate of diffusion across the arachnoid granulations decreased, less CSF would reenter the bloodstream, and CSF would accumulate in the ventricles. The increased pressure within the ventricles due to accumulated CSF could damage the brain. **7.** Many water-soluble molecules are rare or absent in the extracellular (ECF), or cerebrospinal fluid (CSF), of the brain because the blood-brain barrier regulates the movement of such molecules from the blood to the ECF of the brain. **PAGE 505** **8.** The gracile nucleus and cuneate nucleus are responsible for relaying somatic sensory information to the thalamus. **9.** Damage to the medulla oblongata can be lethal because it

contains many vital autonomic reflex centers, including those that control breathing and regulate heart rate and force of contraction, which affect blood pressure. **10.** The pons contains (1) sensory and motor nuclei of cranial nerves (V, VI, VII, and VIII), (2) nuclei involved with the control of respiration, (3) nuclei and tracts that process and relay information sent to or from the cerebellum, and (4) ascending, descending, and transverse pontine fibers. **11.** Damage to the respiratory centers of the pons could result in loss of ability to modify the respiratory rhythmicity centers of the medulla oblongata, which set the basic pace for respiratory movements. **PAGE 506**

12. Two pairs of sensory nuclei make up the corpora quadrigemina: the superior colliculi and inferior colliculi. **13.** The superior colliculi of the midbrain control reflexive movements of the eyes, head, and neck to visual stimuli, such as a bright light. **PAGE 509**

14. Components of the cerebellar gray matter include the cerebellar cortex and cerebellar nuclei. **15.** The arbor vitae, which is the internal, white matter part of the cerebellum, connects the cerebellar cortex and nuclei with the cerebellar peduncles. **PAGE 512**

16. The main components of the diencephalon are the epithalamus, thalamus, and hypothalamus. **17.** Damage to the lateral geniculate body would interfere with the sense of sight. **18.** Changes in body temperature stimulate the pre-optic area of the hypothalamus, a component of the diencephalon. **PAGE 514** **19.** The limbic system is responsible for processing memories and creating emotional states, drives, and associated behaviors. **20.** Damage to the amygdaloid body would interfere with the sympathetic ("fight or flight") division of the autonomic nervous system (ANS). **PAGE 534** **21.** Projection fibers link the cerebral cortex to the spinal cord, passing through the diencephalon, brainstem, and cerebellum. **22.** Damage to the basal nuclei would result in decreased muscle tone and the loss of coordination of learned movement patterns. **23.** The primary motor cortex is located in the precentral gyrus of the frontal lobe of the cerebrum. **24.** Damage to the temporal lobes of the cerebrum would interfere with the processing of olfactory (smell) and auditory (sound) sensations. **25.** The stroke has damaged Broca's area (motor speech area), located in the left cerebral hemisphere.

26. The temporal lobe of the cerebrum is probably involved, specifically, the hippocampus and the amygdaloid body (amygdala). His problems may also involve other parts of the limbic system that act as a gate for loading and retrieving long-term memories. **27.** Cranial reflexes are automatic responses to stimuli that involve the sensory and motor fibers of cranial nerves. Both monosynaptic and polysynaptic reflex arcs occur. Cranial reflex testing is often used to assess damage to cranial nerves or to the associated processing centers in the brain. **28.** Shining a light in a person's eye tests the pupillary reflex and the consensual light reflex, which are visceral reflexes.

29. The cerebellum is involved in the coordination of movement. **30.** The cerebellum is involved in the coordination of movement. **31.** The cerebellum is involved in the coordination of movement. **32.** The cerebellum is involved in the coordination of movement. **33.** The cerebellum is involved in the coordination of movement. **34.** The cerebellum is involved in the coordination of movement. **35.** The cerebellum is involved in the coordination of movement. **36.** The cerebellum is involved in the coordination of movement. **37.** The cerebellum is involved in the coordination of movement. **38.** The cerebellum is involved in the coordination of movement. **39.** The cerebellum is involved in the coordination of movement. **40.** The cerebellum is involved in the coordination of movement. **41.** The cerebellum is involved in the coordination of movement. **42.** The cerebellum is involved in the coordination of movement. **43.** The cerebellum is involved in the coordination of movement. **44.** The cerebellum is involved in the coordination of movement. **45.** The cerebellum is involved in the coordination of movement. **46.** The cerebellum is involved in the coordination of movement. **47.** The cerebellum is involved in the coordination of movement. **48.** The cerebellum is involved in the coordination of movement. **49.** The cerebellum is involved in the coordination of movement. **50.** The cerebellum is involved in the coordination of movement. **51.** The cerebellum is involved in the coordination of movement. **52.** The cerebellum is involved in the coordination of movement. **53.** The cerebellum is involved in the coordination of movement. **54.** The cerebellum is involved in the coordination of movement. **55.** The cerebellum is involved in the coordination of movement. **56.** The cerebellum is involved in the coordination of movement. **57.** The cerebellum is involved in the coordination of movement. **58.** The cerebellum is involved in the coordination of movement. **59.** The cerebellum is involved in the coordination of movement. **60.** The cerebellum is involved in the coordination of movement. **61.** The cerebellum is involved in the coordination of movement. **62.** The cerebellum is involved in the coordination of movement. **63.** The cerebellum is involved in the coordination of movement. **64.** The cerebellum is involved in the coordination of movement. **65.** The cerebellum is involved in the coordination of movement. **66.** The cerebellum is involved in the coordination of movement. **67.** The cerebellum is involved in the coordination of movement. **68.** The cerebellum is involved in the coordination of movement. **69.** The cerebellum is involved in the coordination of movement. **70.** The cerebellum is involved in the coordination of movement. **71.** The cerebellum is involved in the coordination of movement. **72.** The cerebellum is involved in the coordination of movement. **73.** The cerebellum is involved in the coordination of movement. **74.** The cerebellum is involved in the coordination of movement. **75.** The cerebellum is involved in the coordination of movement. **76.** The cerebellum is involved in the coordination of movement. **77.** The cerebellum is involved in the coordination of movement. **78.** The cerebellum is involved in the coordination of movement. **79.** The cerebellum is involved in the coordination of movement. **80.** The cerebellum is involved in the coordination of movement. **81.** The cerebellum is involved in the coordination of movement. **82.** The cerebellum is involved in the coordination of movement. **83.** The cerebellum is involved in the coordination of movement. **84.** The cerebellum is involved in the coordination of movement. **85.** The cerebellum is involved in the coordination of movement. **86.** The cerebellum is involved in the coordination of movement. **87.** The cerebellum is involved in the coordination of movement. **88.** The cerebellum is involved in the coordination of movement. **89.** The cerebellum is involved in the coordination of movement. **90.** The cerebellum is involved in the coordination of movement. **91.** The cerebellum is involved in the coordination of movement. **92.** The cerebellum is involved in the coordination of movement. **93.** The cerebellum is involved in the coordination of movement. **94.** The cerebellum is involved in the coordination of movement. **95.** The cerebellum is involved in the coordination of movement. **96.** The cerebellum is involved in the coordination of movement. **97.** The cerebellum is involved in the coordination of movement. **98.** The cerebellum is involved in the coordination of movement. **99.** The cerebellum is involved in the coordination of movement. **100.** The cerebellum is involved in the coordination of movement.

Answers to Review Questions

PAGE 537

Level 1 Reviewing Facts and Terms

1. (a) cerebrum (b) diencephalon (c) midbrain (d) pons (e) medulla oblongata (f) cerebellum **2.** (a) periosteal cranial dura (b) dural sinus (c) meningeal cranial dura (d) subdural space (e) arachnoid mater (f) subarachnoid space (g) pia mater **3.** d **4.** a **5.** b **6.** c **7.** c **8.** c **9.** a **10.** b **11.** d **12.** a **13.** b **14.** somatosensory association cortex, visual association area, auditory association area, and somatic motor association area **15.** (1) portions of the hypothalamus where the capillary endothelium is extremely permeable; (2) capillaries in the pineal gland; (3) capillaries at the choroid plexus

16. CN I: olfactory nerve; CN II: optic nerve; CN III: oculomotor nerve; CN IV: trochlear nerve; CN V: trigeminal nerve; CN VI: abducens nerve; CN VII: facial nerve; CN VIII: vestibulocochlear nerve; CN IX: glossopharyngeal nerve; CN X: vagus nerve; CN XI: accessory nerve; and CN XII: hypoglossal nerve

Level 2 Reviewing Concepts

17. The brain can respond with greater versatility because it includes many more interneurons, pathways, and connections than the tracts of the spinal cord. **18.** The cerebellum adjusts voluntary and involuntary motor activities based on sensory information and stored memories of previous experiences. **19. c** **20.** When the prefrontal cortex is damaged, estimating temporal relationships between events, and interpreting ongoing events and predicting their consequences become difficult. Prefrontal lobotomy was used to treat mental illnesses associated with violent or antisocial behavior. **21.** Roles of the hypothalamus include (1) secretion of two hormones, (2) regulation of body temperature, (3) control of autonomic function, (4) coordination between voluntary and autonomic functions, (5) coordination of activities of the nervous and endocrine systems, (6) regulation of circadian rhythms, (7) subconscious control of skeletal muscle contractions, and (8) production of emotions and behavioral drives. **22.** The lateral geniculate body relays visual information to the visual cortex, whereas the medial geniculate body relays auditory information to the auditory cortex. **23.** The red nuclei. They subconsciously control the position of the upper limbs and background muscle tone. **24.** The left cerebral hemisphere contains the specialized language areas and speech centers and is responsible for analytical tasks, logical decision making, and language-based skills (reading, writing, and speaking). The right hemisphere analyzes sensory information and relates the body to the sensory environment. Interpretive centers in this hemisphere permit the identification of familiar objects by touch, smell, sight, and taste. The right cerebral hemisphere is also important in understanding three-dimensional relationships and in analyzing the emotional context of a conversation. **25. e** **26. a** **27.** The reticular formation. It is located centrally in the medulla oblongata and extends into the pons and midbrain.

Level 3 Critical Thinking and Clinical Applications

28. Sensory innervation of the nasal mucosa occurs by the maxillary nerve (V_2), a division of the trigeminal nerve (V). Irritation of the nasal lining by ammonia increases the frequency of action potentials along the maxillary nerve through the semilunar ganglion to reach centers in the midbrain, which in turn excite the neurons of the reticular activating system (RAS). Increased activity by the RAS can bring the cerebrum back to consciousness. **29.** The officer is testing the function of Elias's cerebellum. Many drugs, including alcohol, have pronounced effects on cerebellar function. A person who is under the influence of alcohol cannot properly anticipate the range and speed of limb movement, because processing and correction by the cerebellum are slow. Because of disturbance in muscular coordination (ataxia), Elias might have a difficult time walking a straight line or touching his finger to his nose. **30.** The pituitary gland is located in the sella turcica of the skull, filling up the limited available space. It lies in close contact with the optic chiasm, where fibers from the medial half of each retina cross over to the

other side of the brain. Enlargement of the pituitary gland will burden the crossing fibers, resulting in narrowing of the field of view width. Regular measurements will give an indication of the growth of the tumor. **31.** In any inflamed tissue, edema occurs in the area of inflammation. The accumulation of fluid in the subarachnoid space can cause damage by pressing against neurons. If the intracranial pressure is excessive, brain damage can occur, and if the pressure involves vital autonomic reflex areas, death could occur. **32.** Most of the functional problems observed in shaken baby syndrome are the result of trauma to the cerebral hemispheres due to contact between the brain and the inside of the skull. Damage to and distortion of the brainstem and medulla oblongata can cause death.

Answers to Clinical Case Wrap-Up

PAGE 538 **1.** The cell bodies of the motor nerves for the facial nerve (cranial nerve VII) originate in the pons and so damage caused by a stroke to this area specifically is likely to also result in a similar outcome to that seen in Shane's Bell's Palsy. **2.** The facial nerve innervates the muscles on the same (ipsilateral) side of the face that it originates from and so if the left side of the face is experiencing paralysis, then it is the left facial nerve that is affected.

Answers to Figure-Based Questions

FIGURE 14-1 The brainstem is made up of the midbrain, the pons, and the medulla oblongata.

FIGURE 14-3 The layers surrounding the brain (from deepest to most superficial) are the pia mater, the arachnoid mater, and the dura mater (meningeal cranial dura and periosteal cranial dura).

FIGURE 14-9 The cerebellar cortex and cerebellar nuclei make up the gray matter in the cerebellum.

FIGURE 14-13 The central sulcus divides the anterior frontal lobe from the more posterior parietal lobe.

FIGURE 14-15 The globus pallidus of the lentiform nucleus is more medial and the putamen of the lentiform nucleus is more lateral.

FIGURE 14-20 The lateral geniculate body of the thalamus receives visual information before it reaches the visual cortex.

FIGURE 14-22 The divisions of the trigeminal nerve are the ophthalmic nerve (V_1), the maxillary nerve (V_2), and the mandibular nerve (V_3).

Chapter 15

Answers to Checkpoints

PAGE 542 **1.** The specialized cells that monitor specific conditions in the body or the external environment are sensory receptors.

2. Yes, it is possible for somatic motor commands to occur at the subconscious (involuntary) level. They also occur at the conscious (voluntary) level. **PAGE 545** **3.** Receptor A provides more precise sensory information because it has a smaller receptive field on the skin surface. **4.** Adaptation is a decrease in receptor sensitivity or a decrease in perception during constant stimulation. **PAGE 550**

5. The major types of general sensory receptors (and the stimuli that excite them) are nociceptors (pain), thermoreceptors (temperature), mechanoreceptors (physical distortion), and chemoreceptors (chemical concentration). **6.** The three classes of mechanoreceptors are

tactile receptors, baroreceptors, and proprioceptors. **7.** If proprioceptors in a person's legs could not relay information about limb position and movement to the CNS (especially the cerebellum), their movements would be uncoordinated and they likely could not walk. **PAGE 555**

8. The tract being compressed is the gracile fasciculus in the posterior column of the spinal cord, which carries information about touch and pressure from the lower limbs to the brain. **9.** The tracts that carry action potentials generated by nociceptors (pain receptors) are the lateral spinothalamic tracts.

10. The left cerebral hemisphere (specifically, the primary somatosensory cortex) receives impulses carried by the right gracile fasciculus. **PAGE 560** **11.** The anatomical basis for opposite-side motor control is crossing over (decussation) of axons, so the motor fibers of the corticospinal pathway innervate lower motor neurons on the opposite side of the body. **12.** An injury involving the superior portion of the motor cortex would affect the ability to control the muscles in the upper limb and the proximal portion of the lower limb. **13.** Stimulation of the motor neurons of the red nucleus would increase stimulation of the skeletal muscles in the upper limbs, thereby increasing their muscle tone.

Answers to Review Questions

PAGE 561

Level 1 Reviewing Facts and Terms

1. c 2. Tonic 3. c 4. d
5.

6. (1) free nerve endings: sensitive to touch and pressure; (2) root hair plexus: monitors distortions and movements across the body surface; (3) tactile discs: detect fine touch and pressure; (4) bulbous (Ruffini) corpuscles: sensitive to pressure and distortion of the skin; (5) lamellar (Pacinian) corpuscles: sensitive to pulsing or vibrating stimuli (deep pressure); (6) tactile (Meissner) corpuscles: detect fine touch and pressure. **7.** The three major groups of proprioceptors are (1) muscle spindles, (2) Golgi tendon organs, and (3) receptors in joint capsules. **8.** (1) spinothalamic pathway: provides conscious sensations of poorly localized ("crude") touch, pressure, pain, and temperature; (2) posterior column pathway: provides conscious sensations of highly localized ("fine") touch, pressure, vibration, and proprioception; (3) spinocerebellar pathway: carries proprioceptive information about the position of skeletal muscles,

tendons, and joints to the cerebellum. **9.** The corticobulbar tracts provide conscious motor control over skeletal muscles.

10. lower motor neurons of anterior horns of spinal cord **11.** Baroreceptors are pressure receptors. They monitor blood pressure in the walls of major vessels such as the carotid arteries and the aortic arch, thus regulating cardiac function and the blood flow to vital organs. In the lungs they monitor lung expansion, thus controlling the respiration pace. **12.** b **13.** Slow-pain sensations are carried by unmyelinated type C fibers and activate the reticular formation and the thalamus. One is aware of the pain, but with only a general idea of the area affected.

Level 2 Reviewing Concepts

14. In transduction, a sensory receptor converts an arriving stimulus into an action potential. In adaptation, receptor sensitivity is reduced in the presence of a constant stimulus. **15.** A motor homunculus, a mapped-out area of the primary motor cortex, provides an indication of the degree of fine motor control available. A sensory homunculus indicates the relative density of peripheral sensory receptors. **16.** A sensory neuron that delivers sensations to the CNS is a first-order neuron. Within the CNS, the axon of the first-order neuron synapses on a second-order neuron, which is an interneuron located in the spinal cord or brainstem. The second-order neuron synapses on a third-order neuron in the thalamus. The axons of third-order neurons synapse on neurons of the primary somatosensory cortex of the cerebral hemispheres. **17.** Damage to the left side of the primary motor cortex in the region that controls the muscles of the arm and hand would interfere with the movement of the right upper limb. **18.** Amyotrophic lateral sclerosis is caused by a defect in axonal transport. Destruction of the motor neurons controlling a muscle results in atrophy of the muscle concerned. **19.** Visceral organs have fewer sensory receptors than the skin. The sensory information is poorly localized because the receptive fields are very large and widely separated. **20.** Strong pain sensations arriving at a particular segment of the spinal cord can cause stimulation of the interneurons of the spinothalamic pathway. This stimulation is interpreted by the somatosensory cortex as originating in the region of the body surface associated with the origin of that same labeled line or pathway.

Level 3 Critical Thinking and Clinical Applications

21. The cerebellum adjusts the number of motor commands necessary for a movement in a pattern that changes from moment to moment, making the movement precisely controlled. **22.** Injuries to the primary motor cortex eliminate the ability to produce fine control of motor units. However, if the cerebral nuclei are functional, gross movements would still be possible. Harry should still be able to walk, maintain his balance, and perform voluntary and involuntary movements using the rubrospinal and reticulospinal tracts in place of the corticospinal tracts. Although these movements may be awkward or difficult, they will still be possible. **23.** The source of Victor's problems is situated in the basal nuclei of the cerebrum. The basal nuclei control the upper motor neurons in the motor pathways, based on input from the cerebral cortex and the substantia nigra in the midbrain. A good balance between the activity of excitatory and inhibitory neurons is required to result in well-controlled voluntary movement. In Parkinson's disease, however, this balance is lost. In Victor's case, the imbalance results in troubled movement, diminished control of vocal muscles, and shaking hands.

Answers to Clinical Case Wrap-Up

PAGE 562 1. All the principal descending motor pathways carry information that would have been affected by the brain damage causing Michael's cerebral palsy. They include the corticospinal pathway, the medial pathway, and the lateral pathway. 2. Poor motor control of the muscles used in swallowing can contribute to an increased risk of choking and poor infant nutrition, which can affect development and even be life threatening.

Answers to Figure-Based Questions

FIGURE 15-1 The involuntary motor pathway directs a faster response than the voluntary motor pathway.

FIGURE 15-2 The area monitored by a single receptor cell is its receptive field. The branching free nerve endings extend across the area and are receptive to stimuli.

FIGURE 15-4 Root hair plexuses, bulbous (Ruffini) corpuscles, and lamellar (Pacinian) corpuscles are located in the dermis.

FIGURE 15-7 The lateral spinothalamic carries the sensations of pain and temperature.

FIGURE 15-10 The lateral pathway has one tract (the rubrospinal tract), the corticospinal pathway has two tracts (the lateral and anterior corticospinal tracts), and the medial pathway has three tracts (the reticulospinal, the tectospinal, and the vestibulospinal tracts).

Chapter 16

Answers to Checkpoints

PAGE 566 1. The two major divisions of the ANS are the sympathetic division and the parasympathetic division. 2. Two neurons are needed to carry an action potential from the spinal cord to smooth muscles in the intestine. The first neuron carries the action potential from the spinal cord to the autonomic ganglion, and a second neuron carries the action potential from the autonomic ganglion to the smooth muscles in the intestinal wall. 3. The sympathetic division of the ANS is responsible for the physiological changes that occur in response to stress (confronting an angry dog) and increased activity (running). **PAGE 571** 4. Sympathetic chain ganglia lie on each side of the vertebral column; they are also called paravertebral ganglia. Collateral ganglia are anterior to the vertebral column; they are also called prevertebral ganglia. 5. The nerves that synapse in collateral ganglia originate in the inferior thoracic and superior lumbar regions (between T₁ and L₂) of the spinal cord. The preganglionic fibers they contain pass through the sympathetic chain ganglia to the collateral ganglia. **PAGE 573** 6. Because preganglionic fibers of the sympathetic nervous system release acetylcholine (ACh), a drug that stimulates cholinergic receptors would stimulate the postganglionic fibers of sympathetic nerves, resulting in increased sympathetic activity. 7. Blocking the beta receptors on cells would decrease or prevent sympathetic stimulation of tissues containing those cells. Heart rate, force of contraction of cardiac muscle, and contraction of smooth muscle in the walls of blood vessels would decrease, lowering blood pressure. **PAGE 574** 8. The vagus nerve (X) carries preganglionic parasympathetic fibers that innervate the lungs, heart, stomach, liver, pancreas, and parts of the small and large intestines (as well as several other visceral organs). 9. The parasympathetic division is sometimes referred to as the anabolic system because parasympathetic stimulation leads to a general increase in the nutrient content of the blood. Cells throughout the body respond to the increase by absorbing the nutrients and using them to support growth and other anabolic activities. **PAGE 575** 10. The neurotransmitter

acetylcholine (ACh) is released by all parasympathetic neurons.

11. The two types of cholinergic receptors on the postsynaptic membranes of parasympathetic neurons are nicotinic receptors and muscarinic receptors. 12. Stimulation of muscarinic receptors, a type of cholinergic receptor located in postganglionic synapses of the parasympathetic nervous system, would cause K⁺ channels to open, resulting in hyperpolarization of cardiac plasma membranes and a decreased heart rate. **PAGE 576** 13. In the sympathetic division, axons emerge from the thoracic and lumbar segments of the spinal cord and innervate ganglia relatively close to the spinal cord, whereas in the parasympathetic division, axons emerge from the brainstem and sacral segments of the spinal cord and innervate ganglia very close to (or within) target organs. 14. Divergence refers to the number of synapses a single preganglionic fiber may have with ganglionic neurons. The sympathetic division has a much higher degree of divergence than the parasympathetic division. A greater amount of divergence results in more complex and coordinated responses. **PAGE 579** 15. General responses to increased sympathetic activity include heightened mental alertness, increased metabolic rate, reduced digestive and urinary functions, activation of energy reserves, increased respiratory rate and dilation of respiratory passageways, elevated heart rate and blood pressure, and activation of sweat glands. General responses to increased parasympathetic activity include decreased metabolic rate, decreased heart rate and blood pressure, increased secretion by salivary and digestive glands, increased motility and blood flow in the digestive tract, and stimulation of urination and defecation. 16. Most blood vessels receive sympathetic stimulation, so a loss of sympathetic tone would relax the smooth muscles lining the vessels; the resulting vasodilation would increase blood flow to the tissue. 17. In anxious individuals, an increase in sympathetic stimulation would probably cause some or all of the following changes: a dry mouth; increased heart rate, blood pressure, and rate of breathing; cold sweats; an urge to urinate or defecate; a change in the motility of the digestive tract (that is, "butterflies in the stomach"); and dilated pupils.

PAGE 581 18. A visceral reflex is an autonomic reflex initiated in the viscera. It is an automatic motor response that can be modified, facilitated, or inhibited by higher centers, especially those of the hypothalamus. 19. A brain tumor that interferes with hypothalamic function would also interfere with autonomic function, because centers in the hypothalamus are involved with autonomic (visceral) function. **PAGE 586** 20. Higher-order functions require action by the cerebral cortex, involve both conscious and unconscious information processing, and are subject to modification and adjustment over time. 21. Test-taking involves short-term memory, although your instructor would like you to transfer this information to long-term memory. 22. If a person's RAS were suddenly stimulated while they were asleep, it would rouse the cerebrum to a state of consciousness, and the person would wake up. 23. A drug that increases the amount of serotonin released in the brain would produce a heightened perception of certain sensory stimuli (e.g., auditory or visual stimuli) and hallucinations. 24. Amphetamines stimulate the secretion of dopamine. **PAGE 587** 25. Some possible reasons for slower recall and for loss of memory that occur with age include a loss of neurons (possibly those involved in specific memories), changes in synaptic organization of the brain, changes in the neurons themselves, and decreased blood flow, which would affect the metabolic rate of neurons and perhaps slow the retrieval of information from memory. 26. Common age-related anatomical changes in the nervous system include a reduction in brain size and weight, a reduction in the number

of neurons, a decrease in blood flow to the brain, changes in the synaptic organization of the brain, and intracellular and extracellular changes in CNS neurons. **27.** Alzheimer's disease is the most common form of senile dementia. **28.** The nervous system controls the actions of the arrector pili muscles and sweat glands of the integumentary system. It also controls skeletal muscle contractions of the muscular system, which, in turn, affects the thickening of bones of the skeletal system. It also coordinates muscular activities associated with the respiratory and cardiovascular systems.

Answers to Review Questions

PAGE 591

Level 1 Reviewing Facts and Terms

1.

2. d **3. b** **4. e** **5. c** **6.** preganglionic neuron $T_5-L_2 \rightarrow$ collateral ganglia $\rightarrow$ postganglionic fibers $\rightarrow$ visceral effector in abdominopelvic cavity **7.** (1) rectum; (2) kidney; (3) urinary bladder; (4) uterus and ovaries; (5) penis and scrotum **8.** Long visceral reflexes coordinate the activities of an entire organ and involve interneurons within the CNS. Short visceral reflexes bypass the CNS and control patterns of activity in one small part of a target organ. **9.** Increased neurotransmitter release, facilitation of synapses, and the formation of additional synaptic connections are thought to be involved in memory formation and storage. **10.** The RAS is a neural network in the reticular formation of the brain. It extends from the medulla oblongata into the midbrain. Numerous stimuli activating the RAS pass through the thalamus to the cerebral cortex controlling consciousness. Stimulation of the RAS induces activation of the cortex. When the RAS is inactive, so is the cortex. **11.** Aging causes a reduction in brain volume and weight, a reduction in the number of neurons, a decrease in blood flow to the brain, changes in synaptic organization, and intracellular and extracellular changes in CNS neurons. **12. c** **13. a**

14. The sympathetic division stimulates glycogen breakdown and synthesis and release of glucose in the liver and decreases exocrine secretion in the pancreas. The parasympathetic division stimulates synthesis of glycogen in the liver and increases exocrine secretion in the pancreas. **15.** (1) celiac ganglion; (2) superior mesenteric ganglion; (3) inferior mesenteric ganglion **16.** The sympathetic division of the ANS stimulates (1) the secretion from the sweat glands and (2) induces the contraction of the arrector pili muscles. The parasympathetic division has no effect. **17.** The four pairs of cranial nerves are CN III, CN VII, CN IX, and CN X. **18.** (1) cardiac plexus: heart rate increases (sympathetic)/decreases (parasympathetic); force of heart contraction increases (sympathetic)/decreases (parasympathetic); blood pressure increases (sympathetic)/decreases (parasympathetic); (2) pulmonary plexus: respiratory passageways dilate (sympathetic)/constrict (parasympathetic); (3) esophageal plexus: respiratory rate increases (sympathetic)/decreases (parasympathetic); (4) celiac plexus: digestion inhibited (sympathetic)/stimulated (parasympathetic); (5) inferior mesenteric plexus: digestion inhibited (sympathetic)/stimulated (parasympathetic); (6) hypogastric plexus: defecation inhibited (sympathetic)/stimulated (parasympathetic); urination inhibited (sympathetic)/stimulated (parasympathetic); sexual organs: stimulation of secretion (sympathetic)/erection (parasympathetic) **19.** Sleep and coma represent different degrees of the state of unconsciousness. A person who is asleep is unconscious but can still be awakened by normal sensory stimuli. A person in a coma is unconscious and cannot be awakened, even by strong stimuli.

Level 2 Reviewing Concepts

20. a **21. c** **22.** The preganglionic fibers innervating the cervical ganglia originate in the anterior roots of the thoracic segments, which are undamaged. **23. a** **24. a** **25. d** **26.** Due to the stimulation of the sympathetic division, you would experience increased respiratory rate, increased peripheral vasoconstriction and elevation of blood pressure, increased heart rate and force of contraction, and an increased rate of glucose release into the bloodstream. **27.** Beta-1 receptors: increase metabolic activity in skeletal muscles and heart muscle; beta-2 receptors: induce relaxation of smooth muscles along the respiratory tract; beta-3 receptors: induce lipolysis releasing fatty acids into the bloodstream. **28.** Cholinergic receptors are found in all the ganglia of the ANS, so nicotine would stimulate both sympathetic and parasympathetic responses in cardiovascular tissues. Although increased sympathetic stimulation increases heart rate and force of contraction, increased parasympathetic stimulation simultaneously decreases blood flow to the heart muscle. In addition to elevating heart rate and force of contraction, sympathetic stimulation also constricts peripheral blood vessels, all of which contribute to increased blood pressure. **29.** The upsetting situation would be processed by the higher centers of the CNS and relayed to the hypothalamus. The hypothalamus could suppress the vasomotor center of the medulla oblongata, resulting in fewer sympathetic impulses to peripheral blood vessels. This would cause a decrease in sympathetic tone in the smooth muscle of the blood vessels, resulting in vasodilation. The vasodilation would cause blood to pool in the limbs, decreasing the amount of blood returning to the heart and producing shock.

Level 3 Critical Thinking and Clinical Applications

30. The sudden explosive ejection of air called coughing is an example of a parasympathetic visceral reflex, coordinated by the coughing center in the medulla oblongata. **31.** The molecule is probably mimicking NE and binding to alpha-1 receptors.

Answers to Clinical Case Wrap-Up

PAGE 592 1. The first part of Mabella's brain to be affected is the hippocampus in the limbic system where memory is encoded. Later progressive losses in cognition involve wide areas of her cerebral cortex. 2. First, Mabella loses orientation to time, then to place, and finally to person. The memory of person is the last to go because it is a deep-seated, long-term, associative memory. 3. A cholinesterase inhibitor will inactivate acetylcholinesterase, the enzyme whose role is to break down the neurotransmitter acetylcholine at the cholinergic synapse. This will help maintain ACh levels in the early phases of Alzheimer's disease.

FIGURE 16-4 Norepinephrine (NE) is released from most varicosities in the sympathetic division.

FIGURE 16-7 The short reflex bypasses the central nervous system.

FIGURE 16-11 Visual input arrives via CN II and auditory input arrives via CN VIII.

Chapter 17

Answers to Checkpoints

PAGE 598 1. Olfaction is the sense of smell; it involves olfactory sensory neurons in paired olfactory organs responding to airborne chemical stimuli. 2. Axons from the olfactory epithelium collect into bundles that reach the olfactory bulb. In the olfactory pathway, axons leaving the olfactory bulb then travel along the olfactory tract to the olfactory cortex, hypothalamus, and portions of the limbic system. 3. By the end of the lab period, central adaptation has occurred. Inhibition of synapses along the olfactory pathway reduces the amount of information reaching the olfactory cortex, even though the olfactory neurons remain active. **PAGE 600**

4. Gustation is the sense of taste, provided by taste receptor cells (TRCs), also called gustatory epithelial cells, responding to dissolved chemical stimuli. 5. Taste receptor cells (gustatory epithelial cells) in taste buds are sensitive only to molecules and ions that are in solution. If the tongue surface is dry, the salt ions or sugar molecules have no moisture in which to dissolve, so they will not stimulate the cells. 6. The 80-year-old man is experiencing the effects of several age-related gustatory and olfactory changes. The number of taste buds decreases dramatically after age 50, and those that remain are not as sensitive as they once were. In addition, the loss of olfactory sensory neurons contributes to the perception of fewer flavors in foods. **PAGE 608** 7. The conjunctiva would be the first layer of the eye affected by inadequate tear production. Drying of the conjunctiva would produce an irritated, scratchy feeling. 8. Riley will likely be unable to see at all. The fovea centralis (fovea) contains only cones, which need high-intensity light to be stimulated. The dimly lit room contains light that is too weak to stimulate the cones. 9. If the scleral venous sinus (canal of Schlemm) were blocked, the aqueous humor could not drain, producing an eye condition called glaucoma. Accumulation of this fluid increases the pressure within the eye, distorting soft tissues and interfering with vision. If untreated, the condition would ultimately cause blindness. **PAGE 611** 10. The focal point is the point at which the light rays from an object intersect on the retina.

11. When the lens becomes more rounded, the person is looking at

an object that is close to them. **PAGE 619** 12. If a person were born without cones, they would still have vision—so long as they had functioning rods—but they would lack color vision and see in black and white only. 13. A vitamin A deficiency would reduce the quantity of retinal the body could produce, thereby interfering with night vision (which operates at the body's threshold ability to respond to light). 14. Vision would be impaired. Decreased phosphodiesterase activity would increase intracellular cGMP levels, which, by keeping gated sodium ion channels open, would prevent both hyperpolarization of the photoreceptor and a decrease in its neurotransmitter release. There would be no signal to the bipolar cell that a photon had been absorbed. **PAGE 633**

15. If the round window could not move, the perilymph would not be moved by the vibration of the stapes at the oval window, reducing or eliminating the perception of sound. 16. The loss of stereocilia (as a result of constant exposure to loud noises, for instance) would reduce hearing sensitivity and could lead to deafness.

17. If the auditory tube were blocked, it would not be possible to equalize the pressure on both sides of the tympanic membrane. If external pressure then decreases, the pressure in the middle ear would be greater than that on the outside, forcing the tympanic membrane outward and producing pain.

Answers to Review Questions

PAGE 636

Level 1 Reviewing Facts and Terms

1. The vallate papillae appear near the posterior margin of the tongue as an inverted "V". 15. The fibrous layer (a) is composed of the sclera and the cornea and (b) provides mechanical support and some physical protection, serves as an attachment site for the extrinsic eye muscles, and contains structures that assist in the focusing process. 16. The vascular layer consists of the iris, ciliary body, and choroid. 17. The two muscles found in the middle ear are the tensor tympani and stapedius. They protect the tympanic membrane and ossicles from violent movements when we are exposed to very loud noises.

Level 2 Reviewing Concepts

18. Axons leaving the olfactory epithelium collect into 20 or more bundles that penetrate the cribriform plate of the ethmoid to reach the olfactory bulbs of the cerebrum. Axons leaving the olfactory bulb travel along the olfactory tract to reach the olfactory cortex, hypothalamus, and portions of the limbic system. 19. The olfactory receptor surface of a dog is many times greater than that of a human and some other vertebrates, which makes the dog good at detecting drugs and explosives. 20. When the ciliary muscle contracts, the shape of the lens becomes rounder, enabling it to produce sharp images of nearby objects. 21. a 22. c 23. c

Level 3 Critical Thinking and Clinical Applications

24. Taste perception differs between individuals. Broccoli and Brussels sprouts contain a compound related to phenylthiocarbamide (PTC). PTC tastes bitter to some and is tasteless to others. 25. Myopia is corrected by (a) concave lenses. 26. In removing the polyps, some of the olfactory epithelium was probably damaged or destroyed, decreasing the area available for the solution

of odorants and reducing the intensity of the stimulus. As a result, after the surgery it would take a larger stimulus to provide the same level of smell. **27.** The auditory tube forms a direct connection between the nasopharynx and the middle ear. Microorganisms causing infection in the throat can reach the middle ear through this connecting tube and cause infection in the middle ear.

28. When Juan closes his eyes, visual cues are gone, and his brain must rely solely on proprioceptive information from the equilibrium centers of the internal ear to maintain normal posture. Because either the internal ear receptors or the sensory nerves are not functioning normally, he is unstable. The most likely reason for his drift to the left is that he is getting inappropriate sensations from equilibrium receptors, at either the maculae (affecting his ability to determine which way is “down”) or one of the horizontal semi-circular ducts (making him attempt to compensate for a perceived roll to the right).

Answers to Clinical Case Wrap-Up

PAGE 637 **1.** A visual acuity of 20/200 means Makena must be 20 feet away from an object to see it as clearly as someone with normal vision would see it at 200 feet. In the United States she would be considered legally blind. **2.** If Makena’s vision is corrected to a state of emmetropia, her vision would be corrected to normal vision.

Answers to Figure-Based Questions

FIGURE 17-4 The lacrimal gland is located superior and lateral to the eye.

FIGURE 17-7 Amacrine cells are found where bipolar cells synapse with ganglion cells. Horizontal cells are found where bipolar cells synapse with photoreceptors (rods and cones).

FIGURE 17-21 The tympanic cavity and auditory ossicles are found in the middle ear.

FIGURE 17-28 The scala vestibuli and scala tympani contain perilymph (a fluid similar in composition to cerebrospinal fluid). The cochlear duct contains endolymph (a fluid with electrolyte concentrations that differ from other bodily fluids).

Chapter 18

Answers to Checkpoints

PAGE 641 **1.** A hormone is a chemical messenger that is secreted by one cell and travels through the bloodstream to affect the activities of cells in other parts of the body. **2.** Paracrine communication is the use of chemical messengers (paracrine) to transfer information from cell to cell within a single tissue. **3.** The five mechanisms of intercellular communication are direct, paracrine, autocrine, endocrine, and synaptic. **PAGE 646** **4.** A cell’s hormonal sensitivities are determined by the presence or absence of extracellular and intracellular receptors that bind a given hormone. **5.** A substance that inhibits adenylate cyclase, the enzyme that converts ATP to cAMP, would block the action of any hormone that requires cAMP as a second messenger. **6.** Humoral stimuli are those involving changes in the composition of the extracellular fluid. Such a stimulus triggers the secretion of a hormone, and the direct or indirect effects of the hormone reduce the intensity of the stimulus. **PAGE 655** **7.** The two lobes of the pituitary gland are the anterior lobe and the posterior lobe. **8.** In dehydration, blood osmotic concentration is increased, which would stimulate the posterior lobe of the pituitary gland to release more ADH. **9.** Somatomedins

mediate the action of growth hormone. Elevated levels of growth hormone typically accompany elevated levels of somatomedins. **10.** An elevated circulating level of cortisol would inhibit the endocrine cells that control the release of ACTH from the pituitary gland, so the ACTH level would decrease. This is an example of a negative feedback mechanism. **PAGE 660** **11.** Thyroxine (T_4), triiodothyronine (T_3), and calcitonin (CT) are hormones associated with the thyroid gland. **12.** A person whose diet lacks iodine would be unable to form the thyroid hormones thyroxine (T_4) and triiodothyronine (T_3). As a result, you would expect to see signs and symptoms associated with their deficiency: decreased metabolic rate, decreased body temperature, a poor response to physiological stress, and an increase in the size of the thyroid gland (goiter).

13. Most of the body’s reserves of the thyroid hormones T_4 and T_3 are bound to blood-borne proteins called thyroid-binding globulins. Because these compounds represent such a large reservoir of T_4 and T_3 , it takes several days after removal of the thyroid gland for the blood level of T_4 and T_3 to decrease. **PAGE 662**

14. The parathyroid glands are embedded in the posterior surfaces of the lateral lobes of the thyroid gland. **15.** The hormone secreted by the parathyroid glands is parathyroid hormone (PTH).

16. The removal of the parathyroid glands would result in a decrease in the blood concentration of calcium ions. **PAGE 665**

17. The two regions of the adrenal gland are the cortex and medulla. The cortex secretes mineralocorticoids (mainly aldosterone), glucocorticoids (mainly cortisol, corticosterone, and cortisone), and androgens; the medulla secretes epinephrine and norepinephrine. **18.** The three zones of the adrenal cortex from superficial to deep are the zona glomerulosa, zona fasciculata, and zona reticularis. **19.** One function of cortisol is to decrease the cellular use of glucose while increasing both the available glucose (by promoting the breakdown of glycogen) and the conversion of amino acids to carbohydrates. Therefore, the net result of elevated cortisol level would be an elevation of blood glucose. **PAGE 666** **20.** Pinealocytes are the hormone-secreting cells of the pineal gland.

21. Increased amounts of light would inhibit the production (and release) of melatonin from the pineal gland, which receives neural input from the optic tracts. Melatonin secretion is influenced by day–night patterns. **22.** Melatonin influences circadian rhythms, inhibits reproductive functions, and protects against free radical damage. **PAGE 669** **23.** The cells of the pancreatic islets (and their hormones) are alpha cells (glucagon), beta cells (insulin), delta cells (GH–IH), and pancreatic polypeptide cells (pancreatic polypeptide). **24.** A person with Type 1 or Type 2 diabetes has such a high blood glucose level that the kidneys cannot reabsorb all the glucose; some glucose is lost in urine. Because the urine contains a high concentration of glucose, less water can be reclaimed by osmosis, so the volume of urine production increases. The water losses reduce blood volume and elevate blood osmotic pressure, promoting thirst and triggering the secretion of ADH. **25.** An increased blood level of glucagon stimulates the conversion of glycogen to glucose in the liver, which would in turn decrease the amount of glycogen in the liver. **PAGE 675** **26.** Two hormones secreted by the kidneys are erythropoietin (EPO) and calcitriol. **27.** Leptin is a hormone released by adipose tissue. **28.** Once released into the bloodstream, renin functions as an enzyme, catalyzing the conversion of angiotensinogen to angiotensin I. **PAGE 678** **29.** The type of hormonal interaction in which two hormones have opposing actions on their target tissues is called antagonism. **30.** A lack of GH, thyroid hormone, PTH, and the gonadal hormones would inhibit the formation and development of the skeletal system.

31. During the resistance phase of the general adaptation syndrome, there is a high demand for glucose, especially by the nervous system. The hormones GH–RH and CRH increase the levels of GH and ACTH, respectively. Growth hormone (GH) mobilizes fat reserves and promotes the catabolism of protein; ACTH increases cortisol, which stimulates both the conversion of glycogen to glucose and the catabolism of fat and protein. Together, these metabolic processes conserve glucose for use by nervous tissue. **32.** The endocrine system adjusts metabolic rates and substrate use, and regulates growth and development, in all other body systems.

33. Hormones of the endocrine system adjust muscle metabolism, energy production, and growth; hormones also regulate calcium and phosphate levels, which are critical to normal muscle functioning. Skeletal muscles protect some endocrine organs.

Answers to Review Questions

PAGE 682

Level 1 Reviewing Facts and Terms

1. c 2. c 3. d 4. c 5. a 6. d 7. d 8. (a) hypothalamus **(b)** pituitary gland **(c)** thyroid gland **(d)** thymus **(e)** adrenal glands **(f)** pineal gland **(g)** parathyroid glands **(h)** heart **(i)** kidneys **(j)** adipose tissue **(k)** digestive tract **(l)** pancreas (pancreatic islets) **(m)** gonads **9. (1)** The hypothalamus releases ADH and oxytocin into the bloodstream at the posterior lobe of the pituitary gland. **(2)** The hypothalamus produces regulatory hormones that control secretion by endocrine cells in the anterior lobe of the pituitary gland. **(3)** The hypothalamus contains autonomic centers that exert direct neural control over the endocrine cells of the adrenal medulla. These hypothalamic activities are adjusted through negative feedback loops involving hormones released by peripheral endocrine tissues and organs. **10.** The anterior lobe of the pituitary gland releases **(1)** thyroid-stimulating hormone (TSH); **(2)** adrenocorticotrophic hormone (ACTH); **(3)** follicle-stimulating hormone (FSH); **(4)** luteinizing hormone (LH); **(5)** prolactin (PRL); **(6)** growth hormone (GH); and **(7)** melanocyte-stimulating hormone (MSH). **11.** The melanocyte-stimulating hormone is secreted by the pars intermedia of the pituitary gland. This hormone helps increase the production of melanin. **12.** Effects of thyroid hormones are **(1)** increased rate of energy consumption and utilization in cells; **(2)** accelerated production of sodium–potassium ATPase; **(3)** activation of genes coding for the synthesis of enzymes involved in glycolysis and energy production; **(4)** accelerated ATP production by mitochondria; and **(5)** in growing children, normal development of the skeletal, muscular, and nervous systems. **13.** The parathyroid glands contain **(1)** principal parathyroid cells and **(2)** parathyroid oxyphil cells. **14.** The thymus produces thymosins. These hormones promote the development and maturation of lymphocytes. **15.** The kidneys release **(1)** erythropoietin, which stimulates the production of RBCs by the red bone marrow, and **(2)** calcitriol, which stimulates calcium and phosphate absorption along the digestive tract. **16.** Natriuretic peptides **(1)** promote the loss of sodium ions and water at the kidneys; **(2)** inhibit the secretion of water-conserving hormones, such as ADH and aldosterone; **(3)** suppress thirst; and **(4)** inhibit the effects of angiotensin II and norepinephrine and decreases blood pressure. Angiotensin II opposes these actions by stimulating aldosterone secretion by the adrenal cortex and ADH by the posterior lobe of the pituitary gland, and further by retaining salt and water by the kidneys. Angiotensin II also stimulates thirst and elevates blood pressure. **17. (1)** alpha (α) cells: glucagon; **(2)** beta (β) cells: insulin; **(3)** delta (δ) cells: growth hormone–inhibiting

hormone (GH–IH, or somatostatin); **(4)** pancreatic polypeptide cells: pancreatic polypeptide

Level 2 Reviewing Concepts

18. The primary difference involves speed and duration. In the nervous system, the source and destination of communication are quite specific, and the effects are extremely quick and short-lived. In endocrine communication, the effects are slow to appear and commonly persist for days. A single hormone can alter the metabolic activities of multiple tissues and organs simultaneously.

19. Hormones can **(1)** direct the synthesis of an enzyme (or other protein) not already present in the cytoplasm, **(2)** turn an existing enzyme “on” or “off,” and **(3)** increase the rate of synthesis of a particular enzyme or other protein. **20.** Since steroid hormones are bound to specific transport proteins in the plasma, they stay in circulation longer than peptide hormones. **21.** In men, oxytocin stimulates smooth muscle contractions in the walls of the sperm duct and prostate gland. In women, oxytocin promotes labor and delivery, and induces milk ejection post delivery. **22. b 23. d 24. b**

Level 3 Critical Thinking and Clinical Applications

25. Extreme thirst and frequent urination are characteristic of both diabetes insipidus and diabetes mellitus. To distinguish between the two, glucose levels in Vladki’s blood and urine could be measured. A high glucose concentration would indicate diabetes mellitus. **26.** Sammy suffers from Type 1 diabetes, which is characterized by inadequate insulin production by the pancreatic beta cells and requires insulin replacement. His grandmother has Type 2 diabetes, which means that insulin production is normal, but the tissues are insulin resistant. Hence, there is a difference in treatment. **27.** Sakae’s signs and symptoms suggest hyperthyroidism. Blood tests could be performed to assay the levels of TSH, T_3 , and T_4 . From these tests, the physician could make a positive diagnosis (hormone levels would be elevated in hyperthyroidism) and determine whether the condition is primary (a problem with the thyroid gland) or secondary (a problem with hypothalamo-pituitary control of the thyroid gland). **28.** One benefit of a portal system is that it ensures that the regulatory hormones will be delivered directly to the target cells. Secondly, because the regulatory hormones go directly to their target cells without first passing through the general circulation, they are not diluted. The hypothalamus can control the cells of the anterior lobe of the pituitary gland with much smaller amounts of releasing and inhibiting hormones than would be necessary if the hormones had to first go through the circulatory pathway before reaching the pituitary. **29.** The natural effects of testosterone are to increase muscle mass, increase endurance, and enhance the “competitive spirit.” Side effects in females include hirsutism (abnormal hair growth on the face or body), enlargement of the laryngeal cartilages, premature closure of the epiphyseal cartilages, liver dysfunction, and irregular menstrual periods.

Answers to Clinical Case Wrap-Up

PAGE 683 1. In addition to mobilizing Ca^{2+} from bone, PTH enhances the reabsorption of Ca^{2+} by the kidneys, decreasing urinary losses and keeping blood concentrations high. PTH also stimulates the secretion of calcitriol by the kidneys, which enhances absorption of Ca^{2+} in the digestive tract, which also increases blood concentrations of Ca^{2+} . **2.** Calcitonin, produced by the thyroid, decreases blood Ca^{2+} levels indirectly. Calcitonin does this by causing an increased excretion of Ca^{2+} by the kidneys.

Answers to Figure-Based Questions

FIGURE 18–6 The endocrine cells whose secretion is controlled by regulatory hormones from the hypothalamus are located in the anterior lobe of the pituitary gland.

FIGURE 18–8 In a typical regulation pattern of endocrine secretion, hormone 2 (which is released from the target organ) is responsible for negative feedback.

FIGURE 18–9 Antidiuretic hormone (ADH) and oxytocin (OXT) are released from the posterior lobe of the pituitary gland. Posterior pituitary hormones are released directly from the hypothalamus, and regulatory hormones from the hypothalamus control the release of anterior pituitary hormones.

FIGURE 18–14 The zona glomerulosa produces mineralocorticoids. The primary mineralocorticoid is aldosterone.

FIGURE 18–17 Alpha cells secrete glucagon. Glucagon increases blood glucose level by (1) increasing the breakdown of glycogen to glucose in liver and skeletal muscle, (2) increasing the breakdown of fat to fatty acids in adipose tissue, and (3) increasing the synthesis and release of glucose by the liver.

Chapter 19

Answers to Checkpoints

PAGE 687 **1.** Five major functions of blood are transporting dissolved gases, nutrients, hormones, and metabolic wastes; regulating the pH and ion composition of interstitial fluids; restricting fluid losses at injury sites; defending against toxins and pathogens; and stabilizing body temperature. **2.** The three types of formed elements in blood are red blood cells, white blood cells, and platelets. **3.** The three major types of plasma proteins are albumins, globulins, and fibrinogen. **4.** A decrease in the amount of plasma proteins in the blood would lower plasma osmotic pressure, reduce the ability to fight infection, and decrease the transport and binding of some ions, hormones, and other molecules. **PAGE 695**

5. Hemoglobin is a protein composed of four globular subunits, each bound to a heme molecule, which gives red blood cells the ability to transport oxygen in the blood. **6.** After a significant loss of blood, the hematocrit—the percentage of whole blood occupied by red blood cells—would be reduced. **7.** The hematocrit would increase, because reduced blood flow to the kidneys triggers the release of erythropoietin, which stimulates an increase in erythropoiesis (red blood cell formation). **8.** Bilirubin would accumulate in the blood, producing jaundice, because diseases that damage the liver, such as hepatitis or cirrhosis, impair the liver's ability to excrete bilirubin in the bile. **PAGE 699** **9.** Surface antigens on RBCs are glycoproteins in the plasma membrane; they determine blood type. **10.** Only type O blood can be safely transfused into a person whose blood type is O. **11.** If a person with type A blood receives a transfusion of type B blood, which contains anti-A antibodies, the red blood cells will agglutinate (clump), potentially blocking blood flow to various organs and tissues. **PAGE 705** **12.** The five types of white blood cells are neutrophils, eosinophils, basophils, monocytes, and lymphocytes. **13.** An infected cut would be expected to contain many neutrophils, because these phagocytic white blood cells are the first to arrive at the site of an injury. **14.** The blood of a person fighting a viral infection would be expected to contain elevated numbers of lymphocytes, because B cells (B lymphocytes) produce circulating antibodies. **15.** Basophils respond to an injury by releasing a variety of chemicals, including histamine and

heparin. Histamine dilates blood vessels and heparin prevents blood clotting. Basophils also release other chemicals that attract eosinophils and other basophils to the injured area. **PAGE 707**

16. Thrombocytopoiesis is the term for platelet production.

17. Platelets release chemicals important to the clotting process, they form a temporary patch in the walls of damaged blood vessels, and they reduce the size of a break in a vessel wall. **PAGE 711**

18. Fewer megakaryocytes would interfere with the blood's ability to clot properly, because fewer megakaryocytes would produce fewer platelets. **19.** Vitamin K is necessary for blood clotting, and fats are required for vitamin K absorption. So if a person did not eat foods containing fat, this would lead to a vitamin K deficiency, which would, in turn, result in a decreased production of several clotting factors—most notably, prothrombin. As a result, clotting time would increase. **20.** The activation of Factor XII initiates the intrinsic pathway.

Answers to Review Questions

PAGE 713

Level 1 Reviewing Facts and Terms

1. (a) neutrophil **(b)** eosinophil **(c)** basophil **(d)** monocyte **(e)** lymphocyte **2. b** **3. d** **4. a** **5. c** **6. a** **7. a** **8. d** **9. b** **10.** Blood (1) transports dissolved gases, nutrients, hormones, and metabolic wastes; (2) regulates pH and electrolyte composition of interstitial fluids throughout the body; (3) restricts fluid losses through damaged vessels or at other injury sites; (4) defends against toxins and pathogens; and (5) stabilizes body temperature. **11.** Major types of plasma proteins are (1) albumins, which maintain the osmotic pressure of plasma and are important in the transport of fatty acids; (2) globulins, which (a) bind small ions, hormones, or compounds that might otherwise be filtered out of the blood at the kidneys or have very low solubility in water (transport globulins), or (b) attack foreign proteins and pathogens (immunoglobulins); and (3) fibrinogen, which functions in blood clotting. **12. b** **13.** WBCs exhibit (1) emigration (diapedesis), squeezing between adjacent endothelial cells in the capillary wall; (2) amoeboid movement, a gliding movement that transports the cell; (3) positive chemotaxis, the attraction to specific chemical stimuli, and (4) phagocytosis (engulfing particles for neutrophils, eosinophils, and monocytes). **14.** The rate of platelet formation is influenced by (1) thrombopoietin or thrombocyte-stimulating factor, (2) interleukin-6, and (3) multi-CSF. **15.** The primary lymphocytes are (1) T cells, which are responsible for cell-mediated immunity; (2) B cells, which are responsible for humoral immunity; and (3) NK cells, which are responsible for immune surveillance. **16.** Prothrombin is an inactive precursor that is converted to thrombin during coagulation. Thrombin is an enzyme that causes the clotting of blood by converting fibrinogen to fibrin. **17.** Erythropoietin is released (1) during anemia, (2) when blood flow to the kidneys decreases, (3) when the oxygen content of air in the lungs decreases, and (4) when the respiratory surfaces of the lungs are damaged. **18.** Initiation of the common pathway requires the activation of Factor X by the extrinsic and/or intrinsic pathways.

Level 2 Reviewing Concepts

19. a **20. d** **21. e** **22. c** **23.** The hormone multi-CSF stimulates myeloid stem cells to become progenitor cells. Under the influence of the hormone erythropoietin, progenitor cells develop into proerythroblasts and eventually into RBCs. Under

the influence of the hormone GM-CSF, progenitor cells develop into blast cells. The hormone G-CSF induces blast cells to become myeloblasts and eventually, granulocytes, whereas the hormone M-CSF induces blast cells to become monoblasts and eventually, monocytes. **24.** White blood cells defend against toxins and pathogens. Neutrophils, eosinophils, and monocytes engulf and digest bacteria, protozoa, fungi, viruses, and cellular debris. Lymphocytes are specialized to attack and destroy specific foreign cells, proteins, and cancerous cells, directly or through the production of antibodies. **25.** The higher viscosity of blood results from interactions between dissolved proteins, blood cells and platelets, and water molecules in plasma. **26.** Too much iron can cause problems due to excessive buildup in secondary storage sites, such as the liver and the heart. Too little iron can result in iron-deficiency anemia. **27.** Test tubes containing the anticoagulant heparin are commercially available to be used for blood sampling. Heparin accelerates the activation of antithrombin-III, which inhibits the clotting factor thrombin.

Level 3 Critical Thinking and Clinical Applications

28. A prolonged prothrombin time and a normal partial thromboplastin time indicate a deficiency in the extrinsic system but not in the intrinsic system or common pathway. Factor VII would be deficient. **29.** As the spleen enlarges, so does its capacity to store additional red blood cells, leading to fewer red blood cells in circulation, producing anemia. The decreased number of RBCs in circulation decreases the body's ability to deliver oxygen to the tissues, slowing their metabolism and producing the tired feeling and lack of energy. Because there are fewer RBCs than normal, the blood circulating through the skin is not as red, producing a pale complexion. **30.** Taking a broad-spectrum antibiotic kills a wide range of bacteria, both pathogenic and nonpathogenic, including many of the normal flora, or microbiota, of the intestine. Reducing the intestinal flora substantially decreases the amount of vitamin K they make available to the liver to produce prothrombin, a vital component of the common pathway. With decreased amounts of prothrombin in the blood, normal minor breaks in the vessels of the nasal passageways do not seal off as quickly, producing nosebleeds. **31.** Kolja's iron shortage causes hemoglobin shortage, which in turn leads to problems with the renewal of RBCs and low MCV, causing iron-deficiency anemia. The shortage of RBC and hemoglobin hampers the body's oxygen supply, making Kolja tired, pale, and sensitive to cold. Perhaps there is too little iron present in Kolja's diet or he has problems with iron absorption.

Answers to Clinical Case Wrap-Up

PAGE 714 1. In Clare's sickle cell crisis, the sickled RBCs block blood vessels in her legs, producing severe pain. Additionally, sickled RBCs are piling up and blocking the circulation to her feet. The surrounding tissues are being starved of blood with its oxygen supply and its warmth (blood is 1°C warmer than body temperature). So her feet are freezing and the skin of her legs shows redness and swelling from local inflammation. **2.** Hydration is critical in sickle cell disease because water helps to maintain the proper volume of blood. When Clare's red blood cells become concentrated, the impact of the sickling process is increased.

Answers to Figure-Based Questions

FIGURE 19-3 Each molecule of heme contains an ion of iron (Fe^{2+}).

FIGURE 19-5 Red blood cells are produced in the red bone marrow.

FIGURE 19-6 Type A blood has RBCs with surface antigen A only and contains anti-B antibodies.

FIGURE 19-10 Granulocytes consist of basophils, eosinophils, and neutrophils. Granulocytes differentiate from myeloblasts.

Chapter 20

Answers to Checkpoints

PAGE 730 1. Damage to the semilunar valve of the right ventricle, or pulmonary valve, would affect blood flow to the pulmonary trunk. **2.** Contraction of the papillary muscles (just before the rest of the ventricular myocardium contracts) pulls on the chordae tendineae, which prevent the AV valves from opening back into the atria. **3.** The left ventricle is more muscular than the right ventricle because the left ventricle must generate enough force to propel blood throughout the body, except the lungs, whereas the right ventricle must generate only enough force to propel blood a few centimeters to the lungs. **PAGE 739 4.** Autorhythmicity is the ability of cardiac muscle tissue to contract without neural or hormonal stimulation. **5.** The sinoatrial (SA) node is known as the cardiac pacemaker or the natural pacemaker. **6.** If the cells of the SA node did not function, the AV node would act as the pacemaker and set the heart rhythm. The heart would continue to beat, but at a slower rate. **7.** If the impulses from the atria were not delayed at the AV node, they would be conducted through the ventricles so quickly by the bundle branches and Purkinje cells that the ventricles would begin contracting immediately, before the atria had finished their contraction. As a result, the ventricles would not be as full of blood as they could be, and the pumping of the heart would not be as efficient, especially during physical activity. **PAGE 744 8.** The technical term for heart contraction is systole, and the term for heart relaxation is diastole. **9.** The phases of the cardiac cycle are atrial systole, atrial diastole, ventricular systole, and ventricular diastole. **10.** No. When pressure in the left ventricle first rises, the heart is contracting but no blood is leaving the heart. During this initial phase of contraction, both the AV valves and the semilunar valves are closed. The increase in pressure is the result of increased tension as the cardiac muscle contracts. When the blood pressure in the ventricle exceeds the blood pressure in the aorta, the aortic semilunar valves are forced open, and blood is rapidly ejected from the ventricle. **11.** An increase in the size of the QRS complex indicates a larger-than-normal amount of electrical activity during ventricular depolarization. One possible cause is an enlarged heart. Because more cardiac muscle is depolarizing, the magnitude of the electrical event would be greater. **PAGE 751 12.** Cardiac output is the amount of blood pumped by the left ventricle in 1 minute. **13.** Caffeine acts directly on the conducting system and contractile cells of the heart, increasing the rate at which they depolarize. Drinking large amounts of caffeinated drinks would increase the heart rate. **14.** The heart pumps in proportion to the amount of blood that enters. A heart that beats too rapidly does not have sufficient time to fill completely between beats. Thus, when the heart beats too fast, very little blood leaves the ventricles and enters the circulation, so tissues suffer damage from inadequate blood supply. **15.** Stimulating the acetylcholine receptors of the heart would slow the heart rate (parasympathetic neurons release acetylcholine). Since cardiac output is the product of stroke volume and heart rate, a reduction in heart rate will lower the cardiac output (if the stroke volume remains the same or doesn't increase). **16.** The venous return fills the heart with blood, stretching the heart muscle. According to the Frank-Starling principle,

the more the heart muscle is stretched, the more forcefully it will contract (to a point). The more forceful the contraction, the more blood the heart will eject with each beat (stroke volume). Therefore, increased venous return would increase the stroke volume (if all other factors are constant). **17.** $SV = EDV - ESV$, so $SV = 125 \text{ mL} - 40 \text{ mL} = 85 \text{ mL}$

Answers to Review Questions

PAGE 752

Level 1 Reviewing Facts and Terms

1. d **2.** c **3.** c **4.** d **5.** c **6.** a and b **7.** b **8.** (a) superior vena cava (b) auricle of right atrium (c) right ventricle (d) left ventricle (e) aortic arch (f) left pulmonary artery (g) pulmonary trunk (h) auricle of left atrium **9.** (a) ascending aorta (b) opening of coronary sinus (c) right atrium (d) cusp of tricuspid valve (e) chordae tendineae (f) right ventricle (g) pulmonary valve (h) left pulmonary veins (i) left atrium (j) aortic valve (k) cusp of mitral valve (l) left ventricle (m) interventricular septum **10.** d **11.** b **12.** The two atria of the fetal heart are connected through an opening, the foramen ovale. Blood flows from the right to the left atrium. At birth, the foramen ovale closes. Only a shallow depression, the fossa ovalis, remains in the interatrial wall. **13.** (1) The epicardium is the visceral layer of the serous pericardium, which covers the outer surface of the heart. (2) The myocardium is the muscular wall of the heart, which forms both atria and ventricles. It contains cardiac muscle tissue and associated connective tissues, blood vessels, and nerves. (3) The endocardium is made up of a simple squamous epithelium and an areolar layer that covers the inner surfaces of the heart, including the valves. **14.** The tricuspid valve (right atrioventricular valve) and the mitral valve (left atrioventricular valve) prevent the backflow of blood from the ventricles into the atria. The pulmonary and aortic semilunar valves prevent the backflow of blood from the pulmonary trunk and aorta into the right and left ventricles. **15.** The Purkinje fibers radiate from the apex toward the base of the heart. They conduct action potentials very rapidly to all the ventricular cardiac contractile cells in order to start ventricular contraction. **16.** The cardiac cycle comprises the events in a complete heartbeat, including a contraction-relaxation period for both atria and ventricles. The cycle begins with atrial systole as the atria contract and push blood into the relaxed ventricles. As the atria relax (atrial diastole), the ventricles contract (ventricular systole), forcing blood through the semilunar valves into the pulmonary trunk and aorta. The ventricles then relax (ventricular diastole). For the rest of the cardiac cycle, both the atria and ventricles are in diastole; passive filling occurs. **17.** The factors that regulate stroke volume are (1) preload, the stretch on the heart before it contracts; (2) contractility, the force of contraction of individual ventricular contractile cells; and (3) afterload, the pressure that must be exceeded before blood can be ejected from the ventricles.

Level 2 Reviewing Concepts

18. c **19.** b **20.** d **21.** a **22.** Yes, there are blood tests that can help diagnose a myocardial infarction. Damaged myocardial cells release enzymes into the circulation, and these elevated enzymes can be measured in blood tests. These enzymes include cardiac troponin T, cardiac troponin I, and a special form of creatinine phosphokinase, CK-MB. **23.** The coronary arteries provide a constant blood supply to the heart muscle. The interconnections between the arteries, called arterial anastomoses, ensure constant blood supply

to all parts of the myocardium, despite pressure fluctuations in the left and right coronary arteries as the heart beats. **24.** Cardiac reserve is the difference between resting and maximal cardiac outputs. Exercise increases cardiac output significantly. **25.** From the aerobic breakdown of fatty acids and glucose. **26.** Pericarditis is inflammation of the pericardium. It often leads to pericardial fluid accumulating in the pericardial cavity, restricting the movement of the heart. **27.** These drugs lower blood pressure as they block beta receptors, alpha receptors, or both, and prevent sympathetic stimulation of the heart.

Level 3 Critical Thinking and Clinical Applications

28. The doctor tells Elisabeth that angina pectoris or chest pain/spasm is one of the first signs of coronary artery disease. When fatty deposits called plaques are formed in the coronary walls, blood flow to the heart muscles is reduced, hampering the much-needed oxygen supply. When the workload of the heart increases due to physical effort, temporary ischemia can occur, causing chest pain. **29.** Harvey probably has a regurgitating mitral valve, which is also known as the left atrioventricular (AV) valve. When an AV valve fails to close properly, blood flowing back into the atrium produces a murmur. A murmur at the beginning of systole implicates the AV valve because this is the period when the valve has just closed, the blood in the ventricle is under increasing pressure, and the likelihood of backflow is the greatest. A sound heard at the end of systole or the beginning of diastole would implicate a regurgitating semilunar valve—in this case, the aortic valve. **30.** Using $CO = HR \times SV$, person 1 has a cardiac output of 4500 mL, and person 2 has a cardiac output of 8550 mL. According to the Frank-Starling principle, in a normal heart the cardiac output is directly proportional to the venous return. Thus, person 2 has the greater venous return. Ventricular filling decreases with increased heart rate; person 1 has the lower heart rate and therefore the longer ventricular filling time. **31.** By blocking calcium channels, verapamil will decrease the force of cardiac contraction, which directly lowers Karen's stroke volume.

Answers to Clinical Case Wrap-Up

PAGE 754 **1.** The "lubb" heard when the AV valves close, and the "dupp" heard when the semilunar valves close, would be muffled and difficult to hear because the sounds were transmitted through a pericardial cavity filled with blood. This dampens the sounds when heard through a stethoscope. **2.** The right atrium and right ventricle sit anteriorly, just deep to the sternum, and would likely be injured in this collision. Delicate structures that could also be injured include the anterior interventricular artery and great cardiac vein, running in the anterior interventricular sulcus. With a hard enough impact, the papillary muscles and chordae tendineae could rupture, leading to failure of the AV valves.

Answers to Figure-Based Questions

FIGURE 20-1 The left side of the heart supplies blood to the systemic circuit, while the right side of the heart supplies blood to the pulmonary circuit.

FIGURE 20-5 Blood will pass through the tricuspid valve (right AV valve), the pulmonary valve, the mitral valve (left AV valve), and finally the aortic valve.

FIGURE 20-11 When the electrical impulse reaches the AV node, it is delayed about 100 msec.

FIGURE 20-15 The entry of sodium ions (Na^+) causes rapid depolarization. The entry of calcium ions (Ca^{2+}) causes the plateau. The exit of potassium ions (K^+) causes repolarization.

FIGURE 20–21 The sympathetic nervous system would increase heart rate. The cardioacceleratory center controls sympathetic neurons that increase heart rate.

FIGURE 20–24 Average cardiac output at rest is about 5–7.5 L/min.

Chapter 21

Answers to Checkpoints

PAGE 764 1. The five general classes of blood vessels are arteries, arterioles, capillaries, venules, and veins. 2. Blood vessels with thin walls and very little smooth muscle tissue in the tunica media are veins. Arteries and arterioles have a large amount of smooth muscle tissue in a thick, well-developed tunica media. 3. In the arterial system, pressures are high enough to keep the blood moving forward. In the venous system, blood pressure is too low to keep the blood moving on toward the heart. Valves in veins prevent blood from flowing back toward the capillaries whenever the venous pressure drops. 4. Fenestrated capillaries are found where fluids and small solutes move freely into and out of the blood, including endocrine glands, the choroid plexus of the brain, absorptive areas of the intestine, and filtration areas of the kidneys. **PAGE 773** 5. The factors that contribute to total peripheral resistance are vascular resistance, vessel length, vessel luminal diameter, blood viscosity, and turbulence. 6. In a healthy person, blood pressure is greater at the aorta than at the inferior vena cava. Blood, like other fluids, moves along a pressure gradient from areas of high pressure to areas of low pressure. If the pressure were higher in the inferior vena cava than in the aorta, the blood would flow backward. 7. While Lailah was standing for a period of time, blood pooled in her lower limbs, which decreased venous return to her heart. In turn, cardiac output decreased, so less blood reached her brain, causing light-headedness and fainting. A hot day adds to this effect, because the loss of body water through sweating reduces blood volume. 8. Mike's mean arterial pressure (MAP) is approximately 88.3 mm Hg: $70 + (125 - 70)/3 = 70 + 18.3 = 88.3$. **PAGE 780** 9. Vasodilators promote the dilation of precapillary sphincters. Local vasodilators, such as decreased O_2 level or increased CO_2 level, act on tissues to accelerate blood flow. 10. Pressure on the common carotid artery would decrease blood pressure at the baroreceptors in the carotid sinus. This decrease would lower the frequency of action potentials along the glossopharyngeal nerve (IX) to the medulla oblongata, and more sympathetic impulses would be sent to the heart. The net result would be an increase in the heart rate. 11. Vasoconstriction of the renal artery would decrease both blood flow and blood pressure at the kidney. In response, the kidney would increase the amount of renin it releases, which in turn would lead to an increase in the level of angiotensin II. The angiotensin II would bring about increased blood pressure and increased blood volume. **PAGE 784** 12. Blood pressure increases during exercise because (1) cardiac output increases and (2) resistance in visceral tissues increases. 13. The immediate problem during hemorrhaging is maintaining adequate blood pressure and peripheral blood flow; the long-term problem is restoring normal blood volume. 14. Both aldosterone and ADH promote fluid retention and reabsorption at the kidneys, preventing further reductions in blood volume. **PAGE 785** 15. The two circuits of the cardiovascular system are the pulmonary circuit and the systemic circuit. 16. The major patterns are as follows: (1) The peripheral distributions of arteries and veins on the body's left and right sides are generally identical,

except near the heart, where the largest vessels connect to the atria or ventricles; (2) a single vessel may have several names as it crosses specific anatomical boundaries, making accurate anatomical descriptions possible; and (3) tissues and organs are usually serviced by several arteries and veins. **PAGE 786** 17. The pulmonary arteries enter the lungs carrying deoxygenated blood, and the pulmonary veins leave the lungs carrying oxygenated blood. 18. The path of blood through the lungs is right ventricle → pulmonary trunk → left and right pulmonary arteries → pulmonary arterioles → alveolar capillary network → pulmonary venules → pulmonary veins → left atrium. **PAGE 803** 19. A blockage of the left subclavian artery would interfere with blood flow to the left arm. 20. Compression of the common carotid arteries would decrease blood pressure at the carotid sinus and cause a rapid reduction in blood flow to the brain, resulting in a loss of consciousness. An immediate reflexive increase in heart rate and blood pressure would follow. 21. Rupture of the celiac trunk would most directly affect the stomach, spleen, liver, and pancreas. 22. The vein that is bulging in Noah's neck is the external jugular vein. 23. A blockage of the popliteal vein would interfere with blood flow in the tibial and fibular veins (which form the popliteal vein) and the small saphenous vein (which joins the popliteal vein). **PAGE 806** 24. Two umbilical arteries supply blood to the placenta, and one umbilical vein returns blood from the placenta. The umbilical vein then drains into the ductus venosus within the fetal liver. (Remember, arteries carry blood away from the heart, and veins carry blood to the heart.) 25. This blood sample was taken from the umbilical vein, which carries oxygenated, nutrient-rich blood from the placenta to the fetus. 26. Structures specific to the fetal circulation include two umbilical arteries, an umbilical vein, the ductus venosus, the foramen ovale, and the ductus arteriosus. In the newborn, the foramen ovale closes and persists as the fossa ovalis, a shallow depression; the ductus arteriosus persists as the ligamentum arteriosum, a fibrous cord; and the umbilical vessels and ductus venosus persist throughout life as fibrous cords. 27. Components of the cardiovascular system affected by age include the blood, heart, and blood vessels. 28. A thrombus is a stationary blood clot within the lumen of a blood vessel. 29. An aneurysm is the ballooning out of a weakened arterial wall resulting from sudden pressure increases. 30. The cardiovascular system provides other body systems with oxygen, hormones, nutrients, and white blood cells in blood, while removing carbon dioxide and metabolic wastes; it also transfers heat to body tissues. 31. The skeletal system provides calcium needed for normal cardiac muscle contraction, and it protects developing blood cells in the red bone marrow. The cardiovascular system provides calcium and phosphate for bone deposition, delivers erythropoietin to red bone marrow, and transports parathyroid hormone and calcitonin to osteoblasts and osteoclasts.

Answers to Review Questions

PAGE 810

Level 1 Reviewing Facts and Terms

1. (a) brachiocephalic trunk (b) brachial (c) radial (d) external iliac (e) anterior tibial (f) right common carotid (g) left subclavian (h) common iliac (i) femoral 2. b 3. e 4. b 5. d 6. b 7. a 8. d 9. (a) external jugular (b) brachial (c) median cubital (d) radial (e) great saphenous (f) internal jugular (g) superior vena cava (h) left and right common iliac (i) femoral 10. b 11. b 12. a 13. c 14. c 15. b 16. d 17. (a) Capillary hydrostatic pressure forces fluid out of a capillary at the arterial end.

(b) Blood colloid osmotic pressure causes the movement of fluid back into a capillary at its venous end. **18.** Atherosclerosis is the key problem in aging blood vessels, increasing the risk of myocardial infarction and cerebrovascular accident. When calcium salts are deposited on weakened vascular walls and arterial walls lose their elasticity, the risk of myocardial infarction and cerebrovascular accident increases. In the tunica media, the combination of lipid deposits, damaged endothelial lining, and calcium salts lead to the formation of atherosclerotic plaques on which thrombi can be formed.

Level 2 Reviewing Concepts

19. b 20. b 21. b 22. Artery walls are generally thicker and contain more smooth muscle and elastic fibers, enabling them to resist and adjust to the pressure generated by the heart. Venous walls are thinner; the pressure in veins is less than that in arteries. Arteries constrict more than veins do when not expanded by blood pressure, due to a greater degree of elastic tissue. Finally, the endothelial lining of an artery has a pleated appearance because it cannot contract and so forms folds. The lining of a vein looks like a typical endothelial layer. **23.** Bands of smooth muscles, called precapillary sphincters, are present at the entrances of the capillaries. Their contraction and relaxation control blood flow to the tissues. Contraction of the sphincters narrows the capillary entrances, reducing or stopping the flow of blood. When the sphincters relax, the entrances dilate, and blood flows into the capillaries. The central passageway in the arteriole system acts as a thoroughfare channel. Blood flow through this channel is controlled by the sphincter effect of the arteriole. **24.** Contraction of the surrounding skeletal muscles squeezes venous blood toward the heart. This mechanism, the muscular pump, is assisted by the presence of valves in the veins, which prevent backflow of the blood. The respiratory pump, which results from the increase in internal pressure of the thoracic cavity during exhalation, pushes venous blood into the right atrium. **25.** Abnormally high blood pressure is termed hypertension, whereas abnormally low blood pressure is called hypotension. Of the two, hypertension is more common. Many cases of hypotension result from aggressive drug treatment for hypertension. Smoking, stress, and obesity are some of the factors that lead to hypertension. **26.** The brain receives arterial blood from four arteries that form anastomoses within the cranium. An interruption of any one vessel will not compromise the blood flow to the brain. **27.** The cardioacceleratory and vasomotor centers are stimulated when general sympathetic activation occurs. The result is an increase in cardiac output and blood pressure. When the parasympathetic division is activated, the cardioinhibitory center is stimulated, reducing cardiac output.

Level 3 Critical Thinking and Clinical Applications

28. Fluid loss lowers blood volume, leading to sympathetic stimulation, which elevates blood pressure. So Josh's blood pressure is high instead of low. **29.** Antihistamines and decongestants are sympathomimetic drugs; they have the same effects on the body as does stimulation of the sympathetic nervous system. In addition to the desired effects of counteracting the symptoms of the allergy, these medications can produce an increased heart rate, increased stroke volume, and increased peripheral resistance, all of which will contribute to elevating blood pressure. In a person with hypertension (high blood pressure), these drugs would aggravate this condition, with potentially hazardous consequences. **30.** When Jolene stood up rapidly, gravity caused her blood volume to move to the lower parts of her body away from the heart, decreasing venous return. The decreased venous return

resulted in a decreased end-diastolic volume (EDV), leading to a decreased stroke volume and cardiac output. In turn, blood flow to the brain decreased, so the diminished oxygen supply caused her to be light-headed and feel faint. This reaction doesn't happen all the time because as soon as the pressure drops due to inferior movement of blood, baroreceptors in the aortic arch and carotid sinuses trigger the baroreceptor reflex. Action potentials are carried to the medulla oblongata, where appropriate responses are integrated. In this case, we would expect an increase in peripheral resistance to compensate for the decreased blood pressure. If this doesn't compensate enough for the drop, then an increase in heart rate and force of contraction would occur. Normally, these responses occur so quickly that changes in pressure following changes in body position go unnoticed.

Answers to Clinical Case Wrap-Up

PAGE 811 1. Calcification follows the degeneration of smooth muscle in the tunica media of arteries. Calcification in arteries is related to atherosclerotic injury of the vessels. Calcification does not occur in normal, young, healthy blood vessel walls. **2.** Atherosclerosis is never seen in the venous system because veins are never subjected to the pressures of the arterial system. In the average person the systemic arterial pressure is over 100 mm Hg. This causes wear and tear in the arterial walls, leading to gradual degeneration of the smooth muscle in the tunica media, followed by deposition of calcium salts, and then by deposition of atherosclerotic plaques. The pressure within the venous system is always quite low (usually around 16 mm Hg). Damage to the endothelial surfaces does not get started.

Answers to Figure-Based Questions

FIGURE 21-2 (a) Veins have larger lumens than arteries. (b) Arteries, specifically muscular arteries, have the thickest tunica media.

FIGURE 21-7 Factors that would increase vascular resistance are increased vessel length and turbulence. Increased vessel luminal diameter would decrease vascular resistance.

FIGURE 21-12 For blood flow to be autoregulated, physical stress (such as trauma or high temperature), chemical changes (such as decreased oxygen or pH, increased carbon dioxide, or increased prostaglandins), or increased tissue activity are stimuli that signal inadequate local blood pressure and blood flow.

FIGURE 21-15 For short-term regulation of a decrease in blood pressure and blood volume, sympathetic activation and the release of the adrenal hormones epinephrine (E) and norepinephrine (NE) increase cardiac output and peripheral vasoconstriction, which will increase blood pressure.

FIGURE 21-21 The superficial temporal, maxillary, occipital, facial, and lingual arteries are all branches of the external carotid artery.

FIGURE 21-29 The right and left brachiocephalic veins, the mediastinal veins, and the azygos vein directly drain into the superior vena cava.

Chapter 22

Answers to Checkpoints

PAGE 824 1. A pathogen is any disease-causing organism, such as a virus, bacterium, fungus, or parasite that can survive and even thrive inside the body. **2.** The components of the lymphatic system are lymph, lymphatic vessels, lymphoid cells (lymphocytes and other cells), primary lymphoid tissues and organs (red bone marrow and the thymus), and secondary lymphoid tissues and organs

(lymph nodes, tonsils, MALT, the appendix, and the spleen).

3. A blockage of the thoracic duct would impair the drainage of lymph from inferior to the diaphragm and from the left side of the head and thorax, slowing the return of lymph to the venous blood and promoting the accumulation of fluid in the limbs (lymph-edema). **4.** A lack of thymic hormones would drastically reduce the population of T lymphocytes. **5.** Lymph nodes enlarge during some infections because lymphocytes and phagocytes in the nodes multiply to defend against the infectious agent(s). **PAGE 825**

6. Immunity is the body's ability to resist infectious organisms or other substances that could damage tissues and organs. Resistance is the ability of the body to maintain its immunity. **7.** Innate (nonspecific) immunity is a type of body defense that you are born with and does not distinguish among different threats. Adaptive (specific) immunity is acquired after birth and after exposure to a particular antigen. **PAGE 833** **8.** A decrease in the number of monocyte-forming cells in red bone marrow would result in fewer macrophages of all types, including stellate macrophages (Kupffer cells) of the liver, microglia of the central nervous system, and alveolar macrophages. **9.** A rise in the level of interferon suggests that person has a viral infection. Interferon does not help an infected cell, but "interferes" with replication of the virus and thus the virus's ability to infect other cells. **10.** Pyrogens increase body temperature (produce a fever) by stimulating the temperature control area of the pre-optic nucleus of the hypothalamus.

PAGE 836 **11.** In cell-mediated (cellular) immunity, T cells defend against abnormal cells and pathogens inside cells. In antibody-mediated (humoral) immunity, B cells secrete antibodies that defend against antigens and pathogens in body fluids. **12.** The four major types of T cells are cytotoxic T cells, helper T cells, regulatory T cells, and memory T cells. **13.** The two forms of active immunity are naturally acquired active immunity and artificially acquired active immunity; the two forms of passive immunity are naturally acquired passive immunity and artificially acquired passive immunity. **14.** The four general properties of adaptive immunity are specificity, versatility, memory, and tolerance. **PAGE 844**

15. Abnormal peptides in the cytoplasm of a cell can become attached to MHC (major histocompatibility complex) proteins and then be displayed on the surface of the cell's plasma membrane. The recognition of such displayed peptides by T cells can initiate an immune response. **16.** A decrease in the number of cytotoxic T cells would affect cell-mediated immunity, reducing the effectiveness of cytotoxic T cells in killing foreign cells and virus-infected cells. **PAGE 849** **17.** Without helper T cells—which promote B cell division, the maturation of plasma cells, and antibody production by plasma cells—the antibody-mediated immune response would probably not occur. **18.** Sensitization is the process by which a B cell becomes able to react with a specific antigen.

19. Plasma cells produce and secrete antibodies, so observing an elevated number of plasma cells would lead us to expect increasing levels of antibodies in the blood. **20.** An antibody molecule consists of two parallel pairs of polypeptide chains: one pair of heavy chains and one pair of light chains. Each chain contains both constant segments and variable segments. **21.** Because production of a secondary response depends on the presence of memory B cells and memory T cells formed during a primary response, the secondary response would be more negatively affected by a lack of memory B cells for a particular antigen. **PAGE 855** **22.** A developing fetus is protected primarily by naturally acquired passive immunity, through the maternal production of IgG antibodies that have crossed the placenta from the mother's bloodstream.

23. Stress can interfere with the immune response by depressing inflammation, reducing the number and activity of phagocytes, and inhibiting interleukin secretion. **24.** An autoimmune disorder is a condition that results when the immune system's sensitivity to normal cells and tissues causes the production of autoantibodies. **25.** Elderly people are more susceptible to viral and bacterial infections because the number of helper T cells declines with age and B cells are less responsive, so antibody levels rise more slowly after antigen exposure. **26.** As one ages, immune surveillance declines, so cancerous cells are not eliminated as effectively. **27.** Glucocorticoids released by the endocrine system have anti-inflammatory effects; thymic hormones stimulate the development and maturation of lymphocytes; and many hormones affect immune function. The thymus secretes thymic hormones, and cytokines affect cells throughout the body. **28.** The lymphatic system provides defenses against infection, performs immune surveillance to eliminate cancer cells, and returns tissue fluid to the circulation.

Answers to Review Questions

PAGE 859

Level 1 Reviewing Facts and Terms

1. (a) tonsil (b) cervical lymph nodes (c) right lymphatic duct (d) thymus (e) cisterna chyli (f) lumbar lymph nodes (g) appendix (h) lymphatics of lower limb (i) lymphatics of upper limb (j) axillary lymph nodes (k) thoracic duct (l) lymphatics of mammary gland (m) spleen (n) mucosa-associated lymphoid tissue (MALT) (o) pelvic lymph nodes (p) inguinal lymph nodes (q) red bone marrow **2.** d **3.** b **4.** d **5.** c **6.** d **7.** c **8.** a **9.** b **10.** d **11.** c **12.** Primary lymphoid tissues and organs: (1) red bone marrow: maintain normal lymphocyte populations and other defense cells, such as monocytes and macrophages; (2) thymus: production of mature T cells and hormones that promote immune function. Secondary lymphoid tissues and organs: (1) spleen: filtration of blood, recycling of red blood cells, detection of blood-borne pathogens or toxins; (2) lymph nodes: filtration of lymph, detection of pathogens, initiation of immune response; (3) lymphoid nodules and MALT: defense of entrance and passageways of digestive tract and protection of epithelia lining the respiratory, urinary, and reproductive tracts against pathogens and foreign proteins or toxins. **13.** (a) lymphocytes responsible for cell-mediated immunity; (b) stimulate the activation and function of T cells and B cells; (c) inhibit the activation and function of both T cells and B cells; (d) produce and secrete antibodies; (e) recognize and destroy abnormal cells; (f) produce interleukin-7, which promotes the differentiation of B cells; (g) regulate T cell development and function; (h) interfere with viral replication inside the cell and stimulate the activities of macrophages and NK cells; (i) reset the body's thermostat, causing a rise in body temperature (fever); (j) provide cell-mediated immunity, which defends against abnormal cells and pathogens inside cells; (k) provide humoral immunity, which defends against antigens and pathogens in the body (but not inside cells); (l) enhance innate (nonspecific) defenses and increase T cell sensitivity and stimulate B cell activity; (m) slow tumor growth and kill sensitive tumor cells; (n) stimulate the production of blood cells in the red bone marrow and lymphocytes in lymphoid tissues and organs **14.** (1) T cells, derived from the thymus; (2) B cells, derived from red bone marrow; (3) NK cells, derived from red bone marrow **15.** Innate (nonspecific) immunity: (1) physical barriers; (2) phagocytic cells; (3) immune surveillance; (4) interferons; (5) complement system; (6) inflammation; (7) fever

Level 2 Reviewing Concepts

16. d 17. e 18. a 19. b 20. Complement activation can rupture the target cell by forming a membrane attack complex (MAC). It also enhances phagocytosis (opsonization) and inflammation. Interferon interferes with viral replication inside virus-infected cells by triggering the production of antiviral proteins. **21.** Cytotoxic T cells kill by rupturing the target cell's plasma membrane, by stimulating lymphotoxin secretion, or by activating genes in the nucleus that program cell death (apoptosis). **22.** Formation of an antigen–antibody complex eliminates antigens by neutralization, by agglutination and precipitation, by activating complement, by attracting phagocytes, by opsonization, by stimulating inflammation, or by preventing bacterial and viral adhesion. **23.** Innate immunity is genetically programmed; an example is immunity to fish diseases. Naturally acquired active immunity develops after birth from contact with pathogens; an example is exposure to chickenpox in grade school. Artificially acquired active immunity develops after intentional exposure to a pathogen; an example is administration of measles vaccine. Artificially acquired passive immunity is temporary immunity provided by injection with antibodies produced in another organism, such as antibodies against rabies. Naturally acquired passive immunity is gained by acquiring antibodies from mother's milk or placental exchange. **24.** The introduction of genetic engineering has rapidly advanced vaccine technology and resulted in products with more effective formulations and delivery methods. Effective against COVID-19 are messenger RNA (mRNA) vaccines and viral vector vaccines. mRNA vaccines make proteins that trigger an immune response and do not use live or attenuated pathogens. The mRNA is broken down by the individual's cells within a few days after vaccination. Viral vector vaccines use modified versions of a different virus as the vector to deliver protection. For example, adenoviruses that cause the common cold have been modified to be harmless vectors in these vaccines.

Level 3 Critical Thinking and Clinical Applications

25. Yes, the crime lab could determine whether the sample is blood plasma, which contains IgM, IgG, IgD, and IgE, or semen, which contains only IgA. **26.** Santiago cannot yet know whether he'll come down with the measles. Santiago's elevated blood IgM level and antibody titer indicate that he is in the early stages of a primary response to the measles virus. If his immune response proves unable to control and then eliminate the virus, Santiago will develop the measles. **27.** In a radical mastectomy, lymph nodes in the nearby axilla and surrounding region are removed along with the cancerous breast to try to prevent the spread of cancer cells by the lymphatic system. Lymphatic vessels from the limb on the affected side are tied off, and because there is no place for the lymph to drain, over time lymphedema causes swelling of the limb. **28.** A key characteristic of cancer cells is their ability to metastasize—to break free from a tumor and form new tumors in other tissues. The primary route of metastasis is the lymphatic system, including the lymph nodes. Examination of regional lymph nodes for the presence of cancer cells can help the physician determine if the cancer was caught in an early stage or whether it has started to spread to other tissues. **29.** HIV is a retrovirus. It binds to CD4 T cells and can also affect dendritic cells, macrophages, and microglia. Regulatory T cells are relatively unaffected. The gradual destruction of helper T cells impairs the immune response. Circulating antibody levels decline and cell-mediated immunity is reduced. The body can no longer defend itself against a variety of normally harmless microorganisms.

Answers to Clinical Case Wrap-Up

PAGE 860 1. Innate immunity is genetically determined and present at birth. For example, skin and mucous membranes provide an innate physical and chemical barrier to infecting organisms. All humans are susceptible to chickenpox, an infectious disease. The immunity developed after a chickenpox vaccination is artificially acquired adaptive immunity, developed to a specific antigen, the varicella-zoster virus (VZV). **2.** Baby Ruthie has developed lifelong immunity to chickenpox as a result of having the disease. Her immune memory will provoke a secondary immune response if she is exposed to the varicella-zoster virus again. The recommended schedule (according to the Centers for Disease Control and Prevention [CDC]) for varicella-zoster vaccination is 12–15 months of age. However, there is no need for Ruthie to get a chickenpox vaccination after having had the disease.

Answers to Figure-Based Questions

FIGURE 22-3 Lymphatic vessels have valves, similar to veins, which allow lymph to flow in only one direction.

FIGURE 22-8 Lymphocytes are found in the white pulp of the spleen, whereas red blood cells are found in the red pulp of the spleen.

FIGURE 22-12 Interferon alpha attracts and stimulates NK cells to enhance viral resistance to viral infection.

FIGURE 22-17 Artificially acquired active immunity develops after receiving a vaccine.

FIGURE 22-25 During the primary response, IgM peaks sooner than IgG. During the secondary response, the level of IgG is higher than the level of IgM.

FIGURE 22-26 After the appearance of bacteria, NK cells are present for the shortest amount of time (typically less than 1 week).

Chapter 23

Answers to Checkpoints

PAGE 866 1. Functions of the respiratory system include providing an extensive surface area for gas exchange between air and circulating blood; moving air to and from exchange surfaces along the respiratory passageways; protecting respiratory surfaces from dehydration, temperature changes, and pathogens; producing sounds; and detecting odors. **2.** The two anatomical divisions of the respiratory system are the upper respiratory system and the lower respiratory system. **3.** The respiratory mucosa lines the conducting portion of the respiratory tract. **PAGE 869 4.** The upper respiratory system consists of the nose, nasal cavity, paranasal sinuses, and pharynx. **5.** The rich vascularization of the nose delivers body heat to the nasal cavity, so inhaled air is warmed before it leaves the nasal cavity and moves toward the lungs. The heat also evaporates moisture from the epithelium to humidify the incoming air. **6.** The lining of the nasopharynx, which receives air from only the nasal cavity, is the same as that of the nasal cavity: a pseudostratified ciliated columnar epithelium. Because the oropharynx and laryngopharynx receive air from the nasal cavity and potentially abrasive food from the oral cavity, they have a more protective lining: a stratified squamous epithelium. **PAGE 874 7.** The unpaired laryngeal cartilages include the thyroid cartilage, cricoid cartilage, and epiglottis. The paired cartilages are the arytenoid cartilages, corniculate cartilages, and cuneiform cartilages. **8.** The trachea conveys air between the larynx and main bronchi; cilia and the mucus produced by epithelial cells also protect the respiratory tree by trapping inhaled debris and sweeping it toward

the pharynx, where it is removed through coughing or swallowing. **9.** The tracheal cartilages are C-shaped to allow space for expansion of the esophagus when food or liquid is swallowed.

10. Objects are more likely to be lodged in the right main bronchus because it is slightly larger and more vertical than the left main bronchus. **PAGE 876** **11.** Without surfactant, the alveoli would collapse as a result of surface tension in the thin layer of water that moistens the alveolar surfaces. **12.** Air passing through the glottis flows into the larynx and through the trachea. From there, the air flows into a main bronchus, which supplies the lungs. In the lungs, the air passes to lobar bronchi, segmental bronchi, bronchioles, a terminal bronchiole, a respiratory bronchiole, an alveolar duct, an alveolar sac, an alveolus, and ultimately to the blood-air barrier. **PAGE 879** **13.** The pulmonary arteries supply blood to the gas-exchange surfaces; the bronchial capillaries, supplied by the bronchial arteries, which branch from the thoracic aorta, supply the conducting portions of the respiratory system. **14.** The pleura is a serous membrane that secretes pleural fluid, which lubricates the opposing parietal and visceral surfaces to prevent friction during breathing. **PAGE 880** **15.** External respiration includes all the processes involved in the exchange of oxygen and carbon dioxide between the body's interstitial fluids and the external environment. Internal respiration is the absorption of oxygen and the release of carbon dioxide by the body's cells. **16.** The integrated steps involved in external respiration are pulmonary ventilation (breathing), gas diffusion across the blood-air barrier, and the transport of oxygen and carbon dioxide. **PAGE 887** **17.** Compliance is the ease with which the lungs expand. Factors affecting compliance include (a) the connective tissue structure of the lungs, (b) the level of surfactant production, and (c) the mobility of the thoracic cage. **18.** The measurable pulmonary volumes are tidal volume (V_T), expiratory reserve volume (ERV), residual volume, and inspiratory reserve volume (IRV). **19.** When the rib penetrates Bernie's chest wall, it also penetrates the left pleural cavity, allowing atmospheric air to enter and increase the intrapleural pressure within the pleural cavity (a condition called pneumothorax). As a result, the natural elasticity of the left lung may cause the lung to collapse, a condition called atelectasis. **20.** Because the fluid produced in pneumonia takes up space that would normally be occupied by air, vital capacity would decrease. **PAGE 892** **21.** Dalton's law states that each gas in a mixture exerts a pressure equal to its relative abundance. **22.** Henry's law states that at a constant temperature, the quantity of a particular gas that will dissolve in a liquid is directly proportional to the partial pressure of that gas. **PAGE 896** **23.** Carbon dioxide is transported in the bloodstream as bicarbonate ions, bound to hemoglobin, or dissolved in the plasma. **24.** During exercise, active skeletal muscles generate heat, lactate, and hydrogen ions. A combination of increased body temperature and decreased pH causes hemoglobin to release more oxygen when one is exercising than when one is resting. **25.** Blockage of the trachea would interfere with the body's ability to gain oxygen and eliminate carbon dioxide. Because most carbon dioxide is transported in blood as bicarbonate ions formed from the dissociation of carbonic acid, an inability to eliminate carbon dioxide would result in an excess of hydrogen ions, which decreases blood pH. **PAGE 904** **26.** Exciting the pneumotaxic centers would inhibit the inspiratory and apneustic centers, which would result in shorter and more rapid breaths. **27.** Peripheral chemoreceptors are more sensitive to the carbon dioxide level than to the oxygen level. When carbon dioxide dissolves, it forms carbonic acid, which dissociates and releases hydrogen ions, thereby decreasing pH and altering cell

or tissue activity. **28.** Omar isn't likely to turn blue and die. When he holds his breath, the blood carbon dioxide level is increasing, causing increased stimulation of the inspiratory center and forcing him to breathe again. **PAGE 905** **29.** Aging results in deterioration of elastic tissue (reducing compliance), decreased vital capacity, arthritic changes in rib articulations, decreased flexibility at costal cartilages, and some degree of emphysema. **PAGE 907** **30.** The respiratory system provides oxygen and eliminates carbon dioxide for all body systems. **31.** The respiratory system provides alveolar phagocytes and respiratory defenses to trap pathogens and protect deeper tissues. Tonsils within the lymphatic system protect against respiratory infection, and lymph drainage from the lungs mobilizes defenses to ward off infection.

Answers to Review Questions

PAGE 910

Level 1 Reviewing Facts and Terms

1. a **2.** b **3.** a **4.** d **5.** e **6.** (a) nasal cavity (b) pharynx (c) right lung (d) nose (e) larynx (f) trachea (g) bronchus (h) bronchioles (i) left lung **7.** Since the air Sherwin is breathing is dry, large amounts of moisture are leaving the mucus in his respiratory tract to humidify inhaled air. Drying makes the mucus viscous and makes it difficult for the cilia to move, so mucus builds up, producing nasal congestion by morning. When Sherwin showers and drinks fluids, body water is replaced, so the mucus loosens up and can be moved along as usual. **8.** The upper respiratory system consists of the nose, nasal cavity, paranasal sinuses, and pharynx. The lower respiratory system consists of the larynx, trachea, bronchi, bronchioles, and alveoli of the lungs. **9.** The larger part of the nasal cavity is covered by respiratory mucosa, which contributes to the quality of inhaled air; whereas the upper part is covered by olfactory mucosa, which contains the receptors providing the sense of smell. **10.** The thyroid cartilage forms the anterior walls of the larynx; the cricoid cartilage protects the glottis and the entrance to the trachea; the epiglottis forms a lid over the glottis; the arytenoid cartilages and the corniculate cartilages are involved in the formation of sound; and the cuneiform cartilages are found in the folds of the larynx. **11.** The steps of external respiration are (a) pulmonary ventilation (breathing); (b) gas diffusion across the blood-air barrier and between blood and interstitial fluids; and (c) the transport of oxygen and carbon dioxide between alveolar and peripheral capillaries. **12.** Fetal hemoglobin has a higher affinity for oxygen than does adult hemoglobin. Thus, it binds more of the oxygen that is present, enabling it to "steal" oxygen from the maternal hemoglobin. **13.** Chemoreceptor inputs from the nervus glossopharyngeal nerves (IX) and the vagus nerves (X) and from receptors that monitor the composition of the cerebrospinal fluid.

Level 2 Reviewing Concepts

14. c **15.** c **16.** c **17.** d **18.** The nasal cavity cleanses, moistens, and warms inhaled air, whereas the mouth does not. Drier air entering through the mouth can irritate the trachea and cause throat soreness. **19.** Smooth muscle tissue in the walls of bronchioles allows changes in airway diameter (bronchodilation or bronchoconstriction), which provides control of the flow and distribution of air within the lungs, just as vasodilation and vasoconstriction of the arterioles control blood flow and blood distribution. **20.** The epiglottis forms a lid over the entrance of the larynx. During swallowing, the larynx is elevated and the epiglottis folds back over the glottis, preventing food from entering the respiratory tract. **21.** Pulmonary ventilation, the physical

movement of air into and out of the respiratory tract, maintains adequate alveolar ventilation. Alveolar ventilation, air movement into and out of the alveoli, prevents the buildup of carbon dioxide in the alveoli and ensures a continuous supply of oxygen that keeps pace with absorption by the bloodstream. **22. (a)** Boyle's law describes the inverse relationship between gas pressure and volume: If volume decreases, pressure rises; if volume increases, pressure falls. It is the basis for the direction of air movement in pulmonary ventilation. **(b)** Dalton's law states that each of the gases that make up a mixture of gases contributes to the total pressure in proportion to its relative abundance; that is, all the partial pressures added together equals the total pressure exerted by the gas mixture. This relationship is the basis for the calculation of the partial pressures of oxygen and carbon dioxide, and their exchange between blood and alveolar air. **(c)** Henry's law states that, at a given temperature, the amount of a particular gas that dissolves in a liquid is directly proportional to the partial pressure of that gas. Henry's law underlies the diffusion of gases between capillaries, alveoli, and interstitial fluid. **23.** A fish bone or a fine chicken bone that pierces the laryngeal wall can cause a laryngeal spasm and swelling, restricting the airway. **24.** During diaphragmatic breathing, air is drawn into the lungs mainly by contraction of the diaphragm. Air is exhaled passively when the diaphragm relaxes. In costal breathing, inhalation takes place mainly by contractions of the external intercostal muscles. Exhalation occurs passively when these muscles relax. Pregnant women rely more on costal breathing as the enlarging uterus pushes the abdominal organs against the diaphragm, restricting diaphragmatic movements. **25.** The pneumotaxic centers inhibit the apneustic centers and promote passive or active exhalation. The apneustic centers promote inhalation by stimulating the dorsal respiratory group in response to input from the vagus nerves.

Level 3 Critical Thinking and Clinical Applications

26. $AVR = \text{respiratory rate} \times (\text{tidal volume} - \text{dead space})$. In this case, the dead air space is 200 mL (the anatomical dead air space [150 mL] plus the volume of the snorkel [50 mL]); therefore, $AVR = \text{respiratory rate} \times (500 - 200)$. To maintain an AVR of 6.0 L/min, or 6000 mL/min, the respiratory rate must be $6000 / (500 - 200)$, or 20 breaths per minute. **27.** A person with chronic emphysema has constantly elevated blood levels of P_{CO_2} due to an inability to eliminate CO_2 efficiently because of physical damage to the lungs. Over time, the brain ignores the stimulatory signals produced by the increased CO_2 and begins to rely on information from peripheral chemoreceptors to set the pace of breathing. (In other words, accommodation has occurred.) The peripheral chemoreceptors also accommodate to the elevated CO_2 and respond primarily to the level of O_2 in the blood, increasing breathing when O_2 levels are low and decreasing breathing when O_2 levels are high. When pure O_2 was administered, chemoreceptors responded with fewer action potentials to the medulla oblongata, so Mr. M. stopped breathing. **28.** At puberty, the larynx of males enlarges. The vocal cords become thicker and longer and this results in the production of lower tones. In females, this does not happen, so Susy's voice will remain high pitched. **29.** In anemia, the blood's ability to carry oxygen is decreased due to the lack of functional hemoglobin, red blood cells, or both. Anemia does not interfere with the exchange of carbon dioxide within the alveoli, nor with the amount of oxygen that will dissolve in the plasma. Because chemoreceptors respond to dissolved gases and

pH, as long as the pH and the concentrations of dissolved carbon dioxide and oxygen are normal, ventilation patterns should not change significantly. **30.** The obstruction in Margot's right lung would prevent gas exchange. Thus, blood moving through the right lung would not be oxygenated and would retain carbon dioxide, which would lead to a lower blood pH than that of blood leaving the left lung. The lower pH for blood in the right lung would shift the oxygen-hemoglobin saturation curve to the left (the Bohr effect) as compared with the curve for the left lung.

Answers to Clinical Case Wrap-Up

PAGE 911 **1.** Breathing can be obstructed in the nose (a bad cold, growths such as nasal polyps, a broken nasal septum), in the sinuses (a seasonal allergy or sinus infection), in the oral cavity (an enlarged or swollen tongue), or in the pharynx (a swollen, sore throat). **2.** Children who have frequent URT infections often have huge, infected tonsils whose locations (lingual, palatine, and pharyngeal) crowd the back of the throat. These children can become mouth-breathers. A tonsillectomy (surgical removal of the tonsils) may be indicated to help the child breathe better and sleep through the night.

FIGURE 23-16 The inspiratory capacity is a total of the tidal volume and inspiratory reserve volume.

FIGURE 23-20 More oxygen is released when the pH is lower than normal and when temperature is higher than normal.

FIGURE 23-26 Inhibition of medulla oblongata chemoreceptors and respiratory muscles will decrease respiratory rate, the elimination of CO_2 at alveoli, and increase arterial P_{CO_2} .

Chapter 24

Answers to Checkpoints

PAGE 920 **1.** Organs of the digestive system include the oral cavity, pharynx, esophagus, stomach, small intestine, large intestine, and accessory organs (teeth, tongue, salivary glands, liver, pancreas, and gallbladder). **2.** The main function of the digestive system is to break down food, absorb the nutrients that can be used by body cells, and eliminate the remaining waste. **3.** The six primary processes of the digestive system are the following: (1) ingestion = entry of food; (2) mechanical digestion and propulsion = crushing and shearing of food to make it more accessible to enzymes and the propelling of food along the digestive tract; (3) chemical digestion = the chemical breakdown of food into smaller products for absorption; (4) secretion = the release of water, acids, and other substances by the epithelium of the digestive tract and by glandular organs; (5) absorption = movement of digested particles across the digestive epithelium and into the interstitial fluid of the digestive tract; and (6) defecation = the elimination of wastes as feces from the body. **4.** The mesenteries—sheets consisting of two layers of serous membrane connected by their loose connective tissue—support

and stabilize the organs in the abdominopelvic cavity and provide a route for the associated blood vessels, nerves, and lymphatic vessels. **5.** The layers of the gastrointestinal tract, beginning at the surface of the lumen, are the mucosa (adjacent to the lumen), submucosa, muscular layer, and serosa. **6.** The waves of contractions responsible for peristalsis are more efficient in propelling intestinal contents than segmentation, which is basically a churning action that mixes intestinal contents with digestive fluids. **7.** A drug that blocks parasympathetic stimulation, which increases muscle tone and activity in the digestive tract, would slow peristalsis. **PAGE 926** **8.** Structures associated with the oral cavity include the tongue, teeth, and salivary glands. **9.** Stratified squamous epithelium lines the oral cavity. It protects against friction or abrasion by food. **10.** Damage to the parotid glands, which secrete the carbohydrate-digesting enzyme salivary amylase, would interfere with the digestion of complex carbohydrates. **11.** The incisors are the teeth most useful for chopping (or cutting or shearing) pieces of relatively rigid food, such as raw vegetables. **12.** The fauces are the dividing line between the oral cavity and the pharynx. **PAGE 928** **13.** The pharynx is an anatomical space that receives a food bolus or liquid and passes it to the esophagus as part of the swallowing process. Air also passes through the pharynx. **14.** The structure connecting the pharynx to the stomach is the esophagus. **15.** The muscular layer of the esophagus is an unusual segment of the digestive tract because it (1) contains skeletal muscle cells along most of the length of the esophagus and (2) is surrounded by an adventitia. **16.** Muscles associated with the pharynx and deglutition are the palatal muscles, the palatopharyngeus, stylopharyngeus, and pharyngeal constrictors. **17.** When the soft palate and larynx elevate and the glottis closes, swallowing (deglutition) is occurring. **PAGE 933** **18.** The four major regions of the stomach are the cardia, fundus, body, and pyloric part. **19.** The low pH of the stomach creates an acidic environment that kills most microorganisms ingested with food, denatures proteins and inactivates most enzymes in food, helps break down plant cell walls and meat connective tissue, and activates pepsin. **20.** Large meals, especially meals with a high protein content, stimulate increased stomach acid secretion. When gastric glands are secreting, bicarbonate ions enter the bloodstream and increase the blood pH. This phenomenon is referred to as the alkaline tide. **21.** The vagus nerves (X) contain parasympathetic motor fibers that can stimulate gastric secretions, even if food is not present in the stomach (the cephalic phase of gastric activity). Cutting the branches of the vagus nerves that supply the stomach would prevent this type of secretion from occurring and thereby reduce the likelihood of ulcer formation. **PAGE 943** **22.** Damage to the exocrine pancreas would most impair the digestion of fats (lipids), because it is the primary source of lipases. Even though such damage would also reduce carbohydrate and protein digestion, enzymes for digesting these nutrients are produced by other digestive system structures, including the salivary glands (carbohydrates), the small intestine (carbohydrates and proteins), and the stomach (proteins). **23.** The portal triad is a region of a hepatic lobule made up of the interlobular artery, interlobular vein, and interlobular bile duct. **24.** The gallbladder concentrates and stores bile before secreting it into the small intestine. **PAGE 949** **25.** The three regions of the small intestine from proximal to distal are the duodenum, jejunum, and ileum. **26.** The small intestine has several adaptations that increase its surface area and thus its absorptive capacity for nutrients. The walls of the small intestine have folds called circular folds. The mucosa that covers the circular

folds has fingerlike projections, the villi. The epithelial cells that cover the villi have an exposed surface covered by small fingerlike projections, the microvilli. In addition, the small intestine has a very rich supply of blood vessels and lymphatic vessels, which transport the nutrients that are absorbed. **27.** A high-fat meal would raise the cholecystokinin (CCK) level in the blood. **28.** The hormone secretin, among other things, stimulates the pancreas to release fluid high in buffers to neutralize the chyme that enters the duodenum from the stomach. If the small intestine did not produce secretin, the pH of the intestinal contents would be lower than normal. **PAGE 954** **29.** The four regions of the colon are the ascending colon, transverse colon, descending colon, and sigmoid colon. **30.** The large intestine is larger in luminal diameter than the small intestine. The thin walls of the large intestine lack villi and have an abundance of mucous cells and intestinal glands. **31.** In haustral churning, segmentation movements mix the contents of nearby haustra. In mass movements, which occur a few times per day, strong peristaltic contractions move material from the transverse colon through the rest of the large intestine. **PAGE 959** **32.** The nutrients the body requires are carbohydrates, lipids, proteins, vitamins, electrolytes, minerals, and water. **33.** Because chylomicrons are formed from the fats digested in a meal, fats increase the number of chylomicrons in the lacteals. **34.** Removal of the stomach would interfere with the absorption of vitamin B₁₂. Parietal cells of the stomach are the source of intrinsic factor, which is required for the vitamin's absorption. **35.** When someone with diarrhea loses fluid and electrolytes faster than they can be replaced, the resulting dehydration can be fatal. Although constipation can be quite uncomfortable, it does not interfere with any life-supporting processes; the few toxic wastes normally eliminated by the digestive system can move into the blood and be eliminated by the kidneys. **PAGE 960** **36.** General age-related digestive system changes include decreased mitotic activity of epithelial cells, decreased secretory mechanisms, decreased gastric and intestinal motility, and loss of muscle tone associated with tract sphincters; cumulative damage becomes more apparent, cancer rates increase, and dehydration occurs as a result of decreased osmoreceptor sensitivity. **37.** The digestive system absorbs the organic substrates, vitamins, minerals, electrolytes (inorganic ions), and water required by cells of all other body systems. **38.** The skeletal, muscular, nervous, endocrine, and cardiovascular systems may all be affected by inadequate absorption of calcium ions.

Answers to Review Questions

PAGE 964

Level 1 Reviewing Facts and Terms

1. a **2.** b **3.** c **4.** c **5.** (a) oral cavity (mouth) (b) liver (c) gallbladder (d) pancreas (e) large intestine (f) salivary glands (g) pharynx (h) esophagus (i) stomach (j) small intestine (k) anus **6.** (a) mucosa (b) submucosa (c) muscular layer (d) serosa **7.** b **8.** b **9.** d **10.** (a) duodenum (b) jejunum (c) ileum **11.** d **12.** b **13.** b **14.** The six main processes of the digestive system are (1) ingestion, (2) mechanical digestion and propulsion, (3) chemical digestion, (4) secretion, (5) absorption, and (6) defecation. **15.** Layers of the digestive tract from the innermost layer nearest the lumen to the outermost layer are (1) the mucosa: the epithelial layer that performs chemical digestion and absorption of nutrients; (2) the submucosa: the connective tissue layer containing lymphatic and blood vessels and the submucosal nerve plexus; (3) the muscular layer: the smooth

muscle layer containing the myenteric nerve plexus; and (4) the serosa: the outermost layer, epithelium and connective tissue that forms the visceral peritoneum (or connective tissue that forms the adventitia). **16.** Activities of the digestive tract are regulated by local, neural, and hormonal mechanisms. **17.** The three phases of swallowing—the buccal, pharyngeal, and esophageal phases—are controlled by the swallowing center of the medulla oblongata by the trigeminal and glossopharyngeal cranial nerves. The motor commands originating at the swallowing center are distributed by cranial nerves V, IX, X, and XII. Along the esophagus, primary peristaltic contractions are coordinated by afferent and efferent fibers within the glossopharyngeal and vagus cranial nerves, but secondary peristaltic contractions occur in the absence of CNS instructions. **18.** The pancreas provides digestive enzymes, plus bicarbonate ions that elevate the pH of the chyme. The liver produces bile and is also the primary organ involved in regulating the composition of circulating blood. The gallbladder stores and releases bile, which contains additional buffers and bile salts that aid in the digestion and absorption of lipids. **19.** The hormones include the following: enterocrinin, which stimulates the submucosal glands of the duodenum; secretin, which stimulates the pancreas and liver to increase the secretion of water and bicarbonate ions; cholecystokinin (CCK), which causes an increase in the release of pancreatic secretions and bile into the duodenum, inhibits gastric activity, and appears to have CNS effects that reduce the sensation of hunger; gastric inhibitory peptide (GIP), which stimulates insulin release at pancreatic islets and the activity of the duodenal submucosal glands; vasoactive intestinal peptide (VIP), which stimulates the secretion of intestinal glands, dilates regional capillaries, and inhibits acid production in the stomach; gastrin, which is secreted by G cells in the duodenum when they are exposed to large quantities of incompletely digested proteins; and, in small quantities, motilin, which stimulates intestinal contractions; villikin, which promotes the movement of villi and associated lymph flow; and somatostatin, which inhibits gastric secretion. **20.** The large intestine reabsorbs water and compacts the intestinal contents into feces, absorbs important vitamins liberated by bacterial action, and stores fecal material prior to defecation. **21.** Positive feedback loops in the defecation reflex involve (1) stretch receptors in the rectal walls, which promote a series of peristaltic contractions in the colon and rectum, moving feces toward the anus in the intrinsic myenteric defecation reflex; and (2) the sacral parasympathetic defecation reflex, also activated by the stretch receptors, which stimulates peristalsis by motor commands.

Level 2 Reviewing Concepts

22. e 23. c 24. c 25. Your wisdom tooth has developed in a location that will not allow it to erupt. **26.** The stomach is protected from digestion by mucous secretions of its epithelial lining and by neural and hormonal control over the times and rates of acid secretion. **27.** (1) The cephalic phase of gastric secretion begins with the sight or thought of food. Directed by the CNS, this phase prepares the stomach to receive food. (2) The gastric phase begins with the arrival of food in the stomach; this phase is initiated by distension of the stomach, an increase in the pH of the gastric contents, and the presence of undigested materials in the stomach. (3) The intestinal phase begins when chyme starts to enter the small intestine. This phase controls the rate of gastric emptying and ensures that the secretory, digestive, and absorptive functions of the small intestine can proceed reasonably efficiently. **28.** After

a heavy meal, bicarbonate ions pass from the parietal cells of the stomach into the interstitial fluid. The diffusion of bicarbonate ions from the interstitial fluid into the bloodstream increases blood pH. This sudden influx of bicarbonate ions into the bloodstream has been called the alkaline tide.

Level 3 Critical Thinking and Clinical Applications

29. Alcohol is absorbed by the digestive tract and transported to the liver for processing. The cells of the liver are not immune to toxic compounds and chronic exposure to alcohol can lead to cirrhosis. Cirrhosis is characterized by the replacement of healthy liver lobules by fibrous scar tissue. **30.** The darker color of his urine is probably due to increased amounts of the pigment urobilin, which gives urine its normal yellow color. Urobilin is derived from urobilinogen, which is formed in the large intestine by the action of intestinal bacteria on bile pigments. In an intestinal obstruction, the bile pigments cannot be eliminated by their normal route, so a larger-than-normal amount diffuses into the bloodstream, where the kidneys eliminate it. **31.** If an individual cannot digest lactose, this sugar passes into the large intestine in an undigested form. The presence of extra sugar in the chyme increases its osmolarity, so less water is reabsorbed by the intestinal mucosa. The bacteria that inhabit the large intestine can metabolize the lactose, and in the process they produce large amounts of carbon dioxide. This gas overstretches the intestine, which stimulates local reflexes that increase peristalsis. The combination of more-fluid contents and increased peristalsis causes diarrhea. The overexpansion of the intestine by gas, which is directly related to increased gas production by the bacteria, causes the severe pain and abdominal cramping. **32.** The primary effect of such surgeries would be a reduction in the volume of food (and thus in the number of calories) consumed because the person feels full after eating a small amount. This can result in significant weight loss.

Answers to Clinical Case Wrap-Up

PAGE 966 1. If Mirasol's *Clostridium difficile* colitis is not successfully treated with a fecal transplant, she is likely to continue to experience bloody diarrhea. This may result in progressive dehydration that can eventually lead to her death. She may also continue to experience abdominal pain and blood loss. Eventually, she may suffer from a lack of vitamin K (required for clotting factor production), biotin, and vitamin B₅. **2.** A view of the lining of Mirasol's large intestine with a colonoscope would likely reveal an inflamed, swollen, reddened surface and areas of raw, bleeding mucosa. In addition, there might be areas of white blood cells, accumulated in pockets of pus, as Mirasol's immune system tries to fight this *C. difficile* infection.

Answers to Figure-Based Questions

FIGURE 24-4 Circular and longitudinal muscles contract behind the bolus to force the bolus forward, while circular and longitudinal muscles relax ahead of the bolus to ease movement of the bolus through the digestive tract.

FIGURE 24-9 The submandibular glands produce glycoproteins called mucins.

FIGURE 24-12 The cardia is the region of the stomach that connects to the esophagus.

FIGURE 24-23 Chyme in the duodenum stimulates the secretion of GIP, secretin, CCK, and VIP.

FIGURE 24-26 Feces moving into the rectum cause distension, which stimulates stretch receptors.

Chapter 25

Answers to Checkpoints

PAGE 970 1. Metabolism is the sum of all biochemical processes under way within the human body; it includes anabolism and catabolism. Catabolism is the breakdown of organic molecules into simpler components, accompanied by the release of energy. Anabolism is the synthesis of new organic molecules from simpler components, and it requires energy. 2. Oxidation is a gain of oxygen, or loss of hydrogen or electrons, from an atom or molecule. Reduction is the loss of oxygen, or gain of hydrogen or electrons, to an atom or molecule. **PAGE 979** 3. The primary role of the citric acid cycle in ATP production is to transfer electrons from substrates to coenzymes. These electrons provide energy to produce ATP by the electron transport chain. 4. The process of oxidative phosphorylation releases energy from high-energy electrons that powers proton (hydrogen ion) pumps. These pumps move hydrogen ions from the mitochondrial matrix into the intermembrane space, creating an electrochemical proton gradient. In chemiosmosis, protons pass through hydrogen ion channels providing the energy necessary to bind ADP and P_i together into ATP. 5. A decrease in cytosolic NAD would reduce ATP production in mitochondria. Decreased NAD would reduce the amount of pyruvate produced by glycolysis; less pyruvate means that the citric acid cycle could produce less ATP in mitochondria. **PAGE 983** 6. Beta-oxidation is fatty acid catabolism that produces molecules of acetyl-CoA. 7. The four major groups of lipoproteins are chylomicrons, very low-density lipoproteins (VLDLs), low-density lipoproteins (LDLs), and high-density lipoproteins (HDLs). 8. High-density lipoproteins (HDLs) are considered beneficial to health because they reduce the amount of cholesterol in the bloodstream by transporting it to the liver for storage or excretion in the bile. **PAGE 985** 9. Transamination is the removal and transfer of an amino group from one molecule to another, especially from an amino acid to a keto acid. Deamination is the removal of an amino group from an amino acid. 10. A diet deficient in pyridoxine (vitamin B_6), an important coenzyme in deaminating and transaminating amino acids in cells, would interfere with the body's ability to metabolize proteins. **PAGE 987** 11. Glycogenesis (the formation of glycogen) in the liver increases after a high-carbohydrate meal. 12. Blood levels of urea increase during the postabsorptive state because the deamination of many amino acids at that time yields ammonium ions, which are then converted to urea by the liver. 13. Accumulated acetyl-CoA is likely to be converted into ketone bodies. **PAGE 993** 14. The two classes of vitamins are fat-soluble and water-soluble. 15. An athlete who is adding muscle mass through extensive training would try to maintain a positive nitrogen balance. 16. A decrease in the amount of bile salts, which are necessary for digesting and absorbing fats and fat-soluble vitamins (including vitamin A), would result in less vitamin A in the body and perhaps a vitamin A deficiency. **PAGE 1000** 17. The BMR of a pregnant female would be higher than her own BMR when she is not pregnant, due to both the increased metabolism associated with supporting the fetus and the contribution of fetal metabolism. 18. The vasoconstriction of peripheral vessels would decrease blood flow to the skin and thus the amount of heat the body can lose. As a result, body temperature would increase. 19. Infants have higher surface-to-volume ratios than do adults, and the body's temperature-regulating mechanisms are not fully functional at birth. As a result, infants must expend more energy to maintain body temperature, and they get cold more easily than do healthy adults.

Answers to Review Questions

PAGE 1002

Level 1 Reviewing Facts and Terms

1. a 2. e 3. d 4. a 5. d 6. a 7. (a) evaporation (b) radiation (c) convection (d) conduction 8. c 9. Lipoproteins are lipid-protein complexes that contain large insoluble glycerides and cholesterol, with a superficial coating of phospholipids and proteins. The major groups are chylomicrons, which consist of 95% triglyceride, are the largest lipoproteins, and carry absorbed lipids from the intestinal tract to the bloodstream; very low-density lipoproteins (VLDLs), which consist of triglyceride, phospholipid, and cholesterol and transport triglycerides to peripheral tissues; low-density lipoproteins (LDLs, or "bad cholesterol"), which are mostly cholesterol and deliver cholesterol to peripheral tissues; and high-density lipoproteins (HDLs, or "good cholesterol"), which are equal parts protein and lipid (cholesterol and phospholipids) and transport excess cholesterol to the liver for storage or excretion in bile.

Level 2 Reviewing Concepts

10. Oxidative phosphorylation is the generation of ATP as the result of the transfer of electrons from the coenzymes NADH and $FADH_2$ to oxygen by a sequence of electron carriers within mitochondria. The electrons are carried by the electron transport chain in the inner mitochondrial membrane. Energy from the stepwise passage of electrons (from H atoms) along the electron transport chain is used to pump hydrogen ions from the matrix into the intermembrane space. This forms an electrochemical proton (hydrogen ion) gradient across the inner mitochondrial membrane. Through the process of chemiosmosis, the hydrogen ions diffuse back through ATP synthase and generate ATP. The electrons, hydrogen ions, and oxygen combine to produce water as a by-product. 11. When glucose supplies are low and lipid reserves are inadequate, cells use amino acids to generate ATP by breaking them down in the citric acid cycle. All amino acids do not enter the cycle at the same point, so the ATP yield varies. 12. During the absorptive state, insulin prevents a large surge in blood glucose after a meal by causing the liver to remove glucose from the hepatic portal circulation. During the postabsorptive state, blood glucose begins to decline, triggering the liver to release glucose produced through glycogenolysis and gluconeogenesis. 13. Proteins are the most abundant organic components of the body, and they contain a great deal of nitrogen. Therefore, nitrogen balance equals protein balance. And, since a number of vital functions are performed by proteins, nitrogen balance is important for maintaining homeostasis. 14. Vitamins and minerals are essential components of the diet because the body cannot synthesize most of the vitamins and minerals it requires. 15. These terms refer to lipoproteins in the blood that transport cholesterol. "Good cholesterol" (high-density lipoproteins, or HDLs) transports excess cholesterol to the liver for storage or breakdown, whereas "bad cholesterol" (low-density lipoproteins, or LDLs) transports cholesterol to peripheral tissues, which unfortunately may include the arteries. The buildup of cholesterol in the arteries is linked to cardiovascular disease.

Level 3 Critical Thinking and Clinical Applications

16. d 17. Based just on the information given, Armondo would appear to be in good health, at least relative to his diet and probable exercise. Problems are associated with elevated levels of LDLs,

which carry cholesterol to peripheral tissues and make it available for the formation of atherosclerotic plaques in blood vessels. High levels of HDLs indicate that a considerable amount of cholesterol is being removed from the peripheral tissues and carried to the liver for disposal. You would encourage Armondo not to change and to keep up the good work. **18.** It appears that Patricia is suffering from ketoacidosis as a consequence of her anorexia. Because she is literally starving herself, her body is metabolizing large amounts of fatty acids and amino acids to provide energy and in the process is producing large quantities of ketone bodies (normal metabolites from these catabolic processes). One of the ketones formed is acetone, which can be eliminated through the lungs. Acetone has a fruity aroma, so her breath would also smell fruity. The ketones are also converted into keto acids such as acetic acid. In large amounts, this lowers the body's pH. This is probably the cause of her arrhythmias.

Answers to Clinical Case Wrap-Up

PAGE 1003 **1.** Diet and vitamin supplementation are the only known sources of vitamin A. Unlike some other vitamins that can be made by our skin (vitamin D₃) or by intestinal bacteria [vitamin K, biotin (B₇), pantothenic acid (B₅)], vitamin A is a true essential vitamin that must be consumed orally. **2.** Justine's vitamin-deficient diet is likely to lead to deficiencies of all the fat-soluble and water-soluble vitamins, including D, E, K, all the B vitamins, and vitamin C.

Answers to Figure-Based Questions

FIGURE 25-2 Glycolysis produces 2 pyruvate molecules with a net gain of 2 ATP molecules.

FIGURE 25-5 The energy produced from aerobic metabolism comes from the electron transport chain and the citric acid cycle.

Chapter 26

Answers to Checkpoints

PAGE 1006 **1.** The three major functions of the urinary system are (1) the excretion of metabolic wastes from body fluids, (2) the elimination of body wastes to the exterior, and (3) the regulation of homeostasis by maintaining the volume and solute concentration of blood. **2.** The urinary system consists of two kidneys, two ureters, a urinary bladder, and a urethra. **PAGE 1014** **3.** The renal corpuscle, proximal convoluted tubule, distal convoluted tubule, and the proximal part of the nephron loop and collecting duct are all in the renal cortex. (In a cortical nephron, most of the nephron loop is in the renal cortex; in a juxtamedullary nephron, most of the nephron loop is in the renal medulla.) **4.** Plasma proteins are too large to pass through the pores of the glomerular capillaries; only the smallest plasma proteins can pass between the foot processes of the podocytes. **5.** Damage to the juxtaglomerular complex of a nephron would interfere with the hormonal control of blood pressure. **PAGE 1016** **6.** The three distinct processes that form urine in the kidney are filtration, reabsorption, and secretion. **PAGE 1021** **7.** The parts of the glomerulus involved in

filtration are the glomerular capillaries, the basement membrane, and the foot processes of the podocytes. **8.** The factors that influence net filtration pressure are net hydrostatic pressure and blood colloid osmotic pressure. **9.** The factors that influence the rate of filtrate formation are the filtration pressure across glomerular capillaries, plus interactions among the responses by autoregulation, hormonal regulation (endocrine), and autonomic regulation (neural). **10.** A decrease in blood pressure would decrease the GFR by decreasing the blood hydrostatic pressure within the glomerulus. **PAGE 1028** **11.** When the plasma concentration of a substance exceeds its tubular maximum, the excess is not reabsorbed, so it is excreted in the urine. **12.** Increased amounts of aldosterone, which promotes Na⁺ retention and K⁺ secretion by the kidneys, would increase the K⁺ concentration of urine. **13.** If the concentration of Na⁺ in the filtrate decreased, fewer hydrogen ions could be secreted by the countertransport mechanism involving these two ions. As a result, the pH of the tubular fluid would increase. **14.** When the amount of Na⁺ in the tubular fluid passing through the distal convoluted tubule decreases, the cells of the macula densa are stimulated to release renin. The resulting activation of angiotensin II increases blood pressure. **PAGE 1037**

15. Without juxtamedullary nephrons, a steep osmotic concentration gradient could not exist in the medulla, and the kidneys would be unable to form concentrated urine. **16.** Digestion of a high-protein diet would lead to increased production of urea, a nitrogenous waste formed from the metabolism of amino acids during the breakdown of proteins. As a result, the urine would contain more urea, and urine volume might also increase because of the need to flush the excess urea. **PAGE 1041** **17.** An obstruction of a ureter would interfere with the passage of urine between the renal pelvis and the urinary bladder. **18.** The ability to control the urinary reflexes depends on the ability to control the external urethral sphincter, a ring of skeletal muscle, which acts as a valve. **PAGE 1042** **19.** Four general age-related changes in the urinary system are a decrease in the number of functional nephrons, a reduction in the GFR, a reduced sensitivity to ADH, and problems with the urinary reflex. **20.** Nephrolithiasis is the formation of renal calculi, or kidney stones. **21.** Incontinence may develop in elderly individuals as a result of either decreased muscle tone of the sphincter muscles controlling micturition or disorders of the CNS affecting the ability to control urination. **22.** For all systems, the urinary system excretes wastes collected from blood and maintains normal body fluid pH and ion composition. **23.** Body systems that make up the body's excretory system include the urinary, integumentary, respiratory, and digestive systems.

Answers to Review Questions

PAGE 1046

Level 1 Reviewing Facts and Terms

1. (a) renal sinus **(b)** renal pelvis **(c)** hilum **(d)** renal papilla **(e)** ureter **(f)** renal cortex **(g)** renal medulla **(h)** renal pyramid **(i)** minor calyx **(j)** major calyx **(k)** kidney lobe **(l)** renal columns **(m)** fibrous capsule **2. b** **3. e** **4. c** **5. b** **6. d** **7.** The urinary system excretes the metabolic wastes generated by cells throughout the body and eliminates them from the body in urine. It also regulates the volume and solute concentration of body fluids. **8.** The kidneys, ureters, urinary bladder, and urethra are the organs of the urinary system. **9.** renal corpuscle (glomerulus/glomerular capsule) → proximal convoluted tubule → nephron loop → distal convoluted tubule → collecting duct → papillary duct → renal pelvis

10. proximal convoluted tubule: reabsorbs all the useful organic substrates from the filtrate; nephron loop: reabsorbs over 90% of the water in the filtrate; distal convoluted tubule: secretes wastes into the tubular fluid that were not filtered or reabsorbed **11.** The juxtaglomerular complex secretes the enzyme renin and the hormone erythropoietin. **12.** renal artery → segmental arteries → interlobar arteries → arcuate arteries → cortical radiate arteries → afferent arterioles → glomerulus → venules → cortical radiate veins → arcuate veins → interlobar veins → renal vein **13.** Processes in urine production are (1) filtration: the selective removal of large solutes and suspended materials from a solution on the basis of size; requires a filtration membrane and hydrostatic pressure, as provided by gravity or by blood pressure; (2) reabsorption: the removal of water and solute molecules from the filtrate after it enters the renal tubules; and (3) secretion: the transport of solutes from the peritubular fluid, across the tubular epithelium, and into the tubular fluid. **14.** In peripheral capillary beds, angiotensin II causes powerful vasoconstriction of precapillary sphincters, increasing pressures in the renal arteries and their branches. At the nephron, angiotensin II causes the efferent arteriole to constrict, increasing glomerular pressures and filtration rates. At the PCT, it stimulates the reabsorption of sodium ions and water. In the CNS, angiotensin II triggers the release of ADH, stimulating the reabsorption of water in the distal portion of the DCT and the collecting system, and it causes the sensation of thirst. At the adrenal gland, angiotensin II stimulates the secretion of aldosterone by the cortex. Aldosterone accelerates sodium reabsorption in the DCT and the cortical portion of the collection system. **15.** In urine, urea is the most abundant waste product, followed by creatinine, ammonia, and uric acid.

Level 2 Reviewing Concepts

16. d 17. b 18. a 19. a 20. a 21. Creatinine clearance is a test that compares the creatinine level in urine with the creatinine level in blood by estimating the glomerular filtration rate (GFR). It is used as an index of overall kidney function. **22.** Controls on GFR are autoregulation at the local level, hormonal regulation initiated by the kidneys, and autonomic regulation (by the sympathetic division of the ANS). **23.** GHP is the blood pressure in the glomerular capillaries. This pressure tends to push water and solute molecules out of the plasma and into the filtrate. CsHP opposes GHP. CsHP tends to push water and solutes out of the filtrate and into the plasma, and results from the resistance of filtrate already present in the nephron that must be pushed toward the renal pelvis. The difference between GHP and CsHP is the net hydrostatic pressure (NHP). **24.** Countercurrent multiplication (1) is an efficient way to reabsorb solutes and water before the tubular fluid reaches the DCT and collecting system and (2) establishes an osmotic concentration gradient in the medulla that permits the passive reabsorption of water from urine in the collecting system. **25.** Urine storage occurs by spinal reflexes and the pontine storage center. When urine is being stored, afferent impulses from stretch receptors in the bladder wall stimulate sympathetic outflow to the detrusor and internal urethral sphincter, inhibiting contraction of the detrusor and stimulating contraction of the internal urethral sphincter. The pontine storage center inhibits urination by decreasing parasympathetic activity and increasing somatic motor nerve activity at the external urethral sphincter. Urine cannot pass through the urethra and remains stored.

Level 3 Critical Thinking and Clinical Applications

26. d 27. c 28. Increasing the volume of urine produced decreases the total blood volume of the body, which in turn leads to a decreased blood hydrostatic pressure. Edema frequently results when the hydrostatic pressure of the blood exceeds the opposing forces at the capillaries in the affected area. Depending on the actual cause of the edema, decreasing the blood hydrostatic pressure would decrease edema formation and possibly cause some of the fluid to move from the interstitial spaces back to the blood. **29.** Renal arteriosclerosis restricts blood flow to the kidneys and produces renal ischemia. Decreased blood flow and ischemia trigger the juxtaglomerular complex to produce more renin, which leads to elevated levels of angiotensin II and aldosterone. Angiotensin II causes vasoconstriction, increased peripheral resistance, and thus increased blood pressure. The aldosterone promotes sodium retention, which leads to more water retained by the body and an increase in blood volume. This too contributes to a higher blood pressure. Additionally, in response to tissue hypoxia, erythropoietin release is increased, stimulating the formation of red blood cells, which leads to increased blood viscosity and again contributes to hypertension. **30.** Bert probably has kidney stones. Kidney stones create urinary obstruction. This condition can cause extreme pain and decrease or even prevent filtration in the affected kidney. **31.** Carbonic anhydrase catalyzes the reaction that forms carbonic acid, a source of hydrogen ions that are excreted by the kidneys. Hydrogen ion excretion occurs by countertransport in which sodium ions are exchanged for hydrogen ions. Fewer hydrogen ions would be available, so less sodium would be reabsorbed, causing an increased osmolarity of the filtrate. In turn, an increased volume of urine and more frequent urination would result.

Answers to Clinical Case Wrap-Up

PAGE 1047 1. Waylen's x-rays show fractures of the left 11th and 12th ribs, overlying the left kidney. They also show fractures of the transverse processes of the first three lumbar vertebrae on the left. The left renal hilum lies between the fractured ribs and the fractured lumbar vertebral transverse processes. These visible fractures are a strong indication that the soft tissues and organs in this area are also injured. **2.** If Waylen survives this trauma, the GFR of his solitary right kidney is likely to increase to compensate for the loss of his left kidney. This is to be expected if there has been no trauma to his right kidney.

Answers to Figure-Based Questions

Chapter 27

Answers to Checkpoints

PAGE 1051 1. The three interrelated processes essential to stabilizing body fluid volumes are fluid balance, electrolyte balance, and acid–base balance. **PAGE 1055** 2. The components of extracellular fluid (ECF) are interstitial fluid, plasma, and other body fluids; the intracellular fluid (ICF) is the cytosol of a cell. 3. Three hormones affecting fluid and electrolyte balance are antidiuretic hormone (ADH), aldosterone, and natriuretic peptides (ANP and BNP). 4. Consuming a half-gallon of distilled water might temporarily decrease a person's blood osmolarity (osmotic concentration). This decrease in osmolarity would lead to a decrease in the level of ADH in the blood, because ADH release is triggered by increases in osmolarity. **PAGE 1058** 5. Edema (swelling) results from the movement of abnormally large amounts of water from plasma into interstitial fluid. 6. A fluid shift is a rapid movement of water between the ECF and ICF in response to an osmotic gradient. 7. Dehydration is a decrease in the water content of the body that develops when water losses outpace water gains, and this threatens homeostasis. 8. If a person were in the desert without water, they would lose fluid through perspiration, urination, and breathing. As a result, the osmotic concentration of their blood plasma (and other body fluids) would increase. **PAGE 1063** 9. In the ECF, four important cations are sodium, potassium, calcium, and magnesium; two important anions are phosphate and chloride. 10. Sweat is a hypotonic solution with lower sodium ion concentration than the ECF. Sweating causes a greater loss of water than of sodium, increasing the blood plasma sodium ion level. 11. Potassium ion imbalances are more dangerous than sodium ion imbalances because they can lead to extensive muscle weakness or even paralysis when blood concentrations are too low and to cardiac arrhythmias when the levels are too high. Disturbances in sodium balance, by contrast, produce dehydration or tissue edema. **PAGE 1070** 12. The body's three major buffer systems are the phosphate buffer system, the protein buffer systems, and the carbonic acid–bicarbonate buffer system. 13. A decrease in the pH of body fluids accompanies an increase in the partial pressure of carbon dioxide. Chemoreceptors sensitive to P_{CO_2} would stimulate the respiratory centers of the medulla oblongata, resulting in an increase in the respiratory rate. 14. Tubular fluid in nephrons must be buffered to avoid decreasing the pH below approximately 4.5, at which point H^+ secretion cannot continue because the H^+ concentration gradient becomes too steep. The hydrogen ions would leak out of the tubule as fast as they are pumped in. **PAGE 1077** 15. In a prolonged fast, fatty acids are catabolized, producing large numbers of ketone bodies, which are metabolic acids that decrease the blood pH. (The decreased pH would eventually lead to ketoacidosis.) 16. When a person has prolonged vomiting, large amounts of stomach hydrochloric acid (HCl) are lost from the body. More H^+ and Cl^- are then formed by the parietal cells of the stomach. The H^+ that are released were produced by the dissociation of carbonic acid and exchange of bicarbonate ions with chloride ions from the blood. The alkaline tide of released bicarbonate ions increases the blood pH, leading to metabolic alkalosis. **PAGE 1079** 17. A decrease in the glomerular filtration rate and the number of functional nephrons reduces the body's ability to regulate pH through renal compensation. 18. Total body water content gradually decreases with age.

Answers to Review Questions

PAGE 1081

Level 1 Reviewing Facts and Terms

1. c 2. c 3. d 4. (a) carbonic acid (H_2CO_3) (b) bicarbonate ion (HCO_3^-) (c) sodium bicarbonate (NaHCO_3) 5. d 6. d 7. b 8. d 9. a 10. The primary role of the carbonic acid–bicarbonate buffer system is to prevent changes in pH caused by metabolic acids and fixed acids in the ECF. The three limitations are as follows: (1) it cannot protect the ECF from changes in pH that result from an increased or decreased level of CO_2 ; (2) it can function only when the respiratory system and the respiratory control centers are working normally; and (3) the ability to buffer acids is limited by the availability of bicarbonate ions.

Level 2 Reviewing Concepts

11. c 12. b 13. c 14. b 15. Fluid balance is a state in which the amount of water gained each day is equal to the amount lost to the environment. It is vital that the water content of the body remain stable, because water is an essential ingredient of cytoplasm and accounts for about 99% of ECF volume. Electrolyte balance exists when there is neither a net gain nor a net loss of any ion in body fluids. It is important that the ionic concentrations in body water remain within normal limits; if levels of calcium or potassium become too high, for instance, cardiac arrhythmias can develop. Acid–base balance exists when the production of hydrogen ions precisely offsets their loss. The pH of body fluids must remain within a relatively narrow range; variations outside this range can be life threatening. 16. Fluid shifts are rapid water movements between the ECF and the ICF that occur in response to increases or decreases in the osmotic concentration of the ECF. Such water movements dampen extreme shifts in electrolyte balance. 17. Because the primary problem in volume depletion is water loss, an exercising athlete should drink plain water at regular intervals to rehydrate. 18. (a) Acids that can leave solution and enter the atmosphere, such as carbonic acid, are volatile acids. (b) Acids that do not leave solution, such as sulfuric acid, are fixed acids. (c) Acids produced during metabolism, such as pyruvic acid, lactic acid, and ketones, are metabolic acids. Volatile acids are the greatest threat because of the large amounts generated by normal cellular processes. 19. (1) Phosphate buffer system: This buffer system consists of dihydrogen phosphate (H_2PO_4^-), a weak acid that, in solution, reversibly dissociates into a hydrogen ion and monohydrogen phosphate (HPO_4^{2-}). The phosphate buffer system plays a relatively small role in regulating the pH of the ECF, because the ECF contains far higher concentrations of bicarbonate ions than phosphate ions; however, it is important in buffering the pH of the ICF. (2) Protein buffer systems: These depend on the ability of amino acids to respond to changes in pH by accepting or releasing hydrogen ions. If the pH rises, the carboxyl group of the amino acid dissociates to release a hydrogen ion; if the pH drops, the amino group accepts an additional hydrogen ion to form an amino ion (NH_3^+) and the carboxylate ion can accept a hydrogen ion to form a carboxyl group. Plasma proteins contribute to the buffering capabilities of the blood; inside cells, protein buffer systems stabilize the pH of the ECF by absorbing extracellular hydrogen ions or exchanging intracellular hydrogen ions for extracellular potassium. (3) Carbonic acid–bicarbonate system: Most carbon dioxide generated in tissues is converted to carbonic acid, which dissociates into a hydrogen ion

and a bicarbonate ion. Hydrogen ions released by dissociation of organic or fixed acids combine with bicarbonate ions, elevating the P_{CO_2} ; additional CO_2 is lost at the lungs. **20.** A patient with hypocalcemia can develop osteoporosis and muscle spasms, and can also have convulsions. **21.** Respiratory compensation is a change in the respiratory rate that helps stabilize the pH of the ECF. Increasing or decreasing the rate of respiration alters pH by decreasing or increasing the P_{CO_2} . When the P_{CO_2} decreases, the pH increases; when the P_{CO_2} increases, the pH decreases. Renal compensation is a change in the rates of hydrogen and bicarbonate ion secretion or reabsorption in response to changes in blood pH. The secretion of hydrogen ions into tubular fluid results in the diffusion of bicarbonate ions into the ECF. **22.** Respiratory disorders result from abnormal CO_2 levels in the ECF. An imbalance exists between the rate of CO_2 removal by the lungs and its generation in other tissues. Metabolic disorders are caused by the generation of metabolic or fixed acids or by conditions affecting the concentration of bicarbonate ions in the ECF. **23.** After the age of 60, the total body water content declines to about 50% for males and 45% for females. This decrease reduces the dilution of waste products. **24.** Drinks with low glucose concentrations are useful in replenishing exhausted metabolic reserves. Drinks with high glucose concentrations can lead to cramps and diarrhea. **25.** Since sweat is usually hypotonic, the loss of a large volume of sweat causes hypertonicity in body fluids. The loss of fluid volume is primarily from the interstitial space, which leads to a decrease in plasma volume and an increase in the hematocrit. Severe dehydration can cause the blood viscosity to increase substantially, resulting in an increased workload on the heart, ultimately increasing the probability of heart failure.

Level 3 Critical Thinking and Clinical Applications

26. The young boy has metabolic and respiratory acidosis. The metabolic acidosis resulted primarily from the large amounts of lactate and H^+ generated by the boy's muscles as he struggled in the water. Sustained hypoventilation during drowning contributed to both tissue hypoxia and respiratory acidosis. Respiratory acidosis developed as the P_{CO_2} increased in the ECF, increasing the production of carbonic acid and its dissociation into H^+ and HCO_3^- . Prompt emergency treatment is essential. The usual procedure involves some form of artificial or mechanical respiratory assistance (to increase the respiratory rate and decrease H^+ in the ECF) coupled with the intravenous infusion of a buffered isotonic solution containing sodium lactate, sodium gluconate, or sodium bicarbonate that would absorb the H^+ in the ECF and increase body fluid pH. **27. b** **28.** When tissues are burned, cells are destroyed and their cytoplasmic contents leak into the interstitial fluid and then move into the plasma. Since potassium ions are normally found within the cell, damage to many cells release relatively large amounts of potassium ions into the blood. The elevated potassium level stimulates cells of the adrenal cortex to produce aldosterone and cells of the juxtaglomerular complex to produce renin. Renin activates the renin-angiotensin-aldosterone system. Ultimately, angiotensin II stimulates increased aldosterone secretion, which promotes sodium retention and potassium secretion by the kidneys, thereby accounting for the elevated potassium levels in the patient's urine. **29.** Digestive secretions contain high levels of bicarbonate, so individuals with diarrhea can lose significant amounts of this important ion, leading to acidosis. We would expect Alma's blood pH to be lower than 7.35 and that of her urine to be low (due to increased

renal excretion of hydrogen ions). We would also expect an increase in the rate and depth of breathing as the respiratory system tries to compensate by eliminating carbon dioxide. **30.** The hypertonic solution will cause fluid to move from the ICF to the ECF, further aggravating Yuka's dehydration. The slight increase in pressure and osmolarity of the blood should lead to an increase in ADH, even though ADH levels are probably quite high already. Despite the high ADH levels, urine volume would probably increase, because the kidneys could not reabsorb much of the glucose. The remaining glucose would increase the osmolarity of the tubular filtrate, decreasing water reabsorption and increasing urine volume. **31.** Patient 1 has compensated respiratory alkalosis. Patient 2 has acute metabolic acidosis due to the generation or retention of metabolic or fixed acids. Patient 3 has acute respiratory acidosis. Patient 4 has metabolic alkalosis.

Answers to Clinical Case Wrap-Up

PAGE 1082 **1.** Marquis should be treated with potassium replacement. He can take K^+ orally, or it can be given intravenously (IV) for faster replacement. His doctor should consider changing his blood pressure medication to one that does not cause a loss of K^+ . (These are often called potassium-sparing diuretics.) **2.** When Marquis complains of a "frog jumping around" in his chest with dizziness, he is likely describing a cardiac arrhythmia. This can be the most serious complication of hypokalemia and can lead to sudden cardiac death.

Answers to Figure-Based Questions

FIGURE 27-2 Mg^{2+} and K^+ are found in higher concentrations in the intracellular fluid, while Na^+ and Cl^- are found in higher concentrations in the extracellular fluid.

FIGURE 27-7 If the K^+ concentration rises above 7 mEq/L (hyperkalemia), a serious condition that could occur is a cardiac arrhythmia.

FIGURE 27-10 The phosphate and protein buffer systems help regulate the pH of the intracellular fluid (ICF).

FIGURE 27-14 The kidney's response to alkalosis is to conserve H^+ and secrete HCO_3^- .

FIGURE 27-16 In metabolic acidosis, arterial and CSF chemoreceptors are stimulated, which results in increased respiratory rate and a decrease in P_{CO_2} .

Chapter 28

Answers to Checkpoints

PAGE 1085 **1.** A gamete is a functional male or female reproductive cell. **2.** Basic structures of the reproductive system are gonads (reproductive organs), ducts (which receive and transport gametes), accessory glands (which secrete fluids), and external genitalia (perineal structures). **3.** Gonads are reproductive organs that produce gametes and hormones. **PAGE 1093** **4.** Male reproductive structures are the scrotum, testes, epididymides, ductus deferentia, ejaculatory duct, urethra, seminal glands, prostate, bulbo-urethral glands, and penis. **5.** On a warm day, the cremaster (as well as the dartos muscle) would be relaxed so that the scrotum could descend away from the warmth of the body, thereby cooling the testes. **6.** The pathway of sperm is as follows: seminiferous tubule → straight tubule → rete testis → efferent ductules → epididymis → ductus deferens → ejaculatory duct → urethra. **PAGE 1100** **7.** Low FSH levels would lead to low levels of testosterone in the

seminiferous tubules, decreasing both the sperm production rate and sperm count. **PAGE 1110** **8.** Structures of the female reproductive system include the ovaries, uterine tubes, uterus, vagina, and external genitalia (mons pubis, the clitoris and the labia majora and labia minora). **9.** The blockage of both uterine tubes would cause sterility. **10.** The acidic pH of the vagina helps prevent bacterial, fungal, and parasitic infections in this region. **11.** Blockage of a single lactiferous sinus would not interfere with the delivery of milk to the nipple because the mammary gland of each breast generally has 15–20 lactiferous sinuses. **PAGE 1119** **12.** The functional layer of the endometrium is sloughed off, or shed, during menstruation. **13.** If the LH surge did not occur during an ovarian cycle, ovulation and corpus luteum formation would not occur. **14.** Blockage of progesterone receptors in the uterus would inhibit the development of the endometrium, making the uterus unprepared for pregnancy. **15.** A decrease in the levels of estrogens and progesterone signals the beginning of menstruation, the end of the uterine cycle. **PAGE 1121** **16.** When the arteries within the penis dilate, the increased blood flow causes the erectile tissues of the corpora cavernosa and corpus spongiosum to engorge with blood, producing an erection. **17.** The physiological events of sexual intercourse in both sexes are arousal, erection, lubrication, orgasm, and resolution. Emission and ejaculation are additional phases that occur only in males. **18.** An inability to contract the ischiocavernosus and bulbospongiosus muscles would interfere with a male's ability to ejaculate and to experience orgasm. **19.** Parasympathetic stimulation in females during sexual arousal causes **(a)** engorgement of the erectile tissue of the clitoris and vestibular bulbs, **(b)** increased secretion of cervical and greater vestibular glands, **(c)** increased blood flow to the wall of the vagina, and **(d)** engorgement of the blood vessels in the nipples. **PAGE 1124** **20.** The genital tubercle of a sexually indifferent embryo will develop into a penis in the presence of testosterone or a clitoris in its absence. **21.** The male climacteric, or andropause, is a period of declining reproductive function in men, typically between the ages of 50 and 60. **22.** Menopause is the time when ovulation and menstruation cease, typically around ages 45–55. **23.** At menopause, circulating estrogen levels begin to decrease. Estrogen has an inhibitory effect on FSH (and on GnRH). As the level of estrogen decreases, the levels of FSH increase and remain high. **PAGE 1126** **24.** The cardiovascular system distributes reproductive hormones; provides nutrients, oxygen, and waste removal for the fetus; and produces local blood pressure changes responsible for the physical changes that occur during sexual intercourse. The reproductive system supplies estrogens that may help maintain healthy blood vessels and slow the development of atherosclerosis. **25.** Pelvic bones protect reproductive organs in females and portions of the ductus deferentia and accessory glands in males; sex hormones stimulate growth and maintenance of bones and accelerate growth and closure of epiphyseal cartilages at puberty.

Answers to Review Questions

PAGE 1128

Level 1 Reviewing Facts and Terms

1. e 2. d 3. d 4. c 5. a 6. The accessory structures include the seminal glands (seminal vesicles), which provide the nutrients that sperm need for motility; prostaglandins that stimulate smooth muscle contractions along the male and female reproductive tracts thereby propelling sperm and fluids; fibrinogen that temporarily clots the ejaculate within the vagina; buffers that

counteract the acidity of the prostatic secretions and urethral and vaginal contents; the prostate gland, which aids the activation of the sperm (with seminal gland secretions); and the bulbo-urethral glands, which buffer acids in the penile urethra and lubricate the glans penis. The fluids secreted by the accessory glands make up about 95% of the volume of semen. **7.** Interstitial endocrine cells (Leydig cells) produce male sex hormones (androgens), the most important of which is testosterone; nurse cells maintain the blood-testis barrier, support spermatogenesis and spermiogenesis, and secrete inhibin, and androgen-binding protein. **8.** The parasympathetic division of the autonomic nervous system controls sexual arousal. **9.** In males, testosterone stimulates spermatogenesis and promotes the functional maturation of sperm; maintains the male accessory reproductive organs; determines male secondary sex characteristics; stimulates metabolic pathways, especially those concerned with protein synthesis and muscle growth; and affects CNS function by stimulating sexual drive and sexual behaviors. **10.** In 80% of adult females, the uterus bends anteriorly near its base in antelexion and is secured in the pelvic cavity by several ligaments. **11.** At ovulation, an egg is released into the pelvic cavity and is caught in the infundibulum of the uterine tube. Peristalsis and ciliary movements in the tube wall push the egg towards the uterus. **12.** The clitoris—a part of the external genitalia of females that is derived from the same embryonic structures as the penis—contains erectile tissue that becomes engorged with blood during sexual arousal and provides pleasurable sensations. **13.** Path of milk flow: secretory lobules of glandular tissue (lobes) → ducts → lactiferous duct → lactiferous sinus, which opens onto the surface of the nipple **14. (a)** prostatic urethra **(b)** spongy urethra **(c)** ductus deferens **(d)** penis **(e)** epididymis **(f)** testis **(g)** external urethral orifice **(h)** scrotum **(i)** seminal gland **(j)** prostate **(k)** ejaculatory duct **(l)** bulbo-urethral gland

Level 2 Reviewing Concepts

15. a 16. The hypothalamic secretion of GnRH triggers the pituitary secretion of FSH and LH. FSH initiates follicular development, and activated follicles and ovarian thecal endocrine cells produce estrogens. High estrogen levels stimulate LH secretion and increase anterior pituitary lobe sensitivity to GnRH, causing the release of LH. Progesterone is the main hormone of the luteal phase. Changes in estrogen and progesterone levels are responsible for maintaining the uterine cycle. **17.** To produce gametes, diploid parent cells undergo meiosis (I and II) and give rise to four cells, among which the chromosomes are evenly distributed. In males, four spermatids of identical size are produced, and each develops into a functional sperm. In females, one oocyte and three polar bodies are produced, and the oocyte completes meiosis II only if fertilization takes place. **18.** The erectile tissues of the penis include the corpora cavernosa and the corpus spongiosum. The corpora cavernosa underlie the anterior surface of the flaccid penis as far as the neck of the glans penis, and the erectile tissue within each corpus cavernosum surrounds a central artery. The slender corpus spongiosum surrounds the urethra and extends from the superficial fascia of the urogenital diaphragm to the tip of the penis, where it expands to form the glans penis. The sheath surrounding the corpus spongiosum contains more elastic fibers than the corpora cavernosa, and the erectile tissue contains a pair of arteries. When parasympathetic neurons innervating the penile arteries release nitric oxide, smooth muscles in the arteriolar and arterial walls relax, dilating the vessels and increasing blood flow; the resulting engorgement of the vascular channels with blood causes

erection of the penis. **19.** (1) The menstrual phase is the interval marked by the degeneration and loss of the functional layer of the endometrium; it lasts 1–7 days and 35–50 mL (1.2–1.7 oz) of blood is lost. (2) The proliferative phase features growth and vascularization, resulting in the complete restoration of the functional layer; it lasts from the end of menstruation until the beginning of ovulation, around day 14. (3) During the secretory phase, the uterine glands enlarge, accelerating their rates of secretion, and the arteries elongate and spiral through the tissues of the functional layer; this phase begins at ovulation, occurs under the combined stimulatory effects of progesterone and estrogens from the corpus luteum, and persists as long as the corpus luteum remains intact. **20.** As follicular development proceeds, the concentration of circulating estrogen rises and the level of circulating inhibin rises. The rising estrogen and inhibin levels inhibit hypothalamic secretion of GnRH and pituitary production and release of FSH. (GnRH pulse frequency is increased by estrogens and decreased by progesterone.) As tertiary ovarian follicles develop and estrogen levels rise, the pituitary output of LH gradually increases. Estrogens, FSH, and LH continue to support follicular development and maturation despite a gradual decline in FSH levels. In the second week of the ovarian cycle, estrogen levels sharply increase, and the dominant tertiary ovarian follicle enlarges in preparation for ovulation. By day 14, estrogen levels peak, triggering a massive outpouring of LH from the anterior lobe of the pituitary gland. The rupture of the follicular wall results in ovulation. Next, LH stimulates the formation of the corpus luteum, which secretes moderate amounts of estrogens but large amounts of progesterone, the principal hormone of the postovulatory period. About 12 days after ovulation, declining progesterone and estrogen levels stimulate hypothalamic receptors and GnRH production increases, leading to increased FSH and LH production in the anterior lobe of the pituitary gland; the cycle begins again. **21.** The corpus luteum degenerates and progesterone and estrogen levels decrease, causing degeneration of the endometrium and the onset of menstruation. Next, rising levels of FSH, LH, and estrogen stimulate the repair and regeneration of the functional layer of the endometrium. During the postovulatory phase, the combination of estrogen and progesterone causes the enlargement of the uterine glands and an increase in their secretory activity. **22.** During fetal development, the testes form inside the body cavity adjacent to the kidneys. As the body enlarges, the testes gradually move inferiorly and anteriorly toward the anterior abdominal wall. During the seventh developmental month, each testis moves through the abdominal musculature. This process is called the descent of the testes into the scrotum. Descent of the female gonads is much less than that in males. The ovaries come to lie below the rim of the true pelvis. They are held in place by ligaments. **23.** Males aged 50–60 experience the male climacteric, a time when circulating testosterone levels begin to decline and circulating levels of FSH and LH rise. Although sperm production continues, a gradual reduction in sexual activity occurs in older males. Females aged 45–55 experience menopause—the time that ovulation and menstruation cease, accompanied by a sharp and sustained rise in the production of GnRH, FSH, and LH and a drop in the concentrations of circulating estrogen and progesterone. The decline in estrogen levels leads to reductions in the size of the uterus and breasts, accompanied by a thinning of the urethral and vaginal walls. In addition to neural and cardiovascular effects, reduced estrogen concentrations have been linked to the development of osteoporosis, presumably because bone deposition proceeds at a slower rate.

Level 3 Critical Thinking and Clinical Applications

24. An enlargement of the prostate or benign prostatic hyperplasia is common in elderly men as testosterone production decreases with age and the interstitial endocrine cells begin releasing small quantities of estrogens into the blood. The combination of a lower testosterone level and the presence of estrogens stimulates prostatic growth. Prostatic swelling can constrict and block the urethra. **25.** Regardless of their location, endometrial cells have receptors that respond to estrogen and progesterone. Under the influence of estrogen at the beginning of the menstrual cycle, any endometrial cells in the peritoneal cavity proliferate and begin to develop glands and blood vessels, which then further develop under the control of progesterone. The dramatic increase in size of this tissue presses on neighboring abdominal tissues and organs, causing periodic painful sensations. **26.** Slightly elevated levels of estrogen and progesterone inhibit both GnRH release at the hypothalamus and the release of FSH and LH from the anterior lobe of the pituitary gland. Without FSH, tertiary ovarian follicles do not begin to develop, and levels of estrogen remain low. An LH surge, triggered by the peaking of estradiol, is necessary for ovulation to occur. If the level of estradiol is not allowed to rise above the critical level, the LH surge will not occur, and thus ovulation will not occur, even if a tertiary ovarian follicle managed to develop to a stage at which it could ovulate. Any mature follicles would ultimately degenerate, and no new follicles would mature to take their place. Although the ovarian cycle is interrupted, the level of hormones is still adequate to regulate a normal menstrual cycle. **27.** These observations suggest that a certain amount of body fat is necessary for menstrual cycles to occur. The nervous system appears to respond to circulating levels of the adipose tissue hormone leptin; when leptin levels fall below a certain set point, menstruation ceases. Because females who lack adequate fat reserves might not be able to have a successful pregnancy, the body prevents pregnancy by shutting down the ovarian cycle and thus the menstrual cycle. Once sufficient energy reserves become available, the cycles begin again.

Answers to Clinical Case Wrap-Up

PAGE 1129 **1.** Leticia's secondary oocyte leaves the tertiary ovarian follicle and is picked up by the fimbriae of the uterine tube. The oocyte is moved by cilia through the infundibulum, ampulla, and isthmus of the uterine tube. Carlos's spermatozoa will meet and fertilize the oocyte at the junction of ampulla and isthmus. The fertilized oocyte, now an ovum, will continue into the uterine cavity, where it will attach to the endometrium. **2.** Ovulation occurs at the midpoint, or day 14, of a 28-day cycle. Leticia might experience "mittelschmerz" (German, "middle pain"), a discrete painful sensation as the secondary oocyte bursts out of the ovary. Blood tests will show a surge in LH from the anterior lobe of the pituitary gland. Her basal body temperature will rise and stay high until the end of her cycle.

Answers to Figure-Based Questions

FIGURE 28-7 The corpora cavernosa is split into two cylindrical masses and surrounds a central artery. The corpus spongiosum surrounds the urethra.

FIGURE 28-9 During mitosis, the spermatogonium divides, forming another spermatogonium and a primary spermatocyte. During meiosis I, the primary spermatocyte divides into two secondary spermatocytes. During meiosis II, each secondary spermatocyte divides into two spermatids. During spermiogenesis (the physical maturation), the four spermatids develop into four sperm.

- FIGURE 28-11** The centrioles are found in the neck of the sperm.
FIGURE 28-22 During ovulation, the oocyte is a secondary oocyte.
FIGURE 28-23 The functional layer of the endometrium is affected most during the uterine cycle. During menstruation, the entire functional layer is sloughed off and lost.
FIGURE 28-25 Cholesterol is the precursor for all steroid hormones in both males and females.

Chapter 29

Answers to Checkpoints

- PAGE 1133** 1. Cellular differentiation is the formation of different types of cells during development. 2. Development begins at fertilization (conception), the union of a male gamete (a sperm) and a female gamete (oocyte). 3. Inheritance refers to the transfer of genetically determined characteristics from one generation to the next. **PAGE 1135** 4. Two sperm enzymes important to secondary oocyte penetration are hyaluronidase and acrosin. 5. A normal human zygote contains 46 chromosomes. 6. Gestation is the period of prenatal development. It consists of three trimesters. 7. The first trimester is the time of pre-embryonic, embryonic, and early fetal development. The second trimester is a time of organ and organ system development. By the end of this stage, the fetus appears distinctly human. The third trimester is characterized by rapid fetal growth and the deposition of adipose tissue. **PAGE 1145** 8. The inner cell mass of the blastocyst eventually develops into the embryo. 9. Improper development of the yolk sac—the mesoderm-derived structure that gives rise to blood vessels and is an important site of blood cell formation—would affect the development and function of the cardiovascular system. 10. Possible factors include absence of androgen-sensitive receptors, mutations within the SRY gene, low androgen production, or absence or oversecretion of gonadal hormones. **PAGE 1147** 11. From 8 weeks to about 20 weeks, the fetus is measured from crown to rump. From 20 weeks to birth, length is measured from crown to heel. **PAGE 1152** 12. Yes, Betha is pregnant. After fertilization, the developing trophoblast (and later, the placenta) produce and release the hormone hCG. 13. Pregnant individuals experience an increase in respiratory rate and tidal volume. 14. A pregnant individual's blood volume increases during pregnancy to compensate for the reduction in their blood volume resulting from blood flow through the placenta. **PAGE 1155** 15. Three factors opposing the calming action of progesterone on the uterus are increasing estrogen levels, increasing oxytocin levels, and prostaglandin production. 16. The three stages of labor are the dilation stage, expulsion stage, and placental stage. 17. Immature delivery is the birth of a fetus weighing at least 500 g (17.6 oz), which is the normal weight near the end of the second trimester. Premature birth refers to the delivery before 37 weeks of pregnancy. 18. Fraternal twins are dizygotic twins, and identical twins are monozygotic twins. **PAGE 1160** 19. The postnatal stages of development are the neonatal period, infancy, childhood, adolescence, and maturity. These stages are followed by senescence, or aging, and death. 20. The neonatal period is the time from birth to 1 month. Infancy continues from the neonatal period to age 1. Adolescence is the period after childhood in which sexual and physical maturity occur. 21. Colostrum is produced by the mammary glands from the end of the sixth month of pregnancy until a few days after birth. After that, the glands begin producing breast milk, which contains fewer proteins (including antibodies) and far more fat than colostrum. 22. Increases in the blood levels of GnRH, FSH, LH, and sex hormones mark the onset of puberty.

- PAGE 1168** 23. Genotype is a person's genetic makeup. Phenotype is a person's physical and physiological characteristics. It results from the interaction between the person's genotype and the environment. 24. Heterozygous refers to a genotype possessing two different alleles at corresponding sites of a chromosome pair. For a heterozygous trait, one allele or both alleles determine the individual's phenotype. 25. The phenotype of a person who is heterozygous for tongue rolling—who has one dominant allele for tongue-rolling and one recessive allele for non-tongue-rolling—would be “tongue roller.” 26. One reason children are not identical copies of their biological parents is that during meiosis, parental chromosomes are randomly distributed such that each gamete has a unique set of chromosomes. Additionally, crossing over and mutations during meiosis introduce new variations in gametes. Besides gene interactions, environmental factors can also affect the expression of genes and the resulting phenotype through epigenetic mechanisms.

Answers to Review Questions

PAGE 1171

Level 1 Reviewing Facts and Terms

1. e 2. (a) parietal decidua (b) basal decidua (c) amnion (d) chorion (e) capsular decidua 3. b 4. b 5. d 6. a 7. b 8. a 9. When a sperm contacts the secondary oocyte, their plasma membranes fuse. The oocyte is then activated: Its metabolic rate rises; it completes meiosis II; and the cortical reaction prevents additional sperm from entering. (Vesicles beneath the oocyte surface fuse with the plasma membrane and discharge their contents.) The male and female pronuclei replicate their DNA and fuse (amphimixis), and the zygote begins preparing for the first cleavage division. 10. (a) At three weeks, the embryo consists of three layers: the ectoderm, the mesoderm, and the endoderm. (b) The nails (integumentary system), the salivary glands (digestive system), and the brain (nervous system) are ectodermal derivatives; the kidneys (both as part of the endocrine and the urinary systems), the dermis (integumentary system), and the heart (cardiovascular system including the endocrine tissues) are mesodermal derivatives; the thymus (endocrine system), the pancreas (both as part of the endocrine and the digestive systems) and the liver (digestive system) are endodermal derivatives. 11. The dilation stage begins with the onset of true labor, as the cervix dilates and the fetus begins to move toward the cervical canal; late in this stage, the amniochorionic membrane ruptures. The expulsion stage begins as the cervix dilates completely and continues until the fetus has completely emerged from the vagina (delivery). In the placental stage, the uterus gradually contracts, tearing the connections between the endometrium and the placenta and ejecting the placenta. 12. The fetal pituitary secretes oxytocin, which is released into the maternal bloodstream at the placenta. This release may be the trigger for the onset of true labor. 13. (1) Neonatal period (birth to 1 month): The newborn becomes relatively self-sufficient and begins performing respiration (breathing), digestion, and excretion on its own. Heart rates and fluid requirements are higher than those of adults. Neonates have little ability to thermoregulate. (2) Infancy (1 month to 1 year): Major organ systems (other than those related to reproduction) become fully operational. (3) Childhood (1 year to puberty): Growth continues; body proportions change significantly. 14. Three events interact to promote increased hormone production and sexual maturation at puberty: (1) The hypothalamus increases its production of GnRH; (2) the anterior lobe of the pituitary gland becomes more sensitive to the presence of GnRH, and circulating levels of FSH and LH rise rapidly; and (3) ovarian or testicular cells become more sensitive to FSH and LH.

Puberty initiates adolescence, which includes gametogenesis (gamete production) and the production of sex hormones that stimulate the appearance of secondary sexual characteristics and behaviors.

Level 2 Reviewing Concepts

15. c 16. d 17. a 18. Many of the proteins present in colostrum are antibodies that help the neonate ward off infections. The mucins in colostrum provide protection against rotaviruses. Oxytocin induces the milk ejection reflex. **19.** The placenta produces (1) human chorionic gonadotropin, which maintains the integrity of the corpus luteum and promotes the continued secretion of progesterone (keeping the endometrial lining functional); and (2) human placental lactogen and placental prolactin, which help prepare the mammary glands for milk production. Human placental lactogen also ensures adequate levels of glucose and protein for the developing fetus. (3) The placenta also produces relaxin, which increases the flexibility of the pubic symphysis, causes dilation of the cervix, and suppresses the release of oxytocin by the hypothalamus, delaying the onset of labor contractions. (4) The placenta becomes the main source of progesterone to maintain the endometrial lining after the first trimester. (5) Placental estrogen production rapidly increases in the third trimester and plays a role in stimulating labor and delivery. **20.** Respiratory rate and tidal volume increase, allowing the lungs to obtain the extra oxygen the fetus needs and to remove the excess carbon dioxide the fetus generates. Maternal blood volume increases, compensating for blood flowing into the placenta. Nutrient and vitamin requirements increase 10–30%, reflecting the fact that some of the mother's nutrients go to nourish the fetus. Glomerular filtration rate increases by about 50%, which corresponds to the increased blood volume, and this accelerates the excretion of metabolic wastes generated by the fetus. The uterus and mammary glands increase in size, and secretory activity begins in the mammary glands. **21.** In breech births, risks to the fetus are high as the umbilical cord can become constricted and cut off placental blood flow. **22.** A neonate must fill its lungs (which are collapsed and filled with fluid at birth) with air, which alters the pattern of cardiovascular circulation due to changes in blood pressure and flow rates. It must excrete the mixture of debris (meconium) that has collected in the fetal digestive system. The neonate must obtain nourishment from a new source—the mother's mammary glands. Neonatal fluid requirements are high because the newborn cannot concentrate its urine significantly. The infant also has little ability to thermoregulate, although as it grows its insulating adipose tissue increases, and its metabolic rate also rises. **23. (a)** Genotype refers to an individual's genetic makeup; phenotype refers to the individual's physical and physiological characteristics. **(b)** A heterozygous genotype carries different alleles for a given gene; a homozygous genotype carries identical alleles for that gene. **(c)** In simple inheritance, phenotypes are determined by interactions between a single pair of alleles; in polygenic inheritance, interactions occur among multiple genes. **24. (a)** dominant **(b)** recessive **(c)** X-linked **(d)** autosomal

Level 3 Critical Thinking and Clinical Applications

25. The probability that this couple's daughters will have hemophilia is 0, because each daughter will receive a normal allele from her father. There is a 50% chance that a son will have

hemophilia, because each son has a 50% chance of receiving the mother's normal allele and a 50% chance of receiving the mother's recessive allele. **26.** Although technically it only takes one sperm to fertilize an egg, the probability of this occurring is very low if too few sperm are present. Most sperm that enter the female reproductive tract are killed or disabled before they reach the uterus. Many of the sperm reaching the uterus are incapable of reaching the secondary oocyte, which is in a uterine tube. Once at the oocyte, the sperm must penetrate the corona radiata, which requires the combined acrosomal enzymes of dozens of sperm. If too few sperm are present in the vagina, the number reaching the uterine tube is too low for any one sperm to penetrate the corona radiata. **27.** The most obvious possibility is that the infant has a problem with the cardiovascular supply to the lungs. A good guess would be a patent ductus arteriosus (the ductus arteriosus has failed to close off completely). When the baby is not being stressed (bathing creates heat loss and thermal stress) or eating (less air is entering the lungs), the infant appears normal. Because some of the blood flow to the lungs is being shunted over to the aorta during stress and eating, too little blood is being oxygenated, so the infant becomes cyanotic. **28.** In Jie's case, the implantation of the blastocyst most likely did not occur in the fundus or in the body of the uterus, but in one of the uterine tubes. The walls of the uterine tubes are not adapted to sustain a growing embryo and will rupture, causing life-threatening bleeding.

Answers to Clinical Case Wrap-Up

PAGE 1172 1. Implanting the blastocysts on the sixth day after ovulation matches the fertility cycle in nature. This timing ensures the blastocysts are available for implantation in the uterine wall by days 7 through 10 after ovulation. **2.** Daan and Hendrik are not monozygotic twins because they did not result from the fertilization of a single oocyte with a single sperm, forming a single zygote that subsequently split. Neither are they technically dizygotic twins. They are the developmental result of two separate oocytes from the same mother, but unlike dizygotic twins, they have different biological fathers. In terms of biological inheritance, they are half brothers. Socially, they are fraternal twins.

Answers to Figure-Based Questions

FIGURE 29-2 The outer cell layer of a blastocyst is called the trophoblast. The function of the trophoblast is to provide nutrients to the developing embryo.

FIGURE 29-4 The third germ layer that forms during gastrulation is called mesoderm.

FIGURE 29-11 Oxytocin and prostaglandins stimulate and increase the excitability of the myometrium.

FIGURE 29-15 The 23rd pair of chromosomes in this karyotype are the sex chromosomes. They are characteristic of a male because both X and Y sex chromosomes are present. A female karyotype would have two X sex chromosomes.

FIGURE 29-16 Simple inheritance is involved in determining nearsightedness (dominant trait) and normal vision (recessive trait), and sex-linked inheritance is involved in determining red-green color blindness.

Glossary of Key Terms

This glossary is an alphabetical list of key terms related to topics covered in the textbook. Brief explanations, along with the chapter number(s) where the topic was covered, are given.

A

abdomen: The region of the trunk between the inferior margin of the rib cage and the superior margin of the pelvis. (1)

abdominopelvic cavity: The term used to refer to the general region bounded by the abdominal wall and the pelvis; it contains the peritoneal cavity and visceral organs. (1)

abducens nerve: Cranial nerve VI, which innervates the lateral rectus muscle of the eye. (14)

abduction: Movement away from the midline of the body, as viewed in the anatomical position. (9)

abortion: The premature loss or expulsion of an embryo or fetus. (29)

abscess: A localized collection of pus within a damaged tissue. (4, 22)

absorption: The active or passive uptake of gases, fluids, or solutes. (24, 25)

accommodation: An alteration in the curvature of the lens of the eye to focus an image on the retina. (17)

acetabulum: The fossa on the lateral aspect of the pelvis that accommodates the head of the femur. (8)

acetylcholine (ACh): A chemical neurotransmitter in the brain and peripheral nervous system; the dominant neurotransmitter in the peripheral nervous system, released at neuromuscular junctions and synapses of the parasympathetic division. (10, 12, 16)

acetylcholinesterase (AChE): An enzyme found in the synaptic cleft, bound to the postsynaptic membrane, and in tissue fluids; breaks down and inactivates acetylcholine molecules; also called *cholinesterase*. (10, 12)

acetyl-CoA: An acetyl group bound to coenzyme A, a participant in the anabolic and catabolic pathways for carbohydrates, lipids, and many amino acids. (25)

acetyl group: $\text{—CH}_3\text{CO}$; an acetic acid molecule without the hydroxyl group. (25)

acid: A compound whose dissociation in solution releases a hydrogen ion and an anion; an acidic solution has a pH below 7.0 and has an excess of hydrogen ions. (2, 27)

acidosis: An abnormal physiological state characterized by blood pH below 7.35. (2, 25, 26, 27)

acinus/acini: A histological term referring to a blind pocket, pouch, or sac.

acoustic: Pertaining to sound or the sense of hearing. (17)

acquired immunodeficiency syndrome (AIDS): A disease caused by the human immunodeficiency virus (HIV); characterized by the destruction of helper T cells and a resulting severe impairment of the immune response. (22)

acromegaly: A condition caused by the overproduction of growth hormone in adults, characterized by a thickening of bones and an enlargement of cartilages and other soft tissues. (6, 18)

acromion: A continuation of the scapular spine that projects superior to the capsule of the glenohumeral joint. (8)

acrosome: A membranous sac at the tip of a sperm that contains hyaluronidase; also called *acrosomal cap*. (28)

actin: The protein component of microfilaments that forms thin filaments in skeletal muscles and produces contractions of all muscles through interaction with thick (myosin) filaments; *see also sliding-filament theory*. (3, 10)

action potential: A propagated change in the membrane potential of excitable cells, initiated by a change in the membrane permeability to sodium ions; *see also nerve impulse*. (10, 12)

active transport: The ATP-dependent absorption or secretion of solutes across a plasma membrane. (3, 26)

acute: Sudden in onset, typically severe in intensity, and brief in duration.

adaptation: A decrease in receptor sensitivity or perception after chronic stimulation (15); a change in pupillary size in response to changes in light intensity (17); physiological responses that produce acclimatization. (25)

Addison disease: A condition resulting from the hyposecretion of glucocorticoids; characterized by lethargy, weakness, hypotension, and increased skin pigmentation. (5, 18)

adduction: Movement toward the axis or midline of the body, as viewed in the anatomical position. (9)

adenine (A): A purine; one of the nitrogenous bases in the nucleic acids RNA and DNA. (2)

adenohypophysis: The anterior lobe of the pituitary gland. (18)

adenoid: The pharyngeal tonsil. (22, 23)

adenosine: A compound consisting of adenine and ribose. (2)

adenosine diphosphate (ADP): A compound consisting of adenosine with two phosphate groups attached. (2, 25)

adenosine monophosphate (AMP): A nucleotide consisting of adenosine plus a phosphate group (PO_4^{3-}); also called *adenosine phosphate*. (2)

adenosine triphosphate (ATP): A high-energy compound consisting of adenosine with three phosphate groups attached; the third is attached by a high-energy bond. (2, 10, 25)

adenylate cyclase: An enzyme bound to the inner surfaces of plasma membranes that can convert ATP to cyclic AMP; formerly called *adenylyl cyclase*. (12, 18)

adhesion: The fusion of two mesenterial layers after damage or irritation of their opposing surfaces; this process restricts relative movement of the organs involved (4); the binding of a phagocyte to its target. (22)

adipocyte: A fat cell. (4)

adipose tissue: Loose connective tissue dominated by adipocytes. (4, 18, 28)

adrenal cortex: The superficial region of the adrenal gland that produces steroid hormones; also called the *suprarenal cortex*. (18)

adrenal gland: A small endocrine gland that secretes steroids and catecholamines and is located superior to each kidney; also called *suprarenal gland*. (18)

adrenal medulla: A modified sympathetic ganglion that secretes catecholamines into the blood during sympathetic activation; also called *suprarenal medulla* (16); the core of the adrenal gland. (18)

adrenergic: An axon terminal that, when stimulated, releases norepinephrine. (12)

adrenocortical hormone: Any steroid produced by the adrenal cortex. (18)

adrenocorticotrophic hormone (ACTH): The hormone that stimulates the production and secretion of glucocorticoids by the zona fasciculata of the adrenal cortex; released by the anterior lobe of the pituitary gland (adenohypophysis) in response to corticotropin-releasing hormone. (18)

adventitia: The superficial layer of connective tissue surrounding an internal organ; fibers are continuous with those of surrounding tissues, providing support and stabilization. (24)

aerobic: Requiring oxygen.

aerobic metabolism: The complete breakdown of organic substrates into carbon dioxide and water; a process that yields large amounts of ATP but requires mitochondria and oxygen. (3, 10, 25)

afferent: Conducting toward a center.

afferent arteriole: An arteriole that carries blood to a glomerulus of the kidney. (26)

afferent fiber: An axon that carries sensory information to the central nervous system. (12)

agglutination: The aggregation of red blood cells due to interactions between surface antigens and plasma antibodies. (19, 22)

agglutinins: Immunoglobulins (antibodies) in plasma that react with antigens on the surfaces of foreign red blood cells when donor and recipient differ in blood type. (19)

agglutinogens: Genetically determined surface antigens on red blood cells that stimulate the formation of specific agglutinins. (19)

aggregated lymphoid nodules: Lymphoid nodules beneath the epithelium of the small intestine; also called *Peyer's patches*. (22)

agonist: A muscle responsible for a specific movement; also called a *prime mover*. (11)

agranular: Without granules; *agranular leukocytes* are monocytes and lymphocytes. (19)

AIDS: *See acquired immunodeficiency syndrome*. (22)

aldosterone: A mineralocorticoid produced by the zona glomerulosa of the adrenal cortex; stimulates the kidneys to conserve sodium and water; secreted in response to the presence of angiotensin II. (18, 26, 27)

alkalosis: The condition characterized by a blood pH greater than 7.45; associated with a relative deficiency of hydrogen ions or an excess of bicarbonate ions. (2, 27)

alpha (α) receptors: Membrane receptors sensitive to norepinephrine or epinephrine; stimulation normally results in target cell excitation. (16)

alveolar sac: An air-filled chamber at the terminal end of the alveolar duct that gives rise to the alveoli in the lung. (23)

alveolus/alveoli: Terminal pockets at the end of the respiratory tree, lined by a simple squamous epithelium and surrounded by a capillary network; sites of gas exchange with the blood (23); a bony socket that holds the root of a tooth. (24)

Alzheimer's disease: A disorder resulting from degenerative changes in populations of neurons in the cerebrum, causing dementia characterized by problems with attention, short-term memory, and emotions. (16)

- amination:** The attachment of an amino group to a carbon chain; performed by a variety of cells and important in the synthesis of amino acids. (25)
- amino acids:** Organic compounds made up of carbon, hydrogen, oxygen, and nitrogen; building block of protein; chemical structure can be summarized as $R-CHNH_2-COOH$. (2, 25)
- amino group:** $-NH_2$. (2)
- amnion:** One of the four extra-embryonic membranes; surrounds the developing embryo or fetus. (29)
- amniotic fluid:** Fluid that fills the amniotic cavity; cushions and supports the embryo or fetus. (4, 29)
- amphiarthrosis:** A joint (articulation) that permits a small degree of independent movement; *see also* **interosseous membrane** (8) and **pubic symphysis**. (9)
- ampulla/ampullae:** A localized dilation in the lumen of a canal or passageway. (17, 24, 28)
- amygdaloid body:** A basal nucleus that is a component of the limbic system and acts as an interface between the limbic system, the cerebrum, and sensory systems; also called *amygdala*. (14)
- amylase:** An enzyme that breaks down polysaccharides; produced by the salivary glands and pancreas. (24)
- anabolism:** The synthesis of complex organic compounds from simpler precursors. (2, 25)
- anaerobic:** Without oxygen.
- analgesic:** A substance that relieves pain. (15)
- anal triangle:** The posterior subdivision of the perineum. (11)
- anaphase:** The mitotic stage in which the paired chromatids separate and move toward opposite ends of the spindle apparatus. (3)
- anaphylaxis:** A hypersensitivity reaction due to the binding of antigens to immunoglobulins (IgE) on the surfaces of mast cells; the release of histamine, serotonin, and prostaglandins by mast cells then causes widespread inflammation; a sudden decrease in blood pressure may occur, producing anaphylactic shock. (22)
- anastomosis:** The joining of two tubes, usually referring to a connection between two peripheral vessels without an intervening capillary bed. (21)
- anatomical position:** An anatomical reference position; the body viewed from the anterior surface with the palms facing forward. (1)
- anatomy:** The study of internal and external body structures and their physical relationships among other body parts. (1)
- androgen:** A steroid sex hormone mainly produced by the interstitial cells of the testis and manufactured in small quantities by the adrenal cortex in both sexes. (18, 28)
- anemia:** The condition marked by a decrease in the hematocrit, the hemoglobin content of the blood, or both. (19)
- aneurysm:** A weakening in the arterial wall causing an outpouching or enlargement of the artery. (21)
- angiotensin-converting enzyme (ACE):** A chemical that converts angiotensin I (a hormone) to angiotensin II (a vasoconstrictor), which causes an increase in blood pressure. (26)
- angiotensin I:** The hormone produced by the activation of angiotensinogen by renin (18); angiotensin-converting enzyme (ACE) converts angiotensin I into angiotensin II in lung capillaries. (26)
- angiotensin II:** A hormone that causes an increase in systemic blood pressure, stimulates the secretion of aldosterone, promotes thirst, and causes the release of antidiuretic hormone (18); angiotensin-converting enzyme (ACE) in lung capillaries converts angiotensin I into angiotensin II. (21, 26)
- angiotensinogen:** The blood protein produced by the liver that is converted to angiotensin I by the enzyme renin. (18)
- anion:** An ion having a negative charge. (2, 27)
- anoxia:** Inadequate oxygen reaching body tissues. (23)
- antagonist:** A muscle that opposes the movement of an agonist. (11)
- antebrachium:** The forearm. (8)
- anterior:** On or near the front, or ventral surface, of the body.
- antibiotic:** A chemical agent that selectively kills pathogens, primarily bacteria. (20)
- antibody:** A globular protein produced by plasma cells that will bind to specific antigens and promote their destruction or removal from the body. (19, 22)
- antibody-mediated immunity:** The form of immunity resulting from the presence of circulating antibodies produced by plasma cells; also called *humoral immunity*. (22)
- anticodon:** Three nitrogenous bases on a tRNA molecule that interact with a complementary codon on a strand of mRNA. (3)
- antidiuretic hormone (ADH):** A hormone synthesized in the hypothalamus and secreted at the posterior lobe of the pituitary gland (neurohypophysis); causes the kidneys to retain water and an increase in blood pressure. (18, 21, 26, 27)
- antigen:** A substance capable of inducing an immune response that may include the production of antibodies. (22)
- antigen-antibody complex:** The combination of an antigen and a specific antibody. (22)
- antigenic determinant site:** A region of an antigen that can interact with an antibody molecule. (22)
- antigen-presenting cell (APC):** A cell that processes antigens and displays them, bound to class II MHC proteins; essential to the initiation of a normal immune response. (22)
- antihistamine:** A chemical that blocks the action of histamine on peripheral tissues. (22)
- antrum:** A chamber or pocket. (28)
- annulus:** A cartilage or bone shaped like a ring; also spelled *annulus*. (9)
- anus:** The external opening of the anal canal. (24)
- aorta:** The large, elastic artery that carries blood away from the left ventricle and into the systemic circuit. (20)
- aortic bodies:** Receptors in the aortic arch that are sensitive to changes in oxygen, carbon dioxide, and pH levels in the blood. (21)
- aortic sinus:** Space between the superior portion of each of the three aortic valve cusps and the dilated portion of the wall of the ascending aorta. (21)
- apnea:** Cessation of breathing. (23)
- apocrine secretion:** A mode of secretion in which the glandular cell sheds portions of its cytoplasm. (4, 5)
- aponeurosis/aponeuroses:** Broad tendinous sheet(s) that may serve as the origin or insertion of a skeletal muscle. (4, 6, 10)
- apoptosis:** Genetically programmed cell death. (3)
- appendicular:** Pertaining to the upper or lower limbs. (7, 8)
- appendix:** A blind sac connected to the cecum of the large intestine; also called *vermiform appendix*. (24)
- appositional growth:** The enlargement of a cartilage or bone by the addition of cartilage or bony matrix at its surface. (4, 6)
- aqueous humor:** A fluid similar to perilymph or cerebrospinal fluid that fills the anterior chamber of the eye. (17)
- arachidonic acid:** One of the essential fatty acids. (2, 18)
- arachnoid granulations:** Processes of the arachnoid mater that project into the superior sagittal sinus; sites where cerebrospinal fluid enters the venous circulation. (14)
- arachnoid mater:** The middle meninx (layer) that encloses cerebrospinal fluid and protects the central nervous system. (13, 14)
- arbor vitae:** The central, branching mass of white matter inside the cerebellum. (14)
- arcuate:** Curving.
- areolar:** Containing minute spaces, as in areolar tissue.
- areolar tissue:** Loose connective tissue with an open framework. (4)
- erector pili:** Smooth muscles whose contractions force hairs to stand erect. (5)
- arrhythmias:** Abnormal patterns of cardiac contractions. (20)
- arteriole:** A small arterial branch that delivers blood to a capillary network. (21)
- artery:** A blood vessel that carries blood away from the heart and toward a peripheral capillary. (4, 20, 21)
- articular:** Pertaining to a joint.
- articular capsule:** The dense collagen fiber sleeve that surrounds a joint and provides protection and stabilization; also called *joint capsule*. (6, 9)
- articular cartilage:** The cartilage pad that covers the surface of a bone inside a joint cavity. (6, 9)
- articulation:** A joint. (9)
- arytenoid cartilages:** A pair of small cartilages in the larynx. (23)
- ascending tract:** A tract carrying information from the spinal cord to the brain. (13, 14)
- association areas:** Cortical areas of the cerebrum that are responsible for the integration of sensory inputs and/or motor commands. (14)
- association neuron:** *See interneuron*. (12)
- astrocyte:** One of the four types of neuroglia in the central nervous system; responsible for maintaining the blood brain barrier by the stimulation of endothelial cells. (12)
- atherosclerosis:** The formation of fatty plaques in the walls of arteries, restricting blood flow. (21)
- atom:** The smallest stable unit of matter. (1, 2)
- atomic number:** The number of protons in the nucleus of an atom. (2)
- atomic weight:** The average of the different atomic masses and isotope proportions of a particular element. (2)
- atria:** Thin-walled chambers of the heart that receive venous blood from the pulmonary or systemic circuit.
- atrial natriuretic peptide (ANP):** *See natriuretic peptides*. (20)
- atrial reflex:** The reflexive increase in heart rate after an increase in venous return; due to mechanical and neural factors; also called *Bainbridge reflex*. (20, 21)
- atrioventricular (AV) bundle:** Specialized conducting cells in the interventricular septum that carry the contracting stimulus from the AV node to bundle branches and then to Purkinje fibers; also called *bundle of His*. (20)
- atrioventricular (AV) node:** Specialized cardiac muscle cells that relay the contractile stimulus to the atrioventricular bundle (bundle of His), the bundle branches, the Purkinje fibers, and the ventricular myocardium; located at the boundary between the atria and ventricles. (20)
- atrioventricular (AV) valve:** One of the valves that prevents backflow into the atria during ventricular systole (contraction). (20)

atrophy: The wasting away of tissues from a lack of use, ischemia, or nutritional abnormalities. (10)

auditory: Pertaining to the sense of hearing. (17)

auditory ossicles: The bones of the middle ear: malleus, incus, and stapes. (7, 17)

auditory tube: A passageway that connects the nasopharynx with the middle ear cavity; also called *Eustachian tube* or *pharyngotympanic tube*. (17)

auricle: A broad, flattened process that resembles the external ear; in the ear, the expanded, projecting portion that surrounds the external auditory meatus; also called *pinna* (17); in the heart, the externally visible flap formed by the collapse of the outer wall of a relaxed atrium; clinically referred to as an *atrial appendage*. (20)

autoantibodies: Antibodies that react with antigens on the surfaces of a person's own cells and tissues. (22)

autoimmunity: The immune system's sensitivity to one's own tissues, resulting in the production of autoantibodies. (22)

autolysis: The destruction of a cell due to the rupture of lysosomal membranes in its cytoplasm. (3)

automatcity: The spontaneous depolarization to threshold, characteristic of cardiac pacemaker cells. (10, 20)

autonomic ganglion: A collection of visceral motor neurons outside the central nervous system. (16)

autonomic nerve: A peripheral nerve consisting of preganglionic or postganglionic autonomic fibers. (16)

autonomic nervous system (ANS): Centers, nuclei, tracts, ganglia, and nerves involved in the unconscious regulation of visceral functions; includes components of the central nervous system and the peripheral nervous system. (12, 16)

autoregulation: Changes in activity that maintain homeostasis in direct response to changes in the local environment; does not require neural or endocrine control. (1, 21, 26)

autosome: A chromosome other than the X or Y sex chromosome. (29)

avascular: Without blood vessels. (4)

axilla: The armpit. (1, 8)

axolemma: The plasma membrane of an axon, continuous with the plasma membrane of the cell body and dendrites and distinct from any neuroglial coverings. (12)

axon: The elongated extension of a neuron that conducts an action potential. (4, 12)

axon hillock: In a multipolar neuron, the portion of the cell body adjacent to the initial segment. (12)

axoplasm: The cytoplasm within an axon. (12)

B

bacteria: Single-celled microorganisms, some pathogenic, that are common in the environment and in and on the body. (22)

Bainbridge reflex: The reflexive increase in heart rate after an increase in venous return; due to mechanical and neural factors; also called *atrial reflex*. (20, 21)

baroreception: The ability to detect changes in pressure. (15, 23)

baroreceptor reflex: A reflexive change in cardiac activity in response to changes in blood pressure. (21)

baroreceptors: The nerve endings that sense pressure changes. (15, 21)

basal nuclei: Nuclei of the cerebrum that are important in the subconscious control of skeletal muscle activity. (14, 15)

base: A compound whose dissociation releases a hydroxide ion (OH^-) or removes a hydrogen ion (H^+) from the solution. (2, 27)

basement membrane: A layer of filaments and fibers that attach an epithelium to the underlying connective tissue. (4)

basophils: Circulating granulocytes (white blood cells) similar in size and function to tissue mast cells. (19)

B cells: Lymphocytes capable of differentiating into plasma cells, which produce antibodies. (19, 22)

benign: Not malignant. (3)

beta (β) cells: Cells of the pancreatic islets that secrete insulin in response to increased blood sugar concentrations. (18)

beta-oxidation: Fatty acid catabolism that produces molecules of acetyl-CoA. (25)

beta (β) receptors: Membrane receptors sensitive to epinephrine; stimulation may result in the excitation or inhibition of the target cell. (16)

bicarbonate ion: HCO_3^- ; anion component of the carbonic acid-bicarbonate buffer system. (26, 27)

bicuspid: Having two cusps or points; refers to a premolar tooth, which has two roots, or to the left AV valve, which has two cusps. (24)

bicuspid valve: See *mitral valve*. (20)

bifurcate: To branch into two parts.

bile: The exocrine secretion of the liver; stored in the gallbladder and ejected into the duodenum. (24)

bile duct: The duct formed by the union of the cystic duct from the gallbladder and the common hepatic duct from the liver; terminates at the duodenal ampulla, where it meets the pancreatic duct. (24)

bile salts: Steroid derivatives in bile; responsible for the emulsification of ingested lipids. (2, 24)

bilirubin: A pigment that is the by-product of hemoglobin catabolism. (19)

biopsy: The removal of a small sample of tissue for pathological analysis. (4, 13)

bladder: A muscular sac that distends as fluid is stored and whose contraction ejects the fluid at an appropriate time; used alone, the term usually refers to the urinary bladder. (26)

blastocyst: An early stage in the developing embryo, consisting of an outer trophoblast and an inner cell mass. (29)

blockers/blocking agents: Drugs that block membrane pores or prevent binding to membrane receptors. (16)

blood-brain barrier (BBB): The isolation of the central nervous system from the general circulation; primarily the result of astrocyte regulation of capillary permeabilities. (12, 14)

blood clot: See *clot*. (19)

blood-CSF barrier: The isolation of the cerebrospinal fluid from the capillaries of the choroid plexus; primarily the result of specialized ependymal cells. (14)

blood pressure (BP): A force exerted against vessel walls by the blood in the vessels, due to the push exerted by cardiac contraction and the elasticity of the vessel walls; usually measured along one of the muscular arteries, with systolic pressure measured during ventricular systole (contraction) and diastolic pressure during ventricular diastole (relaxation). (21)

blood-testis barrier: The isolation of the interior of the seminiferous tubules from the general circulation, due to the activities of the nurse (sustentacular) cells. (28)

Bohr effect: The increased oxygen release by hemoglobin in the presence of increased carbon dioxide levels. (23)

bolus: A compact mass; usually refers to compacted ingested material (food) on its way to the stomach. (23, 24)

bone tissue: A strong connective tissue containing specialized cells and a mineralized matrix of crystalline calcium phosphate and calcium carbonate; also called *osseous tissue*.

bony labyrinth: A series of cavities within the petrous part of the temporal bone that is filled with perilymph and in which the membranous labyrinth is suspended. (17)

bowel: The intestinal tract. (24)

Bowman's capsule: See *glomerular capsule*. (26)

brachial: Pertaining to the arm.

brachial plexus: A network formed by branches of spinal nerves C_5 – T_1 en route to innervating the upper limb. (13)

brachium: The arm. (11)

bradycardia: An abnormally slow heart rate, usually below 50 beats per minute. (20)

brainstem: The brain minus the cerebrum, diencephalon, and cerebellum; midbrain, pons, and medulla oblongata. (14)

brevis: Short. (11)

Broca's area: The speech center of the brain, normally located on the neural cortex of the left cerebral hemisphere. (14)

bronchial tree: The trachea, bronchi, and bronchioles. (23)

bronchodilation: The dilation of the bronchial passages; can be caused by sympathetic stimulation. (23)

bronchus/bronchi: Branch/branches of the bronchial tree between the trachea and bronchioles. (23)

B-type natriuretic peptide (BNP): See *natriuretic peptides*. (27)

buccal: Pertaining to the cheeks. (24)

buffer: A compound that stabilizes the pH of a solution by removing or releasing hydrogen ions. (2, 27)

buffer system: Interacting compounds that prevent increases or decreases in the pH of body fluids; includes the carbonic acid-bicarbonate buffer system, the phosphate buffer system, and the protein buffer systems. (27)

bulbar: Pertaining to the brainstem. (14)

bulbo-urethral glands: Mucous glands at the base of the penis that secrete into the penile urethra; the equivalent of the greater vestibular glands of females; also called *Cowper's glands*. (28)

bundle branches: Specialized conducting cells in the ventricles that carry the contractile stimulus from the atrioventricular bundle (bundle of His) to the Purkinje fibers. (20)

bundle of His: See *atrioventricular (AV) bundle*. (20)

bursa: A small sac filled with synovial fluid that cushions adjacent structures and reduces friction. (9)

C

calcaneal tendon: The large tendon that inserts on the calcaneus; tension on this tendon produces extension (plantar flexion) of the foot; also called *Achilles tendon*. (8, 11)

calcaneus: The heel bone, the largest of the tarsal bones. (8)

calcification: The deposition of calcium salts within a tissue. (4, 6)

calcitonin (CT): The hormone secreted by C cells of the thyroid when calcium ion concentrations are abnormally high; restores homeostasis by increasing the rate of bone deposition (mostly in childhood) and the rate of calcium loss by the kidneys. (6, 18)

- calculus/calculi:** Solid mass/masses of insoluble materials that form within body fluids, especially the gallbladder, kidneys, or urinary bladder. (26)
- callus:** A localized thickening of the epidermis due to chronic mechanical stresses (5); a thickened area that forms at the site of a bone break as part of the repair process. (6)
- calorigenic effect:** The stimulation of energy production and heat loss by thyroid hormones. (18)
- canaliculi:** Microscopic passageways between cells; bile canaliculi carry bile to bile ducts in the liver (24); in bone, canaliculi permit the diffusion of nutrients and wastes to and from osteocytes. (4, 6)
- cancer:** An illness caused by mutations leading to the uncontrolled growth and replication of the affected cells. (3)
- cannula:** A tube that can be inserted into the body; commonly placed in blood vessels prior to transfusion or dialysis. (19)
- capacitation:** The activation process that must occur before a sperm can successfully fertilize an oocyte; occurs in the vagina after ejaculation. (28, 29)
- capillary:** A small blood vessel, located between an arteriole and a venule, whose thin wall permits the diffusion of gases, nutrients, and wastes between plasma and interstitial fluids. (4, 19, 20, 21)
- capitulum:** A general term for a small, elevated articular process; refers to the rounded distal surface of the humerus that articulates with the head of the radius. (8)
- caput:** The head. (7)
- carbaminohemoglobin:** Hemoglobin bound to carbon dioxide molecules. (19, 23)
- carbohydrase:** An enzyme that breaks down carbohydrate molecules. (24)
- carbohydrate:** An organic compound containing carbon, hydrogen, and oxygen in a ratio that approximates 1:2:1. (2, 25)
- carbon dioxide:** CO_2 ; a compound produced by the decarboxylation reactions of aerobic metabolism. (2, 23)
- carbonic anhydrase:** An enzyme that catalyzes the reaction $\text{H}_2\text{O} + \text{CO}_2 \rightarrow \text{H}_2\text{CO}_3$; important in carbon dioxide transport (23), gastric acid secretion (24), and renal pH regulation. (26)
- carcinogen:** Cancer-causing substance. (3)
- cardia:** The region of the stomach surrounding its connection with the esophagus. (24)
- cardiac:** Pertaining to the heart. (10, 20)
- cardiac cycle:** One complete heartbeat, including atrial and ventricular systole and diastole. (20)
- cardiac output (CO):** The amount of blood ejected by the left ventricle each minute; normally about 5 liters. (20)
- cardiac reserve:** The potential percentage increase in cardiac output above resting levels. (20)
- cardiac tamponade:** A compression of the heart due to fluid accumulation in the pericardial cavity. (20)
- cardiovascular:** Pertaining to the heart, blood, and blood vessels. (19, 20, 21)
- cardiovascular (CV) centers:** Poorly localized area in the reticular formation of the medulla oblongata of the brain; includes cardioacceleratory, cardioinhibitory, and vasomotor centers. (14, 21)
- carotene:** A yellow-orange pigment, found in carrots, sweet potatoes, and other vegetables, that the body can convert to vitamin A. (5)
- carotid artery:** The main artery of the neck, servicing cervical and cranial structures; one branch, the internal carotid, provides a major blood supply to the brain. (21)
- carotid body:** A group of receptors, adjacent to the carotid sinus, that are sensitive to changes in the carbon dioxide levels, pH, and oxygen concentrations of arterial blood. (15, 21)
- carotid sinus:** A dilated segment at the base of the internal carotid artery whose walls contain baroreceptors sensitive to changes in blood pressure. (21)
- carotid sinus reflex:** Reflexive changes in blood pressure that maintain homeostatic pressures at the carotid sinus, stabilizing blood flow to the brain. (21)
- carpus/carpal:** The wrist. (8, 11)
- cartilage:** A connective tissue with a gelatinous matrix that contains an abundance of fibers. (4)
- catabolism:** The breakdown of complex organic molecules into simpler components, accompanied by the release of energy. (2, 25)
- catalyst:** A substance that accelerates a specific chemical reaction but that is not altered by the reaction. (2)
- catecholamines:** Epinephrine, norepinephrine, dopamine, and related compounds. (18)
- catheter:** A tube surgically inserted into a body cavity or along a blood vessel or excretory passageway for the collection of body fluids, monitoring of blood pressure, or introduction of medications or radiographic dyes. (20)
- cation:** An ion having a positive charge. (2, 27)
- cauda equina:** Bundle of spinal nerve roots arising from the lumbosacral enlargement and medullary cone of the adult spinal cord; they extend caudally inside the vertebral canal en route to lumbar and sacral segments. (13)
- caudal/caudally:** Closest to or toward the tail (coccyx). (1, 7)
- caudate nucleus:** One of the basal nuclei involved with the subconscious control of skeletal muscular activity. (14)
- cell:** The smallest living structural unit in the human body. (1, 3)
- cell body:** The body of a neuron; also called *soma*. (4, 12)
- cell-mediated immunity:** Resistance to disease by sensitized T cells that destroy antigen-bearing cells by direct contact or through the release of lymphotoxins; also called *cellular immunity*. (22)
- cellular differentiation:** The gradual appearance of characteristic cellular specializations during development as the result of gene activation or repression. (3, 29)
- center of ossification:** The site in a connective tissue where bone formation begins. (6)
- central canal:** Longitudinal canal in the center of an osteon that contains blood vessels and nerves; also called *Haversian canal* (6); a passageway along the longitudinal axis of the spinal cord that contains cerebrospinal fluid. (13, 14)
- central nervous system (CNS):** The brain and spinal cord. (12, 13)
- centriole:** A cylindrical intracellular organelle composed of nine groups of microtubules, three in each group (9 + 0 array); functions in mitosis or meiosis by organizing the microtubules of the spindle apparatus. (3)
- centromere:** The localized region where two chromatids remain connected after the chromosomes have replicated; site of spindle fiber attachment. (3)
- centrosome:** A region of cytoplasm that contains a pair of centrioles oriented at right angles to one another. (3)
- cerebellum:** The posterior portion of the metencephalon, containing the cerebellar hemispheres; includes the arbor vitae, cerebellar nuclei, and cerebellar cortex. (14, 15)
- cerebral cortex:** An extensive area of neural cortex covering the surfaces of the cerebral hemispheres. (14)
- cerebral hemispheres:** A pair of expanded portions of the cerebrum covered in neural cortex. (14)
- cerebrospinal fluid (CSF):** Fluid bathing the internal and external surfaces of the central nervous system; secreted by the choroid plexus. (12, 13, 14)
- cerebrovascular accident (CVA):** The occlusion of a blood vessel that supplies a portion of the brain, resulting in damage to the dependent neurons; also called *stroke*. (14)
- cerebrum:** The largest portion of the brain, composed of the cerebral hemispheres; includes the cerebral cortex, the basal nuclei, and the internal capsule. (14)
- cerumen:** The waxy secretion of the ceruminous glands along the external acoustic meatus. (5, 17)
- ceruminous glands:** Integumentary glands that secrete cerumen. (5, 17)
- cervix:** The inferior portion of the uterus. (28)
- chemoreception:** The detection of changes in the concentrations of dissolved compounds or gases (mainly CO_2 and O_2). (15, 17, 21, 23, 25)
- chemotaxis:** The attraction of phagocytic cells to the source of abnormal chemicals in tissue fluids. (22)
- chemotherapy:** The treatment of illness through the administration of specific chemicals. (1)
- chief cells:** Gastric cells near the base of gastric glands that secrete pepsinogen. (24)
- chloride shift:** The movement of plasma chloride ions into red blood cells in exchange for bicarbonate ions generated by the intracellular dissociation of carbonic acid. (23, 27)
- cholecystokinin (CCK):** A duodenal hormone that stimulates the contraction of the gallbladder and the secretion of enzymes by the exocrine pancreas. (24)
- cholesterol:** A steroid component of plasma membranes and a substrate for the synthesis of steroid hormones and bile salts. (2, 25)
- choline:** A breakdown product or precursor of acetylcholine. (12)
- cholinergic synapse:** A synapse where the presynaptic membrane releases acetylcholine on stimulation. (12, 16)
- chondrocyte:** A cartilage cell. (4)
- chondroitin sulfate:** The predominant proteoglycan in cartilage, responsible for the gelatinous consistency of the matrix. (4)
- chordae tendineae:** Fibrous cords that stabilize the position of the AV valves in the heart, preventing backflow during ventricular systole (contraction). (20)
- chorion:** An extra-embryonic membrane, consisting of the trophoblast and underlying mesoderm, that forms the placenta. (29)
- choroid:** The middle, vascular layer in the wall of the eye. (17)
- choroid plexus:** The vascular complex in the roof of the third and fourth ventricles of the brain, responsible for producing cerebrospinal fluid. (14)
- chromatid:** One complete copy of a DNA strand and its associated nucleoproteins. (3, 28, 29)
- chromatin:** A histological term referring to the gray material visible in cell nuclei during interphase; the appearance of the DNA content of the nucleus when the chromosomes are uncoiled. (3)
- chromosomes:** Dense structures, composed of tightly coiled DNA strands and associated histones, that become visible in the nucleus when a cell prepares to undergo mitosis or meiosis; normal human somatic cells each contain 46 chromosomes. (3, 28, 29)

chronic: Habitual or long term.

chylomicrons: Relatively large droplets that may contain triglycerides, phospholipids, and cholesterol in association with proteins; synthesized and released by intestinal cells and transported to the venous blood by the lymphatic system. (24, 25)

ciliary body: A thickened region of the choroid that encircles the lens of the eye; includes the ciliary muscle and the ciliary processes that support the *ciliary zonule* (suspensory ligament) of the lens. (17)

cilia: Organelles that are slender extensions of the plasma membrane on the free surface of an epithelial cell; multiple *motile cilia* generally undergo cycles of movement and are composed of a basal body and microtubules in a $9 + 2$ array; a nonmotile, solitary *primary cilium* acts as an environmental sensor and has microtubules arranged in a $9 + 0$ array. (3)

circulatory system: The network of blood vessels and lymphatic vessels that facilitate the distribution and circulation of extracellular fluid. (21, 22)

circumduction: A movement at a synovial joint in which the distal end of the bone moves in a circular direction, but the shaft does not rotate. (9)

cisterna: An expanded or flattened chamber derived from and associated with the endoplasmic reticulum. (3, 10)

citric acid cycle: The reaction sequence that occurs in the matrix of mitochondria; in the process, organic molecules are broken down, carbon dioxide molecules are released, and hydrogen molecules are transferred by coenzymes to the electron transport chain. (3, 10, 25)

clot: A network of fibrin fibers and trapped blood cells; also called a *thrombus* if it occurs within blood vessels. (19)

clotting factors: Plasma proteins, synthesized by the liver, that are essential to the clotting response. (19)

clotting response: The series of events that result in the formation of a clot. (19)

coccygeal ligament: The fibrous extension of the dura mater and filum terminale; provides longitudinal stabilization to the spinal cord. (13)

coccyx: The terminal portion of the spinal column, consisting of relatively tiny, fused vertebrae. (7)

cochlea: The spiral portion of the bony labyrinth of the internal ear that surrounds the organ of hearing. (17)

cochlear duct: See *scala media*. (17)

codon: A sequence of three nitrogenous bases along an mRNA strand that will specify the location of a single amino acid in a peptide chain. (3)

coenzymes: Complex organic cofactors; most are structurally related to vitamins. (2, 25)

cofactors: Ions or molecules that must be attached to the active site before an enzyme can function; examples include mineral ions and several vitamins. (2)

collagen fibers: Strong, insoluble protein fibers common in connective tissues. (4)

collateral ganglion: A sympathetic ganglion located anterior to the spinal column and separate from the sympathetic chain. (12, 16)

colliculus/colliculi: Little mound/mounds; in the brain, refers to one of the thickenings in the roof of the mesencephalon; the superior colliculi are associated with the visual system, and the inferior colliculi with the auditory system. (14, 15, 17)

colloid: A solution containing molecules that do not settle and cannot be separated out by filtering

or centrifuging like particles in a suspension; examples include gels and emulsions. (2, 26)

colon: The large intestine from the cecum to the rectum. (24)

coma: An unconscious state from which an individual cannot be aroused, even by strong stimuli. (16)

comminuted: Broken or crushed into small pieces.

commissure: A crossing over from one side to another.

common pathway: The final clotting pathway that begins with the activation of clotting factor X by enzyme complexes from either the extrinsic or intrinsic pathways; the common pathway ends with the formation of a blood clot when the enzyme thrombin converts soluble fibrinogen to insoluble fibrin. (19)

compact bone: Dense bone that contains parallel osteons. (6)

complement system: A group of distinct plasma proteins that interact in a chain reaction after exposure to activated antibodies or the surfaces of certain pathogens; complement proteins promote cell lysis, phagocytosis, and other defense mechanisms. (22)

compliance: Expandability; the ability of certain organs to tolerate changes in volume; indicates the presence of elastic fibers and smooth muscles. (23)

compound: A pure chemical substance made up of atoms of two or more different elements in a fixed proportion, regardless of the type of chemical bond joining them. (2)

concentration: The amount (in grams) or number of atoms, ions, or molecules (in moles) per unit volume. (2, 3, 25, 26)

concentration gradient: Regional differences in the concentration of a particular substance. (3, 25, 26)

conception: Fertilization. (29)

concha/conchae: Three pairs of thin, scroll-like bones that project into the nasal cavities; the superior and middle conchae are part of the ethmoid, and the inferior nasal conchae articulate with the ethmoid, lacrimal, maxilla, and palatine bones; also called *turbinate(s)*. (7)

condyle: A rounded articular projection on the surface of a bone. (8)

cone: A photoreceptor responsible for sharp vision and color vision. (17)

congenital: Present at birth.

congestive heart failure (CHF): The failure to maintain adequate cardiac output due to cardiovascular problems or myocardial damage. (23)

conjunctiva: A layer of stratified squamous epithelium that covers the inner surfaces of the eyelids and the anterior surface of the eye to the edges of the cornea. (17)

connective tissue: One of the four primary tissue types; provides a structural framework that stabilizes the relative positions of the other tissue types; includes connective tissue proper, cartilage, bone, and blood; contains cell products, cells, and ground substance. (4)

continuous propagation: The propagation of an action potential along an unmyelinated axon or a muscle plasma membrane, wherein the action potential affects every portion of the membrane surface. (12)

contractility: The ability to contract; possessed by skeletal, smooth, and cardiac muscle cells. (4, 20)

contralateral reflex: A reflex that affects the opposite side of the body from the stimulus. (13)

conus medullaris: The conical tip of the spinal cord that gives rise to the filum terminale. (13)

convergence: In the nervous system, the innervation of a single neuron by axons from several neurons; most common along motor pathways. (13)

coracoid process: A hook-shaped process of the scapula that projects above the anterior surface of the capsule of the shoulder joint. (8)

Cori cycle: The metabolic exchange of lactate from skeletal muscle for glucose from the liver; occurs during the recovery period after muscular exertion. (10)

cornea: The transparent portion of the fibrous layer of the anterior surface of the eye. (17)

corniculate cartilages: A pair of small laryngeal cartilages. (23)

cornu: Horn-shaped.

coronoid: Hooked or curved. (8)

corpora quadrigemina: The superior and inferior colliculi of the mesencephalic tectum (roof) in the brain. (14)

corpus/corpora: Body/bodies. (14, 28)

corpus callosum: A large bundle of axons that links centers in the left and right cerebral hemispheres. (14)

corpus luteum: The progesterone-secreting mass of follicle cells that develops in the ovary after ovulation. (18, 28)

cortex: The outer layer or region of an organ (5) or bone. (6)

corticobulbar tracts: Descending tracts that carry information or commands from the cerebral cortex to nuclei and centers in the brainstem. (15)

corticospinal tracts: Descending tracts that carry motor commands from the cerebral cortex to the anterior gray horns of the spinal cord. (15)

corticosteroid: A steroid hormone produced by the adrenal (suprarenal) cortex. (2, 18)

corticosterone: A corticosteroid secreted by the zona fasciculata of the adrenal (suprarenal) cortex; a glucocorticoid. (18)

corticotropin-releasing hormone (CRH): The releasing hormone, secreted by the hypothalamus, that stimulates secretion of adrenocorticotropic hormone (ACTH) by the anterior lobe of the pituitary gland (adenohypophysis). (18)

cortisol: A corticosteroid secreted by the zona fasciculata of the adrenal (suprarenal) cortex; a glucocorticoid. (18)

cortisone: A glucocorticoid produced by the adrenal cortex that exerts its effects after it is converted to cortisol. (18)

costa/costae: Rib/ribs. (7, 23)

cotransport: The membrane transport of a nutrient, such as glucose, in company with the movement of an ion, normally sodium; transport requires a carrier protein but does not involve direct ATP expenditure and can occur regardless of the concentration gradient for the nutrient. (3, 24, 26)

countercurrent exchange: The transfer of heat, water, or solutes between two fluids that travel in opposite directions. (25, 26)

countercurrent multiplication: Active transport between two limbs of a loop that contains a fluid moving in one direction in which the effect of the transport increases; responsible for the concentration of urine in the kidney tubules. (26)

covalent bond: A chemical bond between atoms that involves the sharing of electrons. (2)

coxal bone: Hip bone. (7, 8)

cranial: Pertaining to the head. (7)

cranial nerves: Peripheral nerves originating at the brain. (12)

craniosacral division: The parasympathetic division of the autonomic nervous system. (16)

cranium: The braincase; the skull bones that surround and protect the brain. (7)

creatine: A nitrogenous compound, synthesized in the body, that can form a high-energy bond by connecting to a phosphate group and that serves as an energy reserve. (10)

creatine phosphate (CP): A high-energy compound in muscle cells; during muscle activity, the phosphate group is donated to ADP, regenerating ATP; also called *phosphorylcreatine*. (10)

creatinine: A breakdown product of creatine metabolism. (26)

crenation: Cellular shrinkage due to an osmotic movement of water out of the cytoplasm. (3)

criciform plate: A portion of the ethmoid that contains the foramina used by the axons of olfactory receptors en route to the olfactory bulbs of the cerebrum. (7)

cricoid cartilage: A ring-shaped cartilage that forms the inferior margin of the larynx. (23)

crista/cristae: A ridge-shaped collection of hair cells in the ampulla of a semicircular duct; the crista and cupula form a receptor complex sensitive to movement along the plane of the semicircular canal. (3, 17)

cross-bridge: The binding of a myosin head that projects from the surface of a thick filament at the active site of a thin filament in the presence of calcium ions. (10)

cuneiform cartilages: A pair of small cartilages in the larynx. (23)

cupula: A gelatinous mass that is in the ampulla of a semicircular duct in the internal ear and whose movement stimulates the hair cells of the crista. (17)

Cushing disease: A condition caused by the overproduction of adrenal steroids. (18)

cutaneous membrane: The epidermis and papillary layer of the dermis. (4, 5)

cuticle: The layer of dead, keratinized cells that surrounds the shaft of a hair; for nails, *see* **eponychium**. (5)

cyanosis: An abnormal bluish coloration of the skin due to the presence of deoxygenated blood in vessels near the body surface. (5)

cystic duct: A duct that carries bile between the gallbladder and the common bile duct. (24)

cytochrome: A protein-pigment component of the electron transport chain; a structural relative of heme. (25)

cytokinesis: The cytoplasmic movement that separates two daughter cells at the completion of mitosis. (3)

cytology: The study of the internal structures, physiology, and chemistry of cells. (1, 3)

cytoplasm: The material between the plasma membrane and the nuclear membrane; cell contents. (3)

cytosine (C): A pyrimidine; one of the nitrogenous bases in the nucleic acids RNA and DNA. (2)

cytoskeleton: A network of microtubules and microfilaments in the cytoplasm. (3)

cytosol: The fluid portion of the cytoplasm; also called *intracellular fluid*. (3, 27)

cytotoxic: Poisonous to cells. (22)

cytotoxic T cells: Lymphocytes involved in cell-mediated immunity that kill target cells by direct contact or by the secretion of lymphotoxins; also called *killer T cells* and *T_C cells*. (22)

D

daughter cells: Genetically identical cells produced by somatic cell division. (3, 28)

deamination: The removal of an amino group from an amino acid. (25, 26)

decomposition reaction: A chemical reaction that breaks a molecule into smaller fragments. (2)

decussate: To cross over to the opposite side, usually referring to the crossover of the descending tracts of the corticospinal pathway on the ventral surface of the medulla oblongata. (15)

defecation: The elimination of fecal wastes. (24)

degradation: Breakdown, catabolism. (2, 25)

dehydration: A reduction in the water content of the body that threatens homeostasis. (27)

dehydration synthesis reaction: The joining of two molecules associated with the removal of a water molecule. (2)

demyelination: The loss of the myelin sheath of an axon, normally due to chemical or physical damage to Schwann cells or oligodendrocytes. (12)

denaturation: A temporary or permanent change in the three-dimensional structure of a protein. (2)

dendrite: A sensory process of a neuron. (4, 12)

deoxyribonucleic acid (DNA): A nucleic acid consisting of a double chain of nucleotides that contains the sugar deoxyribose and the nitrogenous bases adenine, guanine, cytosine, and thymine. (2)

deoxyribose: A five-carbon sugar resembling ribose but lacking an oxygen atom. (2)

depolarization: A change in the membrane potential from a negative value toward 0 mV. (12, 20)

depression: Inferior (downward) movement of a body part. (9)

dermatitis: An inflammation of the skin. (5)

dermatome: A sensory region monitored by the dorsal rami of a single spinal segment. (13)

dermis: The connective tissue layer beneath the epidermis of the skin. (5)

detrusor: Collectively, the three layers of smooth muscle in the wall of the urinary bladder. (26)

detumescence: The loss of a penile erection. (28)

development: Growth and the acquisition of increasing structural and functional complexity; includes the period from conception to maturity. (29)

diabetes insipidus: Disorder of the pituitary gland characterized by polyuria (excessive urination) and polydipsia (excessive thirst) that results from inadequate production of antidiuretic hormone (ADH). (18)

diabetes mellitus: Disorder characterized by polyuria (excessive urination) and glycosuria (glucose in the urine), most commonly due to the inadequate production or diminished sensitivity to insulin with a resulting increase of blood glucose levels. (18)

diapedesis: The movement of white blood cells through the walls of blood vessels by migration between adjacent endothelial cells. (19, 22)

diaphragm: Any muscular partition; the respiratory muscle that separates the thoracic cavity from the abdominopelvic cavity. (1, 11, 23)

diaphysis: The shaft of a long bone. (6)

diarthrosis: A synovial joint. (9)

diastole: A period of relaxation in a chamber of the heart, as part of the cardiac cycle. (20)

diastolic pressure: Pressure measured in the walls of a muscular artery when the left ventricle is in diastole (relaxation). (21)

diencephalon: A division of the brain that includes the epithalamus, thalamus, and hypothalamus. (14)

differential count: An estimate of the number of each type of white blood cell based on a random sampling of 100 white blood cells. (19)

diffusion: Passive molecular movement from an area of higher concentration to an area of lower concentration. (3, 21, 23, 26)

digestion: The chemical breakdown of ingested food into simple molecules that can be absorbed by the cells of the digestive tract. (24)

digestive system: The digestive tract and associated glands. (24)

digestive tract: An internal passageway that begins at the mouth, ends at the anus, and is lined by a mucous membrane; also called *gastrointestinal (GI) tract* or *alimentary canal*. (24)

dilate: To increase in diameter; to enlarge or expand.

disaccharide: A compound formed by the joining of two simple sugars by dehydration synthesis. (2)

dissociation: *See* **ionization**. (2)

distal: A direction away from the point of attachment or origin; for a limb, away from its attachment to the trunk. (1, 8)

distal convoluted tubule (DCT): The segment of the nephron closest to the connecting tubules and collecting duct; an important site of active secretion. (26)

diuresis: Fluid loss by the kidneys; the production of unusually large volumes of urine. (26)

divergence: In nervous tissue, the spread of information from one neuron to many neurons; an organizational pattern common along sensory pathways of the central nervous system. (13)

diverticulum: A sac or pouch in the wall of the colon or other organ. (24)

DNA molecule: Two DNA strands wound in a double helix and held together by hydrogen bonds between complementary nitrogenous base pairs. (3)

dopamine: An important neurotransmitter in the central nervous system. (12)

dorsal: Toward the back, posterior. (1)

dorsal root ganglion: *See* **posterior root ganglion**. (13)

dorsiflexion: Upward movement of the foot through flexion at the ankle. (9)

Down syndrome: A genetic condition resulting from the presence of three copies of chromosome 21; people with this condition have characteristic physical and intellectual deficits; also called *trisomy 21*. (16, 29)

duct: A passageway that delivers exocrine secretions to an epithelial surface. (4)

ductus arteriosus: A vascular connection between the pulmonary trunk and the aorta that functions throughout fetal life; normally closes at birth or shortly thereafter and persists as the ligamentum arteriosum. (21, 23)

ductus deferens: A passageway that carries sperm from the epididymis to the ejaculatory duct; also called the *vas deferens*. (28)

duodenal ampulla: A chamber that receives bile from the common bile duct and pancreatic secretions from the pancreatic duct. (24)

duodenal papilla: A conical projection from the inner surface of the duodenum that contains the opening of the duodenal ampulla. (24)

duodenum: The proximal 25 cm (9.8 in.) of the small intestine that contains short villi and submucosal glands. (24)

dura mater: The outermost membrane of the cranial and spinal meninges. (13, 14)

E

eccrine sweat glands: Sweat glands of the skin that produce a watery secretion. (5)

ectoderm: One of the three primary germ layers; covers the surface of the embryo and gives rise to the nervous system, the epidermis and associated glands, and a variety of other structures. (29)

ectopic: Outside the normal location. (20, 29)

effector: A peripheral gland or muscle cell innervated by a motor neuron. (1, 12)

effluent: Conducting a fluid or nerve impulse away from an organ or structure. (12, 26)

effluent arteriole: An arteriole carrying blood away from a glomerulus of the kidney. (26)

effluent fiber: An axon that carries impulses away from the central nervous system. (12)

ejaculation: The ejection of semen from the penis as the result of muscular contractions of the bulbospongiosus and ischiocavernosus muscles. (28)

ejaculatory ducts: Short ducts that pass within the walls of the prostate and connect the ductus deferens with the prostatic urethra. (28)

elastase: A pancreatic enzyme that breaks down elastin fibers. (24)

elastin: Connective tissue fibers that stretch and recoil, providing elasticity to connective tissues. (4, 5)

electrical coupling: A connection between adjacent cells that permits the movement of ions and the transfer of graded or propagated changes in the membrane potential from cell to cell. (12)

electrocardiogram (ECG, EKG): A graphic record of the electrical activities of the heart, as monitored at specific locations on the body surface. (20)

electroencephalogram (EEG): A graphic record of the electrical activities of the brain. (14)

electrolytes: Soluble inorganic compounds whose ions will conduct an electrical current in solution. (2, 27)

electron: One of the three fundamental subatomic particles; has a negative charge and normally orbits the protons of the nucleus. (2, 25)

electron transport chain (ETC): The system made up of four respiratory protein complexes, coenzyme Q, and electron carriers made up of a series of cytochrome molecules responsible for aerobic energy production in cells; bound to the inner mitochondrial membrane. (25)

element: All the atoms with the same atomic number. (2)

elevation: Movement in a superior, or upward, direction. (9)

elimination: The ejection of wastes from the body through urination or defecation. (24, 26)

embolism: The obstruction of a vessel, typically by a blood clot. (19)

embolus: An air bubble, fat globule, or blood clot drifting in the bloodstream. (19)

embryo: The developmental stage beginning at fertilization and ending at the start of the third developmental month. (28, 29)

embryology: The study of embryonic development, focusing on the first 2 months after fertilization. (1, 28, 29)

endocardium: The simple squamous epithelium that lines the heart and is continuous with the endothelium of the great vessels. (20)

endochondral ossification: The replacement of a cartilaginous model with bone; the characteristic mode of formation for skeletal elements other than the bones of the cranium, the clavicles, and sesamoid bones. (6)

endocrine gland: A gland that secretes hormones into the blood. (4, 18)

endocrine system: The endocrine (ductless) glands and organs of the body. (18)

endocytosis: The movement of relatively large volumes of extracellular material into the cytoplasm by the formation of a membranous vesicle at the cell surface; includes pinocytosis and phagocytosis. (3)

endoderm: One of the three primary germ layers; the layer on the undersurface of the embryonic disc; gives rise to the epithelia and glands of the digestive system, the respiratory system, and portions of the urinary system. (29)

endogenous: Produced within the body.

endolymph: The fluid contents of the membranous labyrinth (the sacculle, utricle, semicircular ducts, and cochlear duct) of the internal ear. (17)

endometrium: The mucous membrane lining the uterus. (28)

endomysium: A delicate network of connective tissue fibers that surrounds individual muscle cells. (10)

endonurium: A delicate network of connective tissue fibers that surrounds individual nerve fibers. (13)

endoplasmic reticulum: A network of membranous channels in the cytoplasm of a cell that function in intracellular transport, synthesis, storage, packaging, and secretion. (3)

endorphins: Neuromodulators, produced in the central nervous system, that inhibit activity along pain pathways. (12)

endosteum: An incomplete cellular lining on the inner (medullary) surfaces of bones. (6)

endothelium: The simple squamous epithelial cells that line blood and lymphatic vessels. (4, 19, 21)

enkephalins: Neuromodulators, produced in the central nervous system, that inhibit activity along pain pathways. (12)

enteric nervous system (ENS): An extensive nerve network in the walls of the digestive tract that initiates and coordinates digestive motility and secretions. (16)

enterocrinin: A hormone secreted by the lining of the duodenum after exposure to chyme; stimulates the secretion of the submucosal glands. (24)

enteroendocrine cells: Endocrine cells scattered among the epithelial cells that line the digestive tract. (24)

enterogastric reflex: The reflexive inhibition of gastric secretion; initiated by the arrival of chyme in the small intestine. (24)

enterohepatic circulation: The excretion of bile salts by the liver, followed by the absorption of bile salts by intestinal cells for return to the liver by the hepatic portal vein. (24)

enteropeptidase: An enzyme in the lumen of the small intestine that activates the proenzymes secreted by the pancreas; formerly called *enterokinase*. (24)

enzyme: A protein that catalyzes a specific biochemical reaction. (2)

eosinophil: A type of white blood cell with a lobed nucleus and red-staining granules; participates in the immune response and is especially important during allergic reactions. (19)

ependymal cells: The layer of cells lining the ventricles and central canal of the central nervous system. (12)

epicardium: A serous membrane covering the outer surface of the heart; also called *visceral pericardium*. (20)

epidermis: The epithelium covering the surface of the skin. (5)

epididymis: A coiled duct that connects the rete testis to the ductus deferens; site of functional maturation of sperm. (28)

epidural space: The space between the spinal dura mater and the walls of the vertebral foramen; contains blood vessels and adipose tissue; a common site of injection for regional anesthesia. (13)

epiglottis: A blade-shaped flap of tissue, reinforced by cartilage, that is attached to the posterior and superior surface of the thyroid cartilage; folds over the entrance to the larynx during swallowing. (23)

epimysium: A dense layer of collagen fibers that surrounds a skeletal muscle and is continuous with the tendons/aponeuroses of the muscle and with the perimysium. (10)

epineurium: A dense layer of collagen fibers that surrounds a peripheral nerve. (13)

epiphyseal cartilage: The cartilaginous region between the epiphysis and diaphysis of a growing bone; also called *epiphyseal plate*. (6)

epiphysis: The head of a long bone. (6)

epithelium: One of the four primary tissue types; a layer of cells that forms a superficial covering or an internal lining of a body cavity or vessel. (4, 24)

eponychium: A narrow zone of stratum corneum that extends across the surface of a nail at its exposed base; also called the *cuticle*. (5)

eponym: A commemorative name for a structure or clinical condition that was originally named for a real or mythical person. (1)

equilibrium: A dynamic state in which two opposing forces or processes are in balance. (1, 15, 17)

erection: The stiffening of the penis due to the erectile tissues of the corpora cavernosa and corpus spongiosum filling with blood. (28)

erythema: Redness and inflammation at the surface of the skin. (5, 22)

erythrocyte: A red blood cell (RBC); has no nucleus and contains large quantities of hemoglobin. (4, 19)

erythropoiesis: The formation of red blood cells. (19)

erythropoietin (EPO): A hormone released by most tissues, and especially by the kidneys, when oxygen levels decrease; stimulates erythropoiesis (red blood cell formation) in red bone marrow. (18, 19, 21)

Escherichia coli: A normal bacterial resident of the large intestine; abbreviated *E. coli*. (24)

esophagus: A muscular tube that connects the pharynx to the stomach. (24)

essential amino acids: Amino acids that cannot be synthesized in the body in adequate amounts and must be obtained from the diet. (25)

essential fatty acids: Fatty acids that cannot be synthesized in the body and must be obtained from the diet. (25)

estrogens: A class of steroid sex hormones that includes estradiol. (2, 18, 28)

evaporation: A movement of molecules from the liquid state to the gaseous state. (25)

eversion: A turning outward. (9)

excitable membranes: Membranes that propagate action potentials, a characteristic of muscle cells and nerve cells. (10, 12)

excitatory postsynaptic potential (EPSP): The depolarization of a postsynaptic membrane by a chemical neurotransmitter released by the presynaptic cell. (12)

excretion: The removal of wastes from the blood, tissues, or organs. (24)

exocrine gland: A gland that secretes onto the body surface or into a passageway connected to the exterior. (4)

exocytosis: The ejection of cytoplasmic materials by the fusion of a membranous vesicle with the plasma membrane. (3)

expiration: Exhalation; breathing out. (23)

extension: An increase in the angle between two articulating bones; the opposite of flexion. (8, 9)

external acoustic meatus: A passageway in the temporal bone that leads to the tympanic membrane of the middle ear. (7, 17)

external ear: The auricle, external acoustic meatus, and tympanic membrane. (17)

external nares: The nostrils; the external openings into the nasal cavity. (23)

external respiration: The diffusion of gases between the alveolar air and the alveolar capillaries and between the systemic capillaries and peripheral tissues. (23)

exteroceptors: General sensory receptors in the skin, mucous membranes, and special sense organs that provide information about the external environment and about our position within it. (12)

extracellular fluid (ECF): All body fluids other than that contained within cells; includes plasma and interstitial fluid. (3, 27)

extra-embryonic membranes: The yolk sac, amnion, chorion, and allantois. (29)

extrafusal muscle fibers: Contractile muscle fibers (as opposed to the sensory intrafusal fibers, or muscle spindles). (13)

extrinsic pathway: A clotting pathway that begins with damage to blood vessels or surrounding tissues and ends with the formation of tissue factor complex. (19)

eyelids: Movable folds that cover the front of the eyeballs; also called *palpebrae*. (17)

F

fabella: A sesamoid bone commonly located in the gastrocnemius. (11)

facilitated: Brought closer to threshold, as in the depolarization of a nerve plasma membrane toward threshold; making the cell more sensitive to depolarizing stimuli. (12)

facilitated diffusion: The passive movement of a substance across a plasma membrane by means of a protein carrier. (3, 24, 26)

falciform ligament: A sheet of mesentery that contains the ligamentum teres, the fibrous remains of the umbilical vein of the fetus. (24, 29)

falx: Sickle shaped. (7, 14)

falx cerebri: The curving sheet of dura mater that extends between the two cerebral hemispheres; encloses the superior sagittal sinus. (7, 14)

fasciae: Connective tissue fibers, primarily collagen, that form sheets or bands beneath the skin to attach, stabilize, enclose, and separate muscles and other internal organs. (4)

fasciculus: A small bundle; usually refers to a collection of nerve axons or muscle fibers. (10, 15)

fatty acids: Hydrocarbon chains that end in a carboxyl group. (2)

fauces: The passage from the mouth to the pharynx, bounded by the palatal arches, the soft palate, and the uvula. (24)

febrile: Characterized by or pertaining to a fever. (22, 25)

feces: Waste products eliminated by the digestive tract at the anus; contains indigestible residue, bacteria, mucus, and epithelial cells. (24)

fenestra/fenestrae: Opening(s). (18, 21)

fertilization: The fusion of a secondary oocyte and a sperm to form a zygote. (28, 29)

fetus: The developmental stage lasting from the start of the third developmental month to delivery. (28, 29)

fibrin: Insoluble protein fiber that forms the basic framework of a blood clot. (19)

fibrinogen: A plasma protein that is the soluble precursor of the insoluble protein fibrin. (19)

fibroblasts: Cells of connective tissue proper that produce extracellular fibers and secrete the organic substances of the extracellular matrix. (4)

fibrocartilage: Cartilage containing an abundance of collagen fibers; located around the edges of joints, in the intervertebral discs, and the menisci of the knee; also referred to as *fibrous cartilage*. (4)

fibrocytes: Mature fibroblasts; maintain connective tissue fibers of connective tissue proper. (4)

fibrous layer: The outermost layer of the eye, composed of the sclera and cornea; also called *fibrous tunic*. (17)

fibula: The lateral, slender bone of the leg. (8)

filariasis: A condition resulting from infection by mosquito-borne parasites; can cause elephantiasis. (21, 22)

filiform papillae: Slender conical projections from the dorsal surface of the anterior two-thirds of the tongue. (17)

filtrate: The fluid produced by filtration at a glomerulus in the kidney. (26)

filtration: The movement of a fluid across a membrane whose pores restrict the passage of solutes based on size. (21, 26)

filtration pressure: The hydrostatic pressure responsible for filtration. (21, 26)

filum terminale: A fibrous extension of the spinal cord, from the conus medullaris to the coccygeal ligament. (13)

fimbriae: Fringes; the fingerlike processes that surround the entrance to the uterine tube. (28)

fissure: An elongated groove or opening. (7, 14)

fistula: An abnormal passageway between two organs or from an internal organ or space to the body surface. (21)

flaccid: Limp, soft, flabby; a muscle without muscle tone. (15)

flagellum/flagella: An organelle that is structurally similar to a motile cilium but is used to propel a cell through a fluid; found on sperm. (3, 28)

flatus: Intestinal gas. (24)

flexion: A movement that decreases the angle between two articulating bones; the opposite of extension. (8, 9)

flexor: A muscle that produces flexion. (11)

flexor reflex: A reflex contraction of the flexor muscles of a limb in response to a painful stimulus. (13)

flexure: A bending. (9)

folia: Leaflike folds; the slender folds in the surface of the cerebellar cortex. (14)

follicle: A small secretory sac or gland. (5, 18, 28)

follicle-stimulating hormone (FSH): A hormone secreted by the adenohypophysis (anterior lobe of the pituitary gland); stimulates oogenesis (female) and spermatogenesis (male). (18, 28)

fontanelle: A relatively soft, flexible, fibrous region between two flat bones in the developing skull; also spelled *fontanel*. (7)

foramen/foramina: Opening/openings or passage/passages through a bone. (7, 20)

forearm: The distal portion of the upper limb between the elbow and wrist. (8)

forebrain: The cerebrum. (14)

fornix: An arch or the space bounded by an arch; in the brain, an arching tract that connects the hippocampus with the mammillary bodies (14); in the eye, a slender pocket located where the

epithelium of the ocular conjunctiva folds back on itself as the palpebral conjunctiva (17); in the vagina, the shallow recess surrounding the protrusion of the cervix. (28)

fossa: A shallow depression or furrow in the surface of a bone. (8, 20)

fourth ventricle: An elongated ventricle of the metencephalon (pons and cerebellum) and the myelencephalon (medulla oblongata) of the brain; the roof contains a region of choroid plexus. (14)

fovea centralis: The portion of the retina within the macula that provides the sharpest vision because it has the highest concentration of cones; also called *fovea*. (17)

fracture: A break or crack in a bone. (6)

frenulum: A bridle; usually referring to a band of tissue that restricts movement, e.g., *lingual frenulum*. (24)

frontal (coronal) plane: A vertical plane that divides the body into anterior and posterior portions. (1)

fructose: A hexose (six-carbon simple sugar) in foods and in semen. (2, 28)

fundus: The base of an organ such as the stomach, uterus, or gallbladder. (24, 28)

G

gallbladder: The pear-shaped reservoir for bile after it is secreted by the liver. (24)

gametes: Reproductive cells (sperm or oocytes) that contain half the normal chromosome complement. (28, 29)

gametogenesis: The formation of gametes. (28)

gamma-aminobutyric acid (GABA): A neurotransmitter of the central nervous system whose effects are generally inhibitory. (12)

gamma motor neurons: Motor neurons that adjust the sensitivities of muscle spindles (intrafusal fibers). (13)

ganglion/ganglia: A collection of neuron cell bodies in the peripheral nervous system. (12, 16)

gangliosides: Glycolipids that are important components of plasma membranes in the central nervous system. (12)

gap junctions: Connections between cells that permit electrical coupling. (4)

gaster: The stomach (24); the body, or belly, of a skeletal muscle. (11)

gastric: Pertaining to the stomach. (24)

gastric glands: The tubular glands of the stomach whose cells produce acid, enzymes, intrinsic factor, and hormones. (24)

gastrointestinal (GI) tract: See *digestive tract*. (24)

gene: A portion of a DNA strand that functions as a hereditary unit, is located at a particular site on a specific chromosome, and codes for a specific protein or polypeptide. (3, 29)

genetic engineering: Research and experiments involving the manipulation of the genetic makeup of an organism. (29)

genetics: The study of heredity and genetic variations. (29)

geniculate body: The medial geniculate body and the lateral geniculate body are in the thalamus of the brain. (14)

genitalia: The reproductive organs. (28)

genotype: Genetic makeup of an organism. (29)

germinal centers: Pale regions in the interior of lymphoid tissues or lymphoid nodules, where cell divisions occur that produce additional lymphocytes. (22)

gestation: The period of intrauterine development; pregnancy. (29)

gland: Cells that produce exocrine or endocrine secretions. (4)

glenoid cavity: A rounded depression that forms the articular surface of the scapula at the shoulder joint. (8)

glial cells: *See neuroglia.* (4, 12)

globular proteins: Proteins whose tertiary structure makes them rounded and compact. (2)

glomerular capsule: The expanded initial portion of the nephron that surrounds the glomerulus; also called *Bowman's capsule.* (26)

glomerular filtration rate (GFR): The rate of filtrate formation at the glomerulus. (26)

glomerulus: A knot of capillaries that projects into the enlarged, proximal end of a nephron; the site of filtration, the first step in the production of urine. (26)

glossopharyngeal nerve: Cranial nerve IX that provides sensations to the pharynx and posterior third of the tongue; it also carries motor fibers to the stylopharyngeus muscle. (14)

glottis: Structure within the larynx that consists of the vocal folds and the rima glottidis. (23)

glucagon: A hormone secreted by the alpha cells of the pancreatic islets; increases blood glucose concentrations. (18)

glucocorticoids: Hormones secreted by the zona fasciculata of the adrenal (suprarenal) cortex to modify glucose metabolism; cortisol and corticosterone are important examples. (18)

gluconeogenesis: The synthesis of glucose from noncarbohydrate precursors (e.g., lactate, glycerol, or amino acids). (25)

glucose: A six-carbon sugar, $C_6H_{12}O_6$; the preferred energy source for most cells and normally the only energy source for neurons. (2, 10, 18, 25)

glycerides: Lipids composed of glycerol bound to fatty acids. (2)

glycogen: A polysaccharide that is an important energy reserve; a polymer consisting of a long chain of glucose molecules. (2, 10, 25)

glycogenesis: The synthesis of glycogen from glucose molecules. (25)

glycogenolysis: Glycogen breakdown and the liberation of glucose molecules. (25)

glycolipids: Compounds created by the combination of carbohydrate and lipid components. (2)

glycolysis: The anaerobic cytosolic breakdown of glucose into two three-carbon molecules of pyruvate, with a net gain of 2 ATP molecules. (3, 10, 25)

glycoprotein: A compound containing a relatively small carbohydrate group attached to a large protein. (2, 18)

glycosuria: The presence of glucose in urine; also called *glucosuria.* (18, 26)

goblet (mucous) cell: A goblet-shaped, mucus-producing, unicellular gland in certain epithelia of the digestive and respiratory tracts; they are called goblet cells in the mucosa of the small intestine, large intestine, terminal bronchioles, and conjunctiva; they are called mucous cells when they are found in the stomach mucosa, respiratory mucosa, and salivary glands; (4, 23, 24)

Golgi apparatus: A cellular organelle consisting of a series of membranous plates that give rise to lysosomes and secretory vesicles. (3)

gomphosis: A fibrous synarthrosis that binds a tooth to the bone of the jaw; *see also periodontal ligament.* (24)

gonadotropin-releasing hormone (GnRH): A hypothalamic releasing hormone that causes the

secretion of both follicle-stimulating hormone and luteinizing hormone by the anterior lobe of the pituitary gland (adenohypophysis). (18, 28)

gonadotropins: Follicle-stimulating hormone and luteinizing hormone, hormones that stimulate gamete development and sex hormone secretion. (18, 28)

gonads: Reproductive organs that produce gametes and sex hormones. (28)

granulocytes: White blood cells containing granules that are visible with the light microscope; includes eosinophils, basophils, and neutrophils; also called *granular leukocytes.* (19)

gray matter: Areas in the central nervous system that are dominated by neuron cell bodies, neuroglia, and unmyelinated axons. (12, 13, 14)

gray ramus communicans: A bundle of postganglionic sympathetic nerve fibers distributed to effectors in the body wall, skin, and limbs by way of a spinal nerve. (13)

greater omentum: A large fold of the dorsal mesentery of the stomach; hangs anterior to the intestines. (24)

groin: The inguinal region. (11)

gross anatomy: The study of the structural features of the body without the aid of a microscope; also called *macroscopic anatomy.* (1)

growth hormone (GH): An adenohypophysis (anterior lobe of the pituitary gland) hormone that stimulates tissue growth and anabolism when nutrients are abundant and restricts tissue glucose dependence when nutrients are in short supply. (18)

growth hormone-inhibiting hormone (GH-IH): A hypothalamic regulatory hormone that inhibits growth hormone secretion by the anterior lobe of the pituitary gland (adenohypophysis); also called *somatostatin.* (18)

growth hormone-releasing hormone (GH-RH): A peptide released by the hypothalamus that causes the release of growth hormone from the anterior pituitary gland. (18)

guanine (G): A purine; one of the nitrogenous bases in the nucleic acids RNA and DNA. (2)

gustation: Sense of taste. (15, 17)

gyrus: A prominent fold or ridge of neural cortex on the surfaces of the cerebral hemispheres. (14)

H

hair: A keratinous strand produced by epithelial cells of the hair follicle. (5)

hair cells: Sensory cells of the internal ear. (17)

hair follicle: An accessory structure of the integument; a tube lined by a stratified squamous epithelium that begins at the surface of the skin and ends at the hair papilla. (5)

hallux: The big toe; also called the *great toe.* (8)

haploid: Possessing half the normal number of chromosomes; a characteristic of gametes. (28, 29)

hard palate: The bony roof of the oral cavity, formed by the maxillae and palatine bones. (23, 24)

helper T cells: Lymphocytes whose secretions and other activities coordinate cell-mediated and antibody-mediated immunities; also called T_H cells. (22)

hematocrit: The percentage of red blood cells in a sample of whole blood. (19)

hematoma: A tumor or swelling filled with blood. (6)

hematuria: The abnormal presence of red blood cells in urine. (19, 26)

heme: A porphyrin ring containing a central iron atom that can reversibly bind oxygen molecules; a component of the hemoglobin molecule. (19)

hemocytoblasts: Stem cells whose divisions produce each of the various populations of blood cells; also called *hematopoietic stem cells.* (19)

hemoglobin (Hb or Hgb): A protein composed of four globular subunits, each bound to a heme molecule; gives red blood cells the ability to transport oxygen in the blood. (5, 19, 23, 27)

homozygous: Having identical alleles at corresponding sites on a chromosome pair. (29)

hemolysis: The breakdown of red blood cells. (3)

hemopoiesis: Blood cell formation and differentiation. (19)

hemorrhage: Blood loss; to bleed. (21)

hemostasis: The stoppage of bleeding. (19)

heparin: An anticoagulant released by activated basophils and mast cells. (4, 19)

hepatic duct: The duct that carries bile away from the liver lobes and toward the union with the cystic duct. (24)

hepatic portal vein: The vessel that carries blood from the intestinal capillaries to the sinusoids of the liver. (21)

hepatocyte: A liver cell. (24)

heterozygous: Possessing two different alleles at corresponding sites on a chromosome pair; a person's phenotype is determined by one or both alleles. (29)

hexose: A six-carbon simple sugar. (2)

hiatus: A gap, cleft, or opening. (11)

high-density lipoprotein (HDL): A lipoprotein with a relatively small lipid content; responsible for the movement of cholesterol from peripheral tissues to the liver. (25)

hilum: A localized region where blood vessels, lymphatic vessels, nerves, and/or other anatomical structures are attached to an organ. (22, 23, 26)

hippocampus: A region, deep to the floor of a lateral ventricle, involved with emotional states and the conversion of short-term to long-term memories. (12, 14)

histamine: The chemical released by stimulated mast cells or basophils to initiate or enhance inflammation. (4, 12)

histology: The study of tissues. (1, 4)

histones: Proteins associated with the DNA of the nucleus; the DNA strands are wound around them. (3)

holocrine secretion: A form of exocrine secretion in which the secretory cell becomes swollen with vesicles and then ruptures. (4)

homeostasis: The maintenance of a relatively constant internal environment. (1)

hormone: A chemical that is secreted by one cell and travels through the bloodstream to affect the activities of cells in another part of the body. (2, 4, 6, 18, 21, 24, 28, 29)

human chorionic gonadotropin (hCG): The placental hormone that maintains the corpus luteum for the first 3 months of pregnancy. (29)

human immunodeficiency virus (HIV): The infectious agent that causes acquired immunodeficiency syndrome (AIDS). (22)

human leukocyte antigen (HLA): *See MHC protein.* (22)

human placental lactogen (hPL): The placental hormone that stimulates the functional development of the mammary glands. (29)

humoral immunity: *See antibody-mediated immunity.* (22)

hyaluronan: A carbohydrate component of proteoglycans in the matrix of many connective tissues; also called *hyaluronic acid.* (4)

hyaluronidase: An enzyme that breaks down the bonds between adjacent follicle cells; produced by some bacteria and found in the acrosome of a sperm. (29)

hydrogen bond: A weak interaction between the hydrogen atom on one molecule and a negatively charged portion of another molecule. (2)

hydrogen ion: A hydrogen atom that has lost an electron; a proton. (2)

hydrolysis reaction: The breakage of a chemical bond through the addition of a water molecule; the reverse of dehydration synthesis. (2)

hydrophilic: Freely associating with water; readily entering into solution; water loving. (2)

hydrophobic: Incapable of freely associating with water molecules; insoluble; water fearing. (2)

hydrostatic pressure: Fluid pressure. (3, 21, 26)

hydroxide ion: OH^- . (2)

hypercapnia: High blood carbon dioxide concentrations, commonly resulting from hypoventilation or inadequate tissue perfusion. (23, 27)

hyperextension: Extension of a body part past the anatomical position. (9)

hyperplasia: An abnormal increase in the number of cells in a tissue or organ. (3)

hyperpolarization: The movement of the membrane potential away from the normal resting potential and farther from 0 mV. (12)

hypersecretion: The overactivity of glands that produce exocrine or endocrine secretions. (18)

hypertension: Abnormally high blood pressure. (21)

hypertonic: In comparing two solutions, the solution with the higher osmolarity. (3)

hypertrophy: An increase in tissue size without cell division. (10)

hyperventilation: A rate of respiration sufficient to decrease blood P_{CO_2} to levels below normal. (23, 27)

hypocapnia: An abnormally low blood P_{CO_2} ; commonly results from hyperventilation. (23, 27)

hypodermic needle: A needle inserted through the skin to introduce drugs into the subcutaneous layer. (5)

hypodermis: The layer of loose connective tissue deep to the dermis; also called *subcutaneous layer*. (4, 5)

hypophyseal portal system: The network of vessels that carries blood from capillaries in the hypothalamus to capillaries in the anterior lobe of the pituitary gland (adenohypophysis). (18)

hypophysis: See **pituitary gland**. (18)

hyposecretion: Abnormally low exocrine or endocrine secretion. (18)

hypothalamus: The floor of the diencephalon; the region of the brain containing centers involved with the subconscious regulation of visceral functions, emotions, drives, and the coordination of neural and endocrine functions. (14, 18)

hypothermia: An abnormally low body temperature. (25)

hypothesis: A prediction that can be subjected to scientific analysis and review.

hypotonic: In comparing two solutions, the solution with the lower osmolarity. (3)

hypoventilation: A respiratory rate that is insufficient to keep blood P_{CO_2} within normal levels. (23, 27)

hypoxia: A low tissue oxygen concentration. (19, 23)

ileum: The distal segment of the small intestine. (24)

ilium: The largest of the three bones whose fusion creates a coxal bone. (8)

immunity: Resistance to infection and disease caused by foreign substances, toxins, or pathogens. (22)

immunization: The production of immunity by the deliberate exposure to antigens under conditions that prevent the development of illness but stimulate the production of memory B cells. (22)

immunoglobulin (Ig): A circulating antibody. (19, 22)

implantation: The attachment of a blastocyst into the endometrium of the uterine wall. (29)

inclusions: Aggregations of insoluble pigments, nutrients, or other materials in cytoplasm. (3)

incus: The central auditory ossicle, located between the malleus and the stapes in the middle ear cavity. (17)

inducer: A stimulus that promotes the activity of a specific gene. (29)

inexcitable: Incapable of propagating an action potential. (12)

infarct: An area of dead cells that results from an interruption of blood flow. (19, 20)

infection: The invasion and colonization of body tissues by pathogens. (4)

inferior: Below, in reference to a particular structure, with the body in the anatomical position. (1)

inferior vena cava (IVC): The vein that carries blood from the parts of the body inferior to the heart to the right atrium. (20, 21)

infertility: The inability to conceive; also called *sterility*. (28, 29)

inflammation: A nonspecific defense mechanism that operates at the tissue level; characterized by swelling, redness, heat (warmth), pain, and sometimes loss of function. (4, 22)

infundibulum: A tapering, funnel-shaped structure; in the brain, the connection between the pituitary gland and the hypothalamus (14, 18); in the uterine tube, the entrance bounded by fimbriae that receives the oocyte at ovulation. (28)

ingestion: The introduction of food into the digestive tract by way of the mouth; eating. (24)

inguinal canal: A passage through the abdominal wall that marks the path of testicular descent and that contains the testicular arteries, veins, and ductus deferens. (11, 28)

inguinal region: The area of the abdominal wall near the junction of the trunk and the thighs that contains the external genitalia; the groin. (28)

inhibin: A hormone, produced by nurse cells of the testes and follicular cells of the ovaries, that inhibits the secretion of follicle-stimulating hormone by the adenohypophysis (anterior lobe of the pituitary gland). (18, 28)

inhibitory postsynaptic potential (IPSP): A hyperpolarization of the postsynaptic membrane after the arrival of a neurotransmitter. (12)

initial segment: The proximal portion of the axon where an action potential first appears. (12)

injection: The forcing of fluid into a body part or organ. (18)

inner cell mass: Cells of the blastocyst that will form the body of the embryo. (29)

innervation: The distribution of sensory and motor nerves to a specific region or organ. (11, 16)

insensible perspiration: Evaporative water loss by diffusion across the epithelium of the skin or evaporation across the alveolar surfaces of the lungs. (5, 27)

insertion: A point of attachment of a muscle; the end that is easily movable. (11)

insoluble: Incapable of dissolving in solution. (2)

inspiration: Inhalation; the movement of air into the respiratory system. (23)

insulin: A hormone secreted by beta cells of the pancreatic islets; causes a decrease in blood glucose concentrations. (18)

integument: The skin. (5)

intercalated discs: Regions where adjacent cardiac muscle cells interlock and where gap junctions permit electrical coupling between the cells. (4, 10, 20)

intercellular fluid: See **interstitial fluid**. (3)

interferons (IFNs): Peptides released by virus-infected cells, especially lymphocytes, that slow viral replication and make other cells more resistant to viral infection. (22)

interleukins: Peptides, released by activated monocytes and lymphocytes, that assist in the coordination of cell-mediated and antibody-mediated immunities. (22)

internal capsule: The collection of afferent and efferent fibers of the white matter of the cerebral hemispheres, visible on gross dissection of the brain. (14)

internal ear: The membranous labyrinth that contains the organs of hearing and equilibrium. (17)

internal respiration: The diffusion of gases between interstitial fluid and cytoplasm. (23)

interneuron: An association neuron; central nervous system neurons that are between sensory and motor neurons. (12)

interoceptors: Sensory receptors monitoring the functions and status of internal organs and systems. (12)

interosseous membrane: The fibrous connective tissue membrane between the shafts of the tibia and fibula and between the radius and ulna; an example of a fibrous amphiarthrosis. (8)

interphase: The stage in the life cycle of a cell during which the chromosomes are uncoiled and all normal cellular functions except mitosis are under way. (3, 29)

intersegmental reflex: A reflex that involves several segments of the spinal cord. (13)

intersex: Umbrella term used to describe a person who is born with a combination of both biologically male and female reproductive organs, genitals, or sexual characteristics and traits including chromosomal variations that are not XY (male) or XX (female). (18)

interstitial fluid: The fluid in the tissues that fills the spaces between cells. (3)

interstitial growth: A form of cartilage growth in which the cartilage expands from within through the growth, mitosis, and secretion of chondrocytes in the matrix. (4)

interventricular foramen: The opening that permits fluid movement between the lateral and third ventricles of the brain. (14)

intervertebral disc: A fibrocartilage pad between the bodies of successive vertebrae that absorbs shocks. (7, 9)

intestinal gland: A tubular epithelial pocket that is lined by secretory cells and opens into the lumen of the digestive tract; also called *intestinal crypt*. (24)

intestine: The tubular organ of the digestive tract. (18, 24)

intracellular fluid (ICF): The cytosol. (27)

intrafusal muscle fibers: Muscle spindle fibers. (13)

intramembranous ossification: The formation of bone within a connective tissue without the prior development of a cartilaginous model. (6)

intrinsic factor: A glycoprotein secreted by the parietal cells of the stomach that facilitates the intestinal absorption of vitamin B_{12} . (19, 24, 25)

intrinsic pathway: A pathway of the clotting system that begins with the activation of platelets and ends with the formation of factor X activator complex. (19)

inversion: A turning inward. (9)
in vitro: Outside the body, in an artificial environment. (29)
involuntary: Not under conscious control. (10)
ion: An atom or molecule having a positive or negative charge due to the loss or gain, respectively, of one or more electrons. (2, 26, 27)
ionic bond: A molecular bond created by the attraction between ions with opposite charges. (2)
ionization: The dissociation of an atom, molecule, or substance into ions; also called *dissociation*. (2)
ipsilateral: A reflex response that affects the same side as the stimulus. (13)
iris: A contractile structure made up of smooth muscle that forms the colored portion of the eye. (17)
ischemia: An inadequate blood supply to a region of the body. (11)
ischium: One of the three bones whose fusion creates a coxal bone. (8)
islets of Langerhans: See **pancreatic islets**. (18, 24)
isotonic: A solution with an osmolarity that does not result in water movement across plasma membranes. (3, 10)
isotopes: Forms of an element whose atoms contain the same number of protons but different numbers of neutrons (and thus differ in atomic mass). (2)
isthmus: A narrow band of tissue connecting two larger masses. (18)

J
jejunum: The middle part of the small intestine. (24)
joint: An area where adjacent bones interact; also called *articulation*. (9)
juxtaglomerular cells: Modified smooth muscle cells between the walls of the distal convoluted tubule and the afferent and efferent arterioles adjacent to the glomerulus and the macula densa. (26)
juxtaglomerular complex (JGC): The macula densa, extraglomerular mesangial cells, and the juxtaglomerular cells; a complex responsible for the release of renin and erythropoietin. (26)

K
keratin: The tough, fibrous protein component of nails, hair, calluses, and the general integumentary surface. (5)
keto acid: The carbon chain that remains after the deamination or transamination of an amino acid. (25)
ketoacidosis: A condition characterized by a decrease in blood pH due to the presence of large numbers of ketone bodies. (25, 26, 27)
ketone bodies: Keto acids produced during the catabolism of lipids and ketogenic amino acids; specifically, acetone, acetoacetate, and beta-hydroxybutyrate. (25)
kidney: A component of the urinary system; an organ functioning in the regulation of blood composition, including the excretion of wastes and the maintenance of normal fluid and electrolyte balances. (18, 26)
killer T cells: See **cytotoxic T cells**. (22)
Krebs cycle: See **citric acid cycle**. (3, 10, 25)
Kupffer cell: See **stellate macrophage**. (22, 24)

L
labium/labia: Lip/lips; the labia majora and labia minora are structures of the female external genitalia. (28)

labrum: A lip or rim. (9, 28)
labyrinth: A maze of passageways; the structures of the internal ear. (17)
lacrimal gland: A tear gland on the dorsolateral surface of the eye. (17)
lactase: An enzyme that breaks down the milk sugar, lactose. (24)
lactate: An anion released by the dissociation of lactic acid, or formed from the reduction of pyruvate. (10)
lactation: The production of milk by the mammary glands. (28)
lacteal: A terminal lymphatic within an intestinal villus. (24)
lacuna/lacunae: A small pit or cavity. (4, 6, 29)
lambdoid suture: The synarthrosis between the parietal and occipital bones of the cranium. (7)
lamellae: Concentric layers; the concentric layers of bone within an osteon. (6)
lamellar corpuscle: A receptor sensitive to vibration. (15)
lamina: A thin sheet or layer. (4, 7)
lamina propria: The areolar tissue that underlies a mucous epithelium and forms part of a mucous membrane. (4, 23, 24)
Langerhans cells: Cells in the epithelium of the skin (15) and digestive tract (24) that participate in the immune response by presenting antigens to T cells; also called *dendritic cells*.
large intestine: The terminal portions of the intestinal tract, consisting of the colon, the rectum, and the anal canal. (24)
laryngopharynx: The division of the pharynx that is inferior to the epiglottis and superior to the esophagus. (23)
larynx: A complex cartilaginous structure that surrounds and protects the glottis and vocal cords; the superior margin is bound to the hyoid bone, and the inferior margin is bound to the trachea. (23)
latent period: The time between the stimulation of a muscle and the start of the contraction phase. (10)
lateral: Pertaining to the side. (1)
lateral apertures: Openings in the roof of the fourth ventricle that permit the circulation of cerebrospinal fluid into the subarachnoid space. (14)
lateral ventricle: A fluid-filled chamber within a cerebral hemisphere. (14)
lens: The transparent refractive structure of the eye that is between the iris and the vitreous humor. (17)
lesion: A localized abnormality in tissue organization. (4)
lesser omentum: A double-layered peritoneal fold formed by the mesentery that connects the lesser curvature of the stomach to the liver. (24)
leukocyte: A white blood cell. (4, 19)
ligament: A dense band of connective tissue fibers that attaches one bone to another. (4, 9)
ligamentum arteriosum: The fibrous strand in adults that is the remnant of the ductus arteriosus of the fetal stage. (21)
ligamentum nuchae: An elastic ligament between the vertebra prominens and the occipital bone. (7)
ligamentum teres: The fibrous strand in the falciform ligament of adults that is the remnant of the umbilical vein; also called the *round ligament of the liver*. (24)
ligate: To tie off. (28)
limbic system: The nuclei and centers in the cerebrum and diencephalon that are involved with emotional states, memories, and behavioral drives. (14)
lingual: Pertaining to the tongue. (17, 24)
lipid: An organic compound containing carbon, hydrogen, and oxygen in a ratio that does not

approximate 1:2:1; includes fats, oils, and waxes. (2, 24, 25)
lipogenesis: The synthesis of lipids from nonlipid precursors. (25)
lipolysis: The catabolism of lipids as a source of energy. (25)
lipoprotein: A compound containing a relatively small lipid bound to a protein. (25)
liver: An organ of the digestive system that has varied and vital functions, including the production of plasma proteins, the excretion of bile, the storage of energy reserves, the detoxification of poisons, and the interconversion of nutrients. (24)
lobule: Histologically, the basic organizational unit of the liver. (24)
local hormone: See **prostaglandin**. (2, 18)
loop of Henle: See **nephron loop**. (26)
loose connective tissue: A loosely organized, easily distorted connective tissue that contains several fiber types, a varied population of cells, and a viscous ground substance. (4)
lumbar: Pertaining to the lower back. (7, 13)
lumen: The central space within a duct or other internal passageway. (4)
lungs: The paired organs of breathing enclosed by the pleural cavities. (23)
luteinizing hormone (LH): A hormone produced by the adenohypophysis (anterior lobe of the pituitary gland); in females, it assists FSH in follicle stimulation, triggers ovulation, and promotes the maintenance and secretion of endometrial glands; in males, it was formerly called *interstitial cell-stimulating hormone* because it stimulates testosterone secretion by the interstitial endocrine cells of the testes. (18, 28)
lymph: The fluid contents of lymphatic vessels, similar in composition to interstitial fluid. (4, 22)
lymphatic vessels: The vessels of the lymphatic system; also called *lymphatics*. (4, 22)
lymphedema: Swelling because of lymphatic vessel obstruction. (22)
lymph nodes: Lymphoid organs that monitor the composition of lymph. (22)
lymphocyte: A cell of the lymphatic system that plays a role in the immune response. (4, 19, 22)
lymphokines: Chemicals secreted by activated lymphocytes. (22)
lymphopoiesis: The production of lymphocytes from lymphoid stem cells. (19, 22)
lymphotoxin: A secretion of lymphocytes that kills the target cells. (22)
lysis: The destruction of a cell through the rupture of its plasma membrane. (3)
lysosome: An intracellular vesicle containing digestive enzymes. (3)
lysozyme: An enzyme, present in some exocrine secretions, that has antibiotic properties. (17)

M
macrophage: A phagocytic cell of the monocyte-macrophage system. (4, 22)
macula: A receptor complex, located in the sacculus or utricle of the internal ear, that responds to linear acceleration or gravity. (17)
macula (of retina): The oval area in the retina whose center (the fovea centralis) is the region of sharpest vision; also called *macula lutea*. (17)
macula densa: A group of specialized secretory cells that is located in a portion of the distal convoluted tubule, adjacent to the glomerulus, extraglomerular mesangial cells, and the juxtaglomerular cells; a component of the juxtaglomerular complex. (26)

major histocompatibility complex: *See* **MHC protein.** (22)

malignant tumor: A form of cancer characterized by rapid cell growth and the spread of cancer cells throughout the body. (3)

malleus: An auditory ossicle, bound to the tympanic membrane and the incus. (17)

malnutrition: An unhealthy state produced by inadequate dietary intake or absorption of nutrients. (25)

mammillary bodies: Nuclei in the hypothalamus that affect eating reflexes and behaviors; a component of the limbic system. (14)

mammary glands: Milk-producing glands of the female breasts. (5, 28)

manus: The hand; manual. (8, 11)

marrow: A tissue that fills the internal cavities in bone; dominated by hemopoietic cells (red bone marrow) or by adipose tissue (yellow bone marrow). (6, 19)

mass: A physical property that determines the weight of an object in Earth's gravitational field; the amount of material in matter. (2)

mast cell: A connective tissue cell that, when stimulated, releases histamine, serotonin, and heparin, initiating the inflammatory response. (4)

mastication: Chewing. (11, 24)

mastoid sinus: Air-filled spaces in the mastoid process of the temporal bone. (7)

matrix: The extracellular fibers and ground substance of a connective tissue. (3, 4)

matter: Anything that takes up space and has mass. (2)

maxillary sinus: One of the paranasal sinuses; an air-filled chamber lined by a respiratory epithelium that is located in a maxilla and opens into the nasal cavity. (7)

meatus: An opening or entrance into a passageway. (23, 26)

mechanoreception: The detection of mechanical stimuli, such as touch, pressure, or vibration. (15)

medial: Toward the midline of the body. (1)

mediastinum: The central tissue mass that divides the thoracic cavity into two pleural cavities. (1, 20)

medulla: The inner layer or core of an organ. (5)

medulla oblongata: The most caudal of the brain regions; also called the *myelencephalon*. (14)

medullary cavity: The space within a bone that contains the marrow. (6)

megakaryocytes: Bone marrow cells responsible for the formation of platelets. (19)

meiosis: Cell division that produces gametes with half the normal somatic chromosome complement. (3, 28)

melanin: The red-yellow or brown-black pigments produced by the melanocytes of the skin. (4, 5)

melanocyte: A specialized cell in the deeper layers of the stratified squamous epithelium of the skin; responsible for the production of melanin. (4, 5, 18)

melanocyte-stimulating hormone (MSH): A hormone, produced by the pars intermedia of the anterior lobe of the pituitary gland (adenohypophysis), that stimulates melanin production. (18)

melatonin: A hormone secreted by the pineal gland; inhibits secretion of MSH and GnRH. (14, 18)

membrane: Any sheet or partition; a layer consisting of an epithelium and the underlying connective tissue. (2)

membrane flow: The continuous movement and exchange of membrane segments. (3)

membrane potential: The potential difference, measured across a plasma membrane and

expressed in millivolts, that results from the uneven distribution of positive and negative ions across the plasma membrane; also called *transmembrane potential*. (3, 10, 12)

membranous labyrinth: Endolymph-filled tubes that enclose the receptors of the internal ear. (17)

memory: The ability to recall information or sensations; can be divided into short-term and long-term memories. (16, 22)

memory T cells: T lymphocytes that provide immunological memory, enabling an enhanced immune response when reexposed to a specific antigen. (22)

meninges: Three membranes that surround the surfaces of the central nervous system; the dura mater, the pia mater, and the arachnoid mater. (13)

meniscus: A fibrocartilage pad between opposing surfaces in a joint. (9)

menstruation: The phase of the uterine cycle in which the endometrial functional layer is shed; also called *menses*. (28)

merocrine secretion: A method of secretion in which the cell ejects materials from secretory vesicles through exocytosis. (4, 5)

mesencephalon: The midbrain; the region between the diencephalon and pons. (14)

mesenchyme: Embryonic or fetal connective tissue. (4)

mesentery: A double layer of serous membrane that supports and stabilizes the position of an organ in the abdominopelvic cavity and provides a route for the associated blood vessels, nerves, and lymphatic vessels. (24)

mesoderm: The middle germ layer, between the ectoderm and endoderm of the embryo. (29)

mesothelium: A simple squamous epithelium that lines the body cavities enclosing the lungs, heart, and abdominal organs. (4)

messenger RNA (mRNA): RNA formed at transcription to direct protein synthesis in the cytoplasm. (2, 3)

metabolic turnover: The continuous breakdown and replacement of organic materials within cells. (2, 25)

metabolism: The sum of all biochemical processes under way within the human body at any moment; includes anabolism and catabolism. (2, 25)

metabolites: Compounds produced in the body as a result of metabolic reactions. (2)

metacarpals: The five bones of the palm of the hand. (8)

metalloproteins: Proteins containing a metal ion cofactor; examples include plasma transport proteins, storage proteins, and enzymes. (19, 25)

metaphase: The stage of mitosis in which the chromosomes line up along the equatorial plane of the cell. (3)

metaphysis: The region of a long bone between the epiphysis and diaphysis, corresponding to the location of the epiphyseal cartilage of the developing bone. (6)

metastasis: The spread of cancer cells from one organ to another, leading to the establishment of secondary tumors. (3)

metatarsal: One of the five bones of the foot that articulate with the tarsal bones (proximally) and the phalanges (distally). (8)

metencephalon: The pons and cerebellum of the brain. (14)

MHC protein: A surface antigen that is important to the recognition of foreign antigens and that plays a role in the coordination and activation of the immune response; also called *major*

histocompatibility complex (MHC) protein or *human leukocyte antigen (HLA)*. (22)

micelle: A droplet with hydrophilic portions on the outside; a spherical aggregation of bile salts, monoglycerides, and fatty acids in the lumen of the intestinal tract. (2, 24)

microfilaments: Fine protein filaments visible with the electron microscope; components of the cytoskeleton. (3)

microglia: Phagocytic neuroglia in the central nervous system. (12, 22)

microphages: Neutrophils and eosinophils. (4, 19, 22)

microtubules: Microscopic tubules that are part of the cytoskeleton and are a component in cilia, flagella, the centrioles, and spindle fibers. (3)

microvilli: Small, fingerlike extensions of the exposed plasma membrane of an epithelial cell. (3)

micturition: Urination. (26)

midbrain: The mesencephalon. (14)

middle ear: The space between the external and internal ears that contains auditory ossicles. (17)

midsagittal plane: A plane passing through the midline of the body that divides it into left and right halves. (1)

mineralocorticoids: Corticosteroids produced by the zona glomerulosa of the adrenal cortex; steroids such as aldosterone that affect mineral metabolism. (18)

mitochondrion: An intracellular organelle responsible for generating most of the ATP required for cellular operations. (3, 25)

mitosis: The division of a single cell nucleus that produces two identical daughter cell nuclei; an essential step in cell division. (3, 28)

mitral valve: The left atrioventricular (AV) valve; also called *bicuspid valve*. (20)

mixed gland: A gland that contains exocrine and endocrine cells, or an exocrine gland that produces serous and mucous secretions. (4)

mixed nerve: A peripheral nerve that contains sensory and motor fibers. (13)

mole: A quantity of an element or compound having a mass in grams equal to the element's atomic weight or to the compound's molecular weight. (2)

molecular weight: The sum of the atomic weights of all the atoms in a molecule or compound. (2, 3)

molecule: A chemical structure containing two or more atoms that are bonded together by shared electrons. (1, 2, 3)

monoclonal antibodies: Antibodies produced by genetically identical cells under laboratory conditions. (22)

monocytes: Phagocytic agranulocytes (white blood cells) in the circulating blood. (19)

monoglyceride: A lipid consisting of a single fatty acid bound to a molecule of glycerol. (2)

monokines: Secretions released by activated cells of the monocyte-macrophage system to coordinate various aspects of the immune response. (22)

monomer: A molecule that can be bonded to other identical molecules to form a polymer. (2)

monosaccharide: A simple sugar, such as glucose or ribose. (2, 24)

monosynaptic reflex: A reflex in which the sensory afferent neuron synapses directly on the motor efferent neuron. (13)

motor unit: All the muscle cells controlled by a single motor neuron. (10)

mucins: Proteoglycans responsible for the lubricating properties of mucus. (2, 24)

mucosa: A mucous membrane; the epithelium plus the lamina propria; also called *mucous membrane*. (4, 24)

mucosa-associated lymphoid tissue (MALT): The extensive collection of lymphoid tissues linked with the epithelia of the digestive, respiratory, urinary, and reproductive tracts. (22)

mucous (adjective): Indicating the presence or production of mucus. (4, 23, 24)

mucous (goblet) cell: A goblet-shaped, mucus-producing, unicellular gland in certain epithelia of the digestive and respiratory tracts; they are called mucous cells when they are found in the stomach mucosa, respiratory mucosa, and salivary glands; they are called goblet cells in the mucosa of the small intestine, large intestine, terminal bronchioles, and conjunctiva. (4, 23, 24)

mucous membrane: See **mucosa**. (4, 24)

mucus (noun): A lubricating fluid that is composed of water and mucins and is produced by unicellular and multicellular glands along the digestive, respiratory, urinary, and reproductive tracts. (2, 4)

multipolar neuron: A neuron with many dendrites and a single axon; the typical form of a motor neuron. (12)

multiunit smooth muscle: A smooth muscle tissue whose muscle cells are innervated in motor units. (10)

muscarinic receptors: Membrane receptors sensitive to acetylcholine and to muscarine, a toxin produced by certain mushrooms; located at all parasympathetic neuromuscular and neuroglandular junctions and at a few sympathetic neuromuscular and neuroglandular junctions. (16)

muscle: A contractile organ composed of muscle tissue, blood vessels, nerves, connective tissues, and lymphatic vessels. (10, 11)

muscle tissue: A tissue characterized by the presence of cells capable of contraction; includes skeletal, cardiac, and smooth muscle tissues. (4, 10)

muscular layer: Concentric layers of smooth muscle responsible for peristalsis. (24)

muscularis mucosae: The layer of circular and longitudinal smooth muscle deep to the lamina propria; responsible for moving the mucosal surface. (24)

mutagens: Chemical agents that induce mutations and may be carcinogenic. (3)

mutation: A change in the nucleotide sequence of the DNA in a cell. (3)

myelencephalon: See **medulla oblongata**. (14)

myelin: An insulating sheath around an axon; consists of multiple layers of neuroglial membrane; significantly increases the nerve impulse propagation rate along the axon. (12)

myelination: The formation of myelin. (12)

myenteric plexus: Parasympathetic motor neurons and sympathetic postganglionic fibers located between the circular and longitudinal layers of the muscularis externa. (24)

myocardial infarction: A heart attack; damage to the heart muscle due to an interruption of regional coronary circulation. (20)

myocardium: The cardiac muscle tissue of the heart. (20)

myofibril: Organized collections of myofilaments in skeletal and cardiac muscle cells. (10)

myofilaments: Fine protein filaments composed primarily of the proteins actin (thin filaments) and myosin (thick filaments). (10)

myoglobin: An oxygen-binding pigment that is especially common in slow skeletal muscle fibers and cardiac muscle cells. (2, 10)

myogram: A recording of the tension produced by muscle fibers on stimulation. (10)

myometrium: The thick layer of smooth muscle in the wall of the uterus. (28)

myosatellite cells: Cells that are the precursors to skeletal muscle cells (fibers). (10)

myosin: The protein component of thick filaments. (3, 10)

N

nail: A keratinous structure produced by epithelial cells of the nail root. (5)

nasal cavity: A chamber in the skull that is bounded by the internal and external nares. (7, 17, 23)

nasolacrimal duct: The passageway that transports tears from the nasolacrimal sac to the nasal cavity. (7, 17)

nasolacrimal sac: A chamber that receives tears from the lacrimal ducts. (17)

nasopharynx: A region that is posterior to the internal nares and superior to the soft palate and ends at the oropharynx. (23)

natriuretic peptides: Hormones released by specialized cardiac muscle cells when they are stretched by an abnormally large venous return; promotes fluid loss and reductions in blood pressure and in venous return. Includes atrial natriuretic peptide (ANP) and B-type natriuretic peptide (BNP). (18, 21, 26, 27)

natural killer (NK) cells: Type of lymphocyte that can kill target cells without previous sensitivity. (19)

N compound: An organic compound containing nitrogen atoms. (25)

necrosis: The death of cells or tissues from disease or injury. (4, 22)

negative feedback: A corrective mechanism that opposes or negates a variation from normal limits. (1, 18)

neonate: A newborn infant, or baby. (29)

neoplasm: A tumor, or mass of abnormal tissue. (3)

nephron: The basic functional unit of the kidney. (26)

nephron loop: The segment of the nephron that creates the concentration gradient in the renal medulla; also called *loop of Henle*. (26)

nerve impulse: An action potential in a neuron plasma membrane. (12)

net filtration pressure (NFP): The difference between the net hydrostatic pressure and the net osmotic pressure. (21, 26)

neural cortex: An area of gray matter at the surface of the central nervous system. (13)

neurofibrils: Microfibrils in the cytoplasm of a neuron. (12)

neurofilaments: Microfilaments in the cytoplasm of a neuron. (12)

neuroglandular junction: A cell junction at which a neuron controls or regulates the activity of a secretory (gland) cell. (12)

neuroglia: Cells of the central nervous system and peripheral nervous system that support and protect neurons; also called *glial cells*. (4, 12)

neurohypophysis: The posterior lobe of the pituitary gland, or pars nervosa; contains the axons of hypothalamic neurons, which release oxytocin and antidiuretic hormone. (18)

neurolemma: The outer surface of a Schwann cell that encircles an axon in the peripheral nervous system. (12)

neuromodulator: A compound, released by a neuron, that adjusts the sensitivities of another neuron to specific neurotransmitters. (12)

neuromuscular junction (NMJ): A synapse between a neuron and a muscle cell. (10, 12)

neuron: A cell in nervous tissue that is specialized for intercellular communication through (1) changes in membrane potential and (2) synaptic connections. (4, 12, 15, 16)

neuroplasticity: The ability of nerve cells to make new connections. (14)

neurotransmitter: A chemical compound released by one neuron to affect the membrane potential of another. (10, 12, 16)

neurotubules: Microtubules in the cytoplasm of a neuron. (12)

neutron: A fundamental particle that does not have a positive or a negative charge. (2)

neutrophil: A white blood cell that is very numerous and normally the first of the mobile phagocytic cells to arrive at an area of injury or infection. (19)

nicotinic receptors: Acetylcholine receptors on the surfaces of sympathetic and parasympathetic ganglion cells; respond to the compound nicotine. (16)

nipple: An elevated epithelial projection on the surface of the breast; contains the openings of the lactiferous sinuses. (28)

Nissl bodies: The ribosomes, Golgi apparatus, rough endoplasmic reticulum, and mitochondria of the perikaryon of a typical neuron. (12)

nitrogenous wastes: Organic waste products of metabolism that contain nitrogen, such as urea, uric acid, and creatinine. (25)

nociception: Pain perception. (15)

nodes: The areas between adjacent neuroglia where the myelin covering of an axon is incomplete; also called *nodes of Ranvier*. (12)

nodose ganglion: A sensory ganglion of cranial nerve X; also called *inferior ganglion*. (14)

noradrenaline: See **norepinephrine (NE)**. (12, 18)

norepinephrine (NE): A catecholamine neurotransmitter in the peripheral nervous system and central nervous system, released at most sympathetic neuromuscular and neuroglandular junctions, and a hormone secreted by the adrenal (suprarenal) medulla; also called *noradrenaline*. (12, 18)

nucleic acid: A polymer of nucleotides that contains a pentose sugar, a phosphate group, and one of four nitrogenous bases that regulate the synthesis of proteins and make up the genetic material in cells. (2)

nucleolus: The dense region in the nucleus that is the site of RNA synthesis. (3)

nucleoplasm: The fluid content of the nucleus. (3)

nucleoproteins: Proteins of the nucleus that are generally associated with DNA. (3)

nucleotide: A compound consisting of a nitrogenous base, a simple sugar, and a phosphate group. (2)

nucleus: The central region of an atom. (1) A cellular organelle that contains DNA, RNA, and proteins; in the central nervous system, a mass of gray matter. (3)

nucleus pulposus: The gelatinous central region of an intervertebral disc. (9)

nurse cells: Supporting cells of the seminiferous tubules of the testis; responsible for the differentiation of spermatids, the maintenance of the blood-testis barrier, and the secretion of inhibin, androgen-binding protein, and Müllerian-inhibiting factor; also called *Sertoli cells*. (18, 28)

nutrient: An inorganic or organic substance that can be used by the body as a cofactor or to produce energy. (2, 25)

nystagmus: An unconscious, continuous movement of the eyes as if to adjust to constant motion. (17)

O

obesity: Body weight more than 20% above the ideal weight for a given individual. (25)

occlusal surface: The opposing surfaces of the teeth that come into contact when chewing food. (24)

ocular: Pertaining to the eye. (17)

oculomotor nerve: Cranial nerve III, which controls the extraocular muscles other than the superior oblique and the lateral rectus muscles. (14)

olecranon: The proximal end of the ulna that forms the prominent point of the elbow. (8)

olfaction: The sense of smell. (15, 17, 23)

olfactory bulb: The expanded ends of the olfactory tracts (17); the sites where the axons of the first cranial nerves (I) synapse on central nervous system interneurons that lie inferior to the frontal lobes of the cerebrum. (14)

oligodendrocytes: Central nervous system neuroglia that maintain cellular organization within gray matter and provide a myelin sheath in areas of white matter. (12)

oligopeptide: A short chain of amino acids. (2)

oocyte: A cell whose meiotic divisions will produce a single ovum and three polar bodies. (3, 28, 29)

oogenesis: Formation and development of an oocyte. (28)

opsonization: An effect of coating an object with antibodies; the attraction and enhancement of phagocytosis. (22)

optic chiasm: The crossing point of the optic nerves. (14, 17)

optic nerve: The second cranial nerve (II), which carries signals from the retina of the eye to the optic chiasm. (14)

optic tract: The tract over which nerve impulses from the retina are transmitted between the optic chiasm and the thalamus. (14)

orbit: The bony recess of the skull that contains the eyeball. (7)

organ: Combinations of tissues that perform complex functions. (1)

organelle: An intracellular structure with a specific function or group of functions. (3)

organic compound: A compound containing carbon, hydrogen, and in most cases oxygen. (2)

organogenesis: The formation of organs during embryonic and fetal development. (29)

organ systems: Groups of organs that function together in a coordinated manner. (1)

origin: In a skeletal muscle, the point of attachment that does not change position when the muscle contracts; usually defined in terms of movements from the anatomical position. (11)

oropharynx: The middle portion of the pharynx, bounded superiorly by the nasopharynx, anteriorly by the oral cavity, and inferiorly by the laryngopharynx. (23)

osmolarity: The total concentration of dissolved materials in a solution, regardless of their specific identities, expressed in moles; also called *osmotic concentration*. (3, 26, 27)

osmoreceptor: A receptor sensitive to changes in the osmolarity of plasma. (27)

osmosis: The movement of water across a selectively permeable membrane from one solution to another solution that contains a higher solute concentration. (3, 21, 26, 27)

osmotic pressure (OP): The force of osmotic water movement; the pressure that must be applied to prevent osmosis across a membrane. (3, 21, 26, 27)

osseous tissue: A strong connective tissue containing specialized cells and a mineralized

matrix of crystalline calcium phosphate and calcium carbonate; also called *bone tissue*. (4, 6)

ossicles: Small bones; middle ear bones. (17)

ossification: The formation of bone; osteogenesis. (6)

osteoblast: A cell that produces the fibers and matrix of bone. (6)

osteoclast: A cell that dissolves the fibers and matrix of bone. (6)

osteocyte: A bone cell responsible for the maintenance and turnover of the mineral content of the surrounding bone. (4, 6)

osteogenic layer: The inner, cellular layer of the periosteum that aids in bone growth and repair. (6)

osteolysis: The breakdown of the mineral matrix of bone. (6)

osteon: The basic histological unit of compact bone, consisting of osteocytes organized around a central canal and separated by concentric lamellae. (6)

osteoporosis: A decrease in bone mass that causes brittle, fragile bones and compromises normal function. (6)

otic: Pertaining to the ear. (17)

otoliths: Calcium carbonate crystals embedded in a gelatinous matrix; located on each macula of the vestibule. (17)

oval window: An opening in the bony labyrinth where the stapes attaches to the membranous wall of the scala vestibuli (vestibular duct). (17)

ovarian cycle: The monthly process of the maturation, ovulation, and degeneration of a tertiary ovarian follicle. (28)

ovary: The female reproductive organ that produces oocytes (gametes). (18, 28)

ovulation: The release of a secondary oocyte, surrounded by cells of the corona radiata, after the rupture of the wall of a tertiary ovarian follicle. (28, 29)

ovum/ova: The functional product of meiosis II, produced after the fertilization of a secondary oocyte. (28, 29)

oxidation: The gain of oxygen, or the loss of hydrogen or electrons. (25)

oxytocin (OXT): A hormone produced by hypothalamic cells and secreted into capillaries at the posterior lobe of the pituitary gland (neurohypophysis); stimulates smooth muscle contractions of the uterus or mammary glands in females and the prostate in males. (18)

P

pacemaker cells: Cells of the sinoatrial node that set the pace of cardiac contraction. (4, 10, 20)

palate: The horizontal partition separating the oral cavity from the nasal cavity and nasopharynx; divided into an anterior bony (hard) palate and a posterior fleshy (soft) palate. (7, 23, 24)

palatine: Pertaining to the palate. (24)

palpate: To examine by touch. (1)

palpebrae: See *eyelids*. (17)

pancreas: A digestive organ containing exocrine and endocrine tissues; the exocrine portion secretes pancreatic juice, and the endocrine portion secretes hormones, including insulin and glucagon. (18, 24)

pancreatic duct: A tubular duct that carries pancreatic juice from the pancreas to the duodenum. (18, 24)

pancreatic islets: Aggregations of endocrine cells in the pancreas; also called *islets of Langerhans*. (18, 24)

pancreatic juice: A mixture of buffers and digestive enzymes that is discharged into the duodenum under the stimulation of the enzymes, secretin and cholecystokinin. (18, 24)

Papanicolaou test (Pap smear): A test for the detection of malignancies based on the cytological appearance of epithelial cells, especially those of the cervix and uterus. (28)

papilla: A small, conical projection. (5, 17, 24, 26)

paralysis: The loss of voluntary motor control over a portion of the body. (13)

paranasal sinuses: Bony chambers, lined by respiratory epithelium, that open into the nasal cavity; the frontal, ethmoidal, sphenoidal, and maxillary sinuses. (7)

parasagittal plane: A plane that parallels the midsagittal plane but that does not pass along the midline. (1)

parasympathetic division: One of the two divisions of the autonomic nervous system; generally responsible for activities that conserve energy and lower the metabolic rate; the "rest and digest" division; also called *craniosacral division*. (16)

parathyroid glands: Four small glands embedded in the posterior surface of the thyroid gland that secrete parathyroid hormone. (6, 18)

parathyroid hormone (PTH): A hormone secreted by the parathyroid glands when blood calcium levels decrease below the normal range; causes increased osteoclast activity, increased intestinal calcium uptake, and decreased calcium ion loss by the kidneys. (6, 18)

parenchyma: The cells of a tissue or organ that are responsible for fulfilling its functional role; distinguished from the stroma of that tissue or organ. (4)

paresthesia: A sensory abnormality that produces a tingling sensation. (15)

parietal: Relating to the parietal bone (7); referring to the wall of a cavity. (23)

parietal cells: Cells of the gastric glands that secrete hydrochloric acid and intrinsic factor. (24)

parotid glands: Large salivary glands that secrete saliva with high concentrations of salivary (alpha) amylase. (24)

pars distalis: The large, anterior portion of the anterior lobe of the pituitary gland (adenohypophysis). (18)

pars intermedia: The portion of the anterior lobe of the pituitary gland (adenohypophysis) that is immediately adjacent to the posterior lobe of the pituitary gland (neurohypophysis) and the infundibulum. (18)

pars nervosa: The posterior lobe of the pituitary gland (neurohypophysis). (18)

pars tuberalis: The portion of the anterior lobe of the pituitary gland (adenohypophysis) that wraps around the infundibulum superior to the posterior lobe (neurohypophysis). (18)

patella: The sesamoid bone of the knee; also called the *kneecap*. (8)

pathogen: A disease-causing organism. (1, 22)

pathologist: A physician specializing in the identification of diseases based on characteristic structural and functional changes in tissues and organs.

pelvic cavity: The inferior subdivision of the abdominopelvic cavity; encloses the urinary bladder, the sigmoid colon and rectum, and male or female reproductive organs. (1, 8)

pelvis: A bony complex created by the articulations among the coxal bones, the sacrum, and the coccyx. (8, 11)

penis: A component of the male external genitalia; a copulatory organ that surrounds the urethra and introduces semen into the female vagina; the developmental equivalent of the female clitoris. (28)

peptide: A chain of amino acids linked by peptide bonds. (2, 18)

peptide bond: A covalent bond between the amino group of one amino acid and the carboxyl group of another. (2)

perforating canals: Passageways within compact bone that extend perpendicular to the surface. (6)

pericardial cavity: The space between the parietal pericardium and the epicardium (visceral pericardium) that encloses the outer surface of the heart. (1, 20)

pericardium: The fibrous sac that surrounds the heart; its inner, serous lining is continuous with the epicardium. (4, 20)

perichondrium: The layer that surrounds a cartilage, consisting of an outer fibrous region and an inner cellular region. (4)

perikaryon: The cytoplasm that surrounds the nucleus in the cell body of a neuron. (12)

perilymph: A fluid similar in composition to cerebrospinal fluid; located in the spaces between the bony labyrinth and the membranous labyrinth of the internal ear. (17)

perimetrium: The incomplete serosa of the uterus. (28)

perimysium: A connective tissue partition that separates adjacent fasciculi in a skeletal muscle. (10)

perineum: The pelvic floor and its associated structures. (11)

perineurium: A connective tissue partition that separates adjacent bundles of nerve fibers in a peripheral nerve. (13)

periodontal ligament: Collagen fibers that anchor a tooth within its alveolus. (24)

periosteum: The layer that surrounds a bone, consisting of an outer fibrous region and inner cellular region. (4, 6)

peripheral nervous system (PNS): All nervous tissue outside the central nervous system and the enteric nervous system. (12, 13)

peripheral resistance: The resistance to blood flow; primarily caused by friction with the vessel walls. (21)

peristalsis: A wave of smooth muscle contractions that propels materials along the lumen of a tube such as the digestive tract (24), the ureters (26), or the ductus deferens. (28)

peritoneal cavity: The potential space within the abdominopelvic cavity lined by the peritoneum. (1)

peritoneum: The serous membrane that lines the peritoneal cavity. (4, 24, 28)

peritubular capillaries: A network of capillaries that surrounds the proximal and distal convoluted tubules of the kidneys. (26)

permeability: The ease with which dissolved materials can cross a membrane; if the membrane is freely permeable, any molecule can cross it; if impermeable, nothing can cross; most biological membranes are selectively permeable (allow some and restrict others). (3)

peroxisome: A membranous vesicle containing enzymes that break down hydrogen peroxide (H_2O_2). (3)

pes: The foot. (8, 11)

petrosal ganglion: A sensory ganglion of the glossopharyngeal nerve (N IX). (14, 15)

petrous: Stony; usually refers to the thickened portion of the temporal bone that encloses the internal ear. (17)

pH: The negative exponent (negative logarithm) of the hydrogen ion concentration, expressed in moles per liter. (2, 27)

phagocyte: A cell that performs phagocytosis. (22)

phagocytosis: The engulfing of extracellular materials or pathogens; the movement of extracellular materials into the cytoplasm by enclosure in a membranous vesicle. (3, 19, 22)

phalanx/phalanges: Bone(s) of the finger(s) or toe(s). (8)

pharmacology: The study of drugs, their physiological effects, and their clinical uses. (6)

pharynx: The throat; a muscular passageway shared by the digestive and respiratory tracts. (11, 23, 24)

phasic response: A pattern of response to stimulation by sensory neurons that are normally inactive; stimulation causes a burst of neural activity that ends when the stimulus either stops or stops changing in intensity. (15)

phenotype: Physical characteristics that are genetically determined. (29)

phosphate group: PO_4^{3-} ; a functional group that can be attached to an organic molecule; required for the formation of high-energy bonds. (2, 25, 27)

phospholipid: An important membrane lipid whose structure includes both hydrophilic and hydrophobic regions. (2, 3)

phosphorylation: The addition of a high-energy phosphate group to a molecule. (2, 25)

photoreception: Sensitivity to light. (17)

physiology: The study of how living organisms perform their functions. (1)

pia mater: The innermost layer of the meninges bound to the underlying nervous tissue. (13, 14)

pineal gland: Nervous tissue in the posterior portion of the roof of the diencephalon; secretes melatonin. (14, 18)

pinna: See **auricle**. (17)

pinocytosis: The introduction of fluids into the cytoplasm by enclosing them in membranous vesicles at the cell surface. (3)

pituitary gland: An endocrine organ that is located in the sella turcica of the sphenoid bone and is connected to the hypothalamus by the infundibulum; includes the posterior lobe (neurohypophysis) and the anterior lobe (adenohypophysis); also called the *hypophysis*. (14, 18)

placenta: A temporary structure in the uterine wall that permits diffusion between the fetal and maternal circulatory systems. (29)

plantar: Referring to the sole of the foot (1); muscles (11); plantar reflex. (13)

plantar flexion: Ankle extension; toe pointing. (8, 9, 11)

plasma: The fluid ground substance of whole blood; what remains after the cells have been removed from a sample of whole blood. (4, 19)

plasma cell: An activated B cell that secretes antibodies. (4, 19, 22)

plasma membrane: A cell membrane; also called a *plasmalemma*. (3)

platelets: Small packets of cytoplasm that contain enzymes important in the clotting response; manufactured in bone marrow by megakaryocytes. (4, 19)

pleura: The serous membrane that lines the pleural (lung) cavities. (4, 23)

pleural cavities: Body cavities of the thoracic region that surround the lungs. (1, 23)

plexus: A network or braid. (16)

polar body: A nonfunctional packet of cytoplasm that contains chromosomes eliminated from an oocyte during meiosis. (28, 29)

polarized: Referring to cells that have regional differences in organelle distribution or

cytoplasmic composition along a specific axis, such as between the basement membrane and free surface of an epithelial cell. (4)

pollex: The thumb. (8)

polymer: A large molecule consisting of a long chain of monomer subunits. (2)

polypeptide: A chain of amino acids strung together by peptide bonds; those containing more than 100 peptides are called *proteins*. (2)

polyribosome: Several ribosomes linked by their translation of a single mRNA strand. (3)

polysaccharide: A complex sugar, such as glycogen or a starch. (2)

polysynaptic reflex: A reflex in which interneurons are interposed between the sensory fiber and the motor neuron(s). (13)

polyunsaturated fats: Fatty acids containing carbon atoms that are linked by double bonds. (1, 2)

pons: The portion of the metencephalon that is anterior to the cerebellum. (14)

popliteal: Pertaining to the back of the knee. (9, 11, 21)

porphyrins: Ring-shaped molecules that form the basis of important respiratory and metabolic pigments, including heme and the cytochromes. (23)

positive feedback: A mechanism that increases a deviation from normal limits after an initial stimulus. (1)

postcentral gyrus: The primary sensory cortex, where touch, vibration, pain, temperature, and taste sensations arrive and are consciously perceived. (14)

posterior: Toward the back; dorsal. (1)

posterior root ganglion: A peripheral nervous system ganglion containing the cell bodies of sensory neurons; see also **dorsal root ganglion**. (13)

postganglionic neuron: An autonomic neuron in a peripheral ganglion, whose activities control peripheral effectors. (16)

postsynaptic membrane: The portion of the plasma membrane of a postsynaptic cell that is part of a synapse. (12)

potential difference: The separation of opposite charges; requires a barrier that prevents ion migration. (3, 12)

precentral gyrus: The primary motor cortex of a cerebral hemisphere, located anterior to the central sulcus. (14)

prefrontal cortex: The anterior portion of each cerebral hemisphere; thought to be involved with higher intellectual functions, predictions, and calculations. (14)

preganglionic neuron: A visceral motor neuron in the central nervous system whose output controls one or more ganglionic motor neurons in the peripheral nervous system. (16)

premotor cortex: The motor association area between the precentral gyrus and the prefrontal area. (14)

pre-optic body: The hypothalamic nucleus that coordinates thermoregulatory activities. (14)

presynaptic membrane: The synaptic surface where neurotransmitter release occurs. (12)

prevertebral ganglion: See **collateral ganglion**. (12, 16)

prime mover: A muscle that performs a specific action; also called an *agonist*. (11)

proenzyme: An inactive enzyme secreted by an epithelial cell. (19)

progesterone: The most important hormone secreted by the corpus luteum after ovulation. (18, 28)

projection fibers: Axons carrying information from the thalamus to the cerebral cortex. (14)

prolactin (PRL): The hormone that stimulates functional development of the mammary glands in females; a secretion of the anterior lobe of the pituitary gland (adenohypophysis). (18)

pronation: The rotation of the forearm that makes the palm face posteriorly. (9)

prone: Lying face down with the palms facing the floor. (1)

pronucleus: An enlarged ovum or sperm nucleus that forms after fertilization but before amphimixis. (29)

prophase: The initial phase of mitosis; characterized by the appearance of chromosomes, the breakdown of the nuclear membrane, and the formation of the spindle apparatus. (3)

proprioceptor: Sensory organ that monitors the position and movement of skeletal muscles and joints. (12)

proprioception: The awareness of the positions of bones, joints, and muscles. (15)

prostaglandin: A fatty acid secreted by one cell that alters the metabolic activities or sensitivities of adjacent cells; also called *local hormone*. (2, 18)

prostate: An accessory gland of the male reproductive tract, contributing about one-third of the volume of semen; also called *prostate gland*. (28)

prosthesis: An artificial substitute for a body part. (9)

protease: An enzyme that breaks down proteins into peptides and amino acids. (2, 3, 24)

protein: A large polypeptide with a complex structure. (2, 25)

proteoglycan: A substance containing a large polysaccharide complex linked by polypeptide chains; examples include hyaluronan (hyaluronic acid) and chondroitin sulfate. (2, 4)

proton: A fundamental subatomic particle having a positive charge. (2)

protraction: Movement anteriorly in the horizontal plane. (9)

proximal: A direction toward the point of attachment or origin; for a limb, toward its attachment to the trunk. (1, 8)

proximal convoluted tubule (PCT): The segment of the nephron between the glomerular capsule (Bowman's capsule) and the nephron loop; the major site of active reabsorption from filtrate. (26)

pseudopodia: Temporary cytoplasmic extensions typical of mobile or phagocytic cells. (3)

pseudostratified epithelium: An epithelium that contains several layers of nuclei but whose cells are all in contact with the underlying basement membrane. (4)

puberty: A period of rapid growth, sexual maturation, and the appearance of secondary sexual characteristics; normally occurs at ages 10–15 years. (18, 28, 29)

pubic symphysis: The fibrocartilaginous amphiarthrosis between the pubic bones of the hip. (8, 9)

pubis: The anterior, inferior component of the hip bone. (8)

pudendum: The external genitalia. (28)

pulmonary circuit: Blood vessels between the pulmonary semilunar valve of the right ventricle and the entrance to the left atrium; the blood flow through the lungs. (20)

pulmonary ventilation: The movement of air into and out of the lungs. (23)

pulvinar nucleus: The thalamic nucleus involved in the integration of sensory information prior to projection to the cerebral hemispheres. (14)

pupil: The opening in the center of the iris through which light enters the eye. (17)

purine: A nitrogen compound with a double ring-shaped structure; examples include adenine and guanine, two nitrogenous bases that are common in nucleic acids. (2, 12)

Purkinje cell layer: A large, branching neuron of the cerebellar cortex. (14)

Purkinje fibers: Specialized conducting cardiac muscle cells in the ventricles of the heart. (20)

pus: An accumulation of debris, fluid, dead and dying cells, and necrotic tissue. (4, 20, 22)

pyloric part: The gastric region between the body of the stomach and the duodenum; includes the muscular pylorus and the pyloric sphincter. (24)

pyloric sphincter: A ring of smooth muscle that regulates the passage of chyme from the stomach to the duodenum. (24)

pyrimidine: A nitrogen compound with a single ring-shaped structure; examples include cytosine, thymine, and uracil, nitrogenous bases that are common in nucleic acids. (2)

pyruvate: The anion formed by the dissociation of pyruvic acid, which is a three-carbon compound produced by glycolysis. (25)

Q

quaternary structure: The three-dimensional protein structure produced by interactions between protein subunits. (2)

R

radiodensity: The relative resistance to the passage of x-rays. (1)

radiographic techniques: Methods of visualizing internal structures by using various forms of radiational energy. (1)

radiopaque: Having a high radiodensity. (1)

rami communicantes: Axon bundles that link the spinal nerves with the ganglia of the sympathetic chain. (13)

ramus/rami: Branch/branches. (7, 8, 13)

raphe: A seam. (11, 28)

receptive field: The area monitored by a single sensory receptor. (15)

rectum: The inferior 15 cm (6 in.) of the digestive tract. (24)

rectus: Straight. (11)

red blood cell (RBC): See *erythrocyte*. (4, 19)

reduction: The loss of oxygen, or the gain of hydrogen or electrons. (25)

reductional division: The first meiotic division, which reduces the chromosome number from 46 to 23. (28)

reflex: A rapid, automatic response to a stimulus. (12, 13, 16, 18, 21)

reflex arc: The receptor, sensory neuron, motor neuron, and effector involved in a particular reflex; interneurons may be present, depending on the reflex considered. (13)

refractory period: The time between the initiation of an action potential and the restoration of the normal resting membrane potential; during this period, the membrane will not respond normally to stimulation. (12, 20)

regulatory T cells: Population of T lymphocytes that suppress the immune response. (22)

relaxation phase: The period after a contraction when the tension in the muscle fiber returns to resting levels. (10)

relaxin: A hormone that loosens the pubic symphysis; secreted by the placenta. (29)

renal: Pertaining to the kidneys. (26)

renal corpuscle: The initial segment of the nephron, consisting of an expanded chamber that encloses the glomerulus. (26)

renin: The enzyme released by cells of the juxtaglomerular complex when renal blood flow decreases; converts angiotensinogen to angiotensin I. (18, 26)

rennin: A gastric enzyme that breaks down milk proteins. (24)

replication: Duplication. (29)

repolarization: The movement of the membrane potential away from a positive value and toward the resting potential. (12, 20)

respiration: The exchange of gases between cells and the environment; includes pulmonary ventilation, external respiration, and internal respiration. (23, 27)

respiratory minute volume (V_E): The amount of air moved into and out of the respiratory system each minute. (23)

respiratory pump: A mechanism by which changes in the intrapleural pressures during the respiratory cycle assist the venous return to the heart; also called *thoracoabdominal pump*. (21, 23)

respiratory rhythmicity center: The center in the medulla oblongata that sets the background pace of respiration; includes inspiratory and expiratory centers. (14, 23)

resting membrane potential: The membrane potential of a normal cell under homeostatic conditions. (3, 12)

rete: An interwoven network of blood vessels or passageways. (28)

reticular activating system (RAS): The midbrain portion of the reticular formation; responsible for arousal and the maintenance of consciousness. (16)

reticular formation: A diffuse network of gray matter that extends the entire length of the brainstem (medulla oblongata to the midbrain). (14)

reticulospinal tracts: Descending tracts of the medial pathway that carry involuntary motor commands issued by neurons of the reticular formation. (15)

retina: The innermost layer of the eye, lining the vitreous chamber; also called *inner layer*. (17)

retinal: A visual pigment derived from vitamin A. (17)

retraction: Movement posteriorly in the horizontal plane. (9)

retroperitoneal: Behind or outside the peritoneal cavity. (1, 24)

reverberation: A positive feedback along a chain of neurons such that they remain active once stimulated. (13)

rheumatism: A general term used to describe pain in muscles, tendons, bones, or joints. (9)

Rh factor: A surface antigen that may be present (Rh positive) or absent (Rh negative) from the surfaces of red blood cells. (19)

rhodopsin: The visual pigment in the membrane discs of the distal segments of rods. (17)

ribonucleic acid: A nucleic acid consisting of a chain of nucleotides that contain the sugar ribose and the nitrogenous bases adenine, guanine, cytosine, and uracil. (2, 3)

ribose: A five-carbon sugar that is a structural component of RNA. (2, 3)

ribosome: An organelle that contains rRNA and proteins and is essential to mRNA translation and protein synthesis. (2, 3)

rod: A photoreceptor responsible for vision in dim lighting. (17)

rough endoplasmic reticulum (RER): A membranous organelle that is a site of protein synthesis and storage. (3)

round window: An opening in the bony labyrinth of the internal ear that exposes the membranous wall of the tympanic duct to the air of the middle ear cavity. (17)

rubrospinal tracts: Descending tracts of the lateral pathway that carry involuntary motor commands issued by the red nucleus of the midbrain. (15)

rugae: Mucosal folds in the lining of the empty stomach that disappear as gastric distension occurs (24); folds in the urinary bladder. (26)

S

saccul: A portion of the vestibular apparatus of the internal ear; contains a macula important for providing sensations of gravity and linear acceleration in a vertical dimension. (17)

sagittal plane: A vertical plane that divides the body into left and right portions. (1)

salt: An inorganic compound consisting of a cation other than H^+ and an anion other than OH^- . (2)

saltatory propagation: The relatively rapid propagation of an action potential between successive nodes of a myelinated axon. (12)

sarcolemma: The plasma membrane of a muscle cell. (10)

sarcomere: The smallest contractile unit of a striated muscle cell. (10)

sarcoplasm: The cytoplasm of a muscle cell. (10)

scala media: The central membranous tube within the cochlea that is filled with endolymph and contains the spiral organ (*organ of Corti*); also called *cochlear duct*. (17)

scala tympani: The perilymph-filled chamber of the internal ear, adjacent to the basilar membrane; pressure changes there distort the round window; also called *tympanic duct*. (17)

scala vestibuli: The perilymph-filled chamber of the internal ear, adjacent to the vestibular membrane; pressure waves are induced by movement of the stapes at the oval window; also called *vestibular duct*. (17)

scar tissue: The thick, collagenous tissue that forms at an injury site. (5)

Schwann cells: Neuroglia responsible for the neurolemma that surrounds axons in the peripheral nervous system. (12)

sciatic nerve: A nerve innervating the posteromedial portions of the thigh and leg. (13)

scientific method: A system of advancing knowledge that begins by proposing a hypothesis to answer a question, and then testing that hypothesis with data collected through observation and experimentation. (1)

sclera: The fibrous, outer layer of the eye that forms the white area of the anterior surface; a portion of the fibrous layer of the eye. (17)

sclerosis: A hardening and thickening that commonly occurs secondary to tissue inflammation. (4)

scrotum: The loose-fitting, fleshy pouch that encloses the testes of the male. (28)

sebaceous glands: Glands that secrete sebum; normally associated with hair follicles. (5)

sebum: A waxy secretion that coats the surfaces of hairs. (5)

secondary sex characteristics: Physical characteristics that appear at puberty in response to sex hormones but are not involved in the production of gametes. (28)

secretin: A hormone, secreted by the duodenum, that stimulates the production of buffers by the pancreas and inhibits gastric activity. (24)

sectional plane: A view or slice along a two-dimensional flat surface. (1)

semen: The fluid ejaculate that contains sperm and the secretions of accessory glands of the male reproductive tract. (28)

semicircular ducts: The tubular components of the membranous labyrinth of the internal ear; respond to rotational movements of the head. (17)

semilunar valve: A three-cusped valve guarding the exit from one of the cardiac ventricles; the pulmonary and aortic valves. (20)

seminal glands: Glands of the male reproductive tract that produce roughly 60% of the volume of semen; also called *seminal vesicles*. (28)

seminiferous tubules: Coiled tubules where sperm production occurs in the testes. (28)

senescence: Aging. (29)

sensible perspiration: Water loss due to secretion by sweat glands. (5, 27)

septa: Partitions that subdivide an organ. (20, 22)

serosa: See **serous membrane**. (4, 24)

serotonin: A neurotransmitter in the central nervous system; a substance that enhances inflammation and is released by activated mast cells and basophils. (12, 19)

serous cell: A cell that produces a serous secretion. (4)

serous membrane: A squamous epithelium and the underlying loose connective tissue; the lining of the pericardial, pleural, and peritoneal cavities; also called a *serosa*. (4, 24)

serous secretion: A watery secretion that contains high concentrations of enzymes; produced by serous cells. (4)

Sertoli cells: See **nurse cells**. (18, 28)

serum: The ground substance of blood plasma from which clotting agents have been removed. (19)

sesamoid bone: A bone that forms within a tendon. (6)

sigmoid colon: The S-shaped region of the colon between the descending colon and the rectum. (24)

sign: The visible, objective evidence of the presence of a disease. (1)

simple epithelium: An epithelium containing a single layer of cells superficial to the basement membrane. (4)

sinoatrial (SA) node: The natural pacemaker of the heart; located in the wall of the right atrium. (20)

sinus: A chamber or hollow in a tissue; a large, dilated vein. (6, 7, 20)

sinusoid: An exchange vessel that is similar in general structure to a fenestrated capillary. The two differ in size (sinusoids are larger and more irregular in cross section), continuity (sinusoids have gaps between endothelial cells), and support (sinusoids have thin basement membranes, if present at all). (20, 21)

skeletal muscle: A contractile organ of the muscular system. (10)

skeletal muscle tissue: A contractile tissue dominated by skeletal muscle fibers; characterized as striated, voluntary muscle. (4, 10)

sliding-filament theory: The concept that a sarcomere shortens as the thick and thin filaments slide past one another. (10)

small intestine: The duodenum, jejunum, and ileum; the digestive tract between the stomach and the large intestine. (24)

smooth endoplasmic reticulum (SER): A membranous organelle in which lipid and carbohydrate synthesis and storage occur. (3)

smooth muscle tissue: Muscle tissue in the walls of many visceral organs; characterized as nonstriated, involuntary muscle. (4, 10, 24, 26)

soft palate: The fleshy posterior extension of the hard palate, separating the nasopharynx from the oral cavity. (24)

solute: Any materials dissolved in a solution. (2, 21, 26)

solution: A fluid containing dissolved materials. (2, 21)

solvent: The fluid component of a solution. (2, 21)

somatic: Pertaining to the body. (3, 12, 15, 16)

somatic nervous system (SNS): The efferent division of the nervous system that innervates skeletal muscles. (12, 15, 16)

somatomedins: Substances stimulating tissue growth; released by the liver after the secretion of growth hormone; also called *insulin-like growth factors*. (18)

somatotropin: Growth hormone (GH); produced by the anterior lobe of the pituitary gland (adenohypophysis) in response to growth hormone-releasing hormone (GH-RH). (18)

sperm: Male gamete(s). (3, 28, 29)

spermatic cord: Collectively, the spermatic vessels, nerves, lymphatic vessels, and the ductus deferens, extending between the testes and the proximal end of the inguinal canal. (28)

spermatocyte: A cell of the seminiferous tubules that is engaged in meiosis. (28)

spermatogenesis: Sperm production. (28)

sphincter: A muscular ring that contracts to close the entrance or exit of an internal passageway. (10, 11, 26)

spinal nerve: One of 31 pairs of nerves that originate on the spinal cord from anterior and posterior roots. (12, 13)

spindle apparatus: Microtubule-based structure that distributes duplicated chromosomes to opposite ends of a dividing cell during mitosis. (3)

spinocerebellar tracts: Ascending tracts that carry sensory information to the cerebellum. (15)

spinothalamic tracts: Ascending tracts that carry poorly localized touch, pressure, pain, vibration, and temperature sensations to the thalamus. (15)

spinous process: The prominent posterior projection of a vertebra; formed by the fusion of two laminae. (7)

spiral organ: A receptor complex in the scala media of the cochlea that includes the inner and outer hair cells, supporting cells and structures, and the tectorial membrane; provides the sensation of hearing; also called the *organ of Corti*. (17)

spleen: A lymphoid organ important for the phagocytosis of red blood cells, the immune response, and lymphocyte production. (22)

spongy bone: Bone that consists of an open network of struts and plates that resembles a three-dimensional garden lattice. (6)

squama: A broad, flat surface. (4)

squamous: Flattened. (4)

squamous epithelium: An epithelium whose superficial cells are flattened and platelike. (4)

stapes: The auditory ossicle attached to the tympanic membrane. (17)

stellate macrophage: Phagocytic cell of the liver sinusoids; also called *Kupffer cell*. (22, 24)

stenosis: A constriction or narrowing of a passageway. (7)

stereocilia: Elongated microvilli characteristic of the epithelium of the epididymis, sections of the ductus deferens (28), and the internal ear. (17)

steroid: A ring-shaped lipid structurally related to cholesterol. (2, 18)

stimulus: An environmental change that produces a change in cellular activities; often used to refer to events that alter the membrane potentials of excitable cells. (15)

stratified epithelium: An epithelium containing several layers. (4)

stratum/strata: Layer/layers. (4)

stretch receptors: Sensory receptors that respond to stretching of the surrounding tissues. (13)

stretch reflex: Tonic muscle contraction in response to stimulation of muscle proprioceptors. (13)

stroke volume (SV): The amount of blood pumped out of one heart ventricle in a single heartbeat. (20)

stroma: The connective tissue framework of an organ; distinguished from the functional cells (parenchyma) of that organ. (4, 18)

subarachnoid space: A meningeal space containing cerebrospinal fluid; the area between the arachnoid membrane and the pia mater. (13, 14)

subclavian: Pertaining to the region immediately posterior and inferior to the clavicle. (11)

submucosa: The region between the muscularis mucosae and the muscularis externa. (23, 24)

subserous fascia: The loose connective tissue layer deep to the serous membrane that lines body cavities. (4)

substrate: A participant (product or reactant) in an enzyme-catalyzed reaction. (2)

sulcus: A groove or furrow. (14)

summation: The temporal or spatial addition of contractile force or neural stimuli. (10, 12)

superficial fascia: The layer of loose connective tissue below the dermis. (4, 5)

superior: Above, in reference to a portion of the body in the anatomical position. (1)

superior vena cava (SVC): The vein that carries blood to the right atrium from parts of the body that are superior to the heart. (20, 21)

supination: The rotation of the forearm such that the palm faces anteriorly. (9)

supine: Lying face up, with palms facing anteriorly. (1)

suprarenal cortex: See **adrenal cortex**. (18)

suprarenal gland: See **adrenal gland**. (18)

suprarenal medulla: See **adrenal medulla**. (16)

surfactant: A lipid secretion that coats the alveolar surfaces of the lungs and prevents their collapse. (23)

sutural bones: Irregular bones that form in fibrous tissue between the flat bones of the developing cranium; also called *Wormian bones*. (6)

suture: A fibrous joint between flat bones of the skull. (7, 9)

sympathetic division: The division of the autonomic nervous system that is responsible for "fight or flight" reactions; primarily concerned with the elevation of metabolic rate and increased alertness; also called the *thoracolumbar division*. (12, 16)

symphysis: A fibrous amphiarthrosis, such as that between adjacent vertebrae or between the pubic bones of the coxal bones. (9)

symptom: An abnormality of function as a result of disease; subjective experience of patient. (1)

synapse: The site of communication between a nerve cell and some other cell; if the other cell is not a neuron, the term *neuromuscular junction* or *neuroglandular junction* is often used. (12, 16, 18)

synaptic delay: The period between the arrival of an impulse at the presynaptic membrane and the initiation of an action potential in the postsynaptic membrane. (12)

syncytium: A multinucleate mass of cytoplasm, produced by the fusion of cells or repeated mitoses without cytokinesis. (29)

syndrome: A discrete set of signs and symptoms that occur together. (1)

synergist: A muscle that assists a prime mover in performing its primary action. (11)

synovial cavity: A fluid-filled chamber in a synovial joint. (4, 9)

synovial fluid: The substance secreted by synovial membranes that lubricates joints. (4, 9)

synovial joint: A freely movable joint where the opposing bone surfaces are separated by synovial fluid; a diarthrosis. (4, 9)

synovial membrane: An incomplete layer of fibroblasts confronting the synovial cavity, plus the underlying loose connective tissue. (4)

synthesis: Manufacture; anabolism. (23)

system: An interacting group of organs that performs one or more specific functions. (1)

systemic circuit: The vessels between the aortic valve and the entrance to the right atrium; the system other than the vessels of the pulmonary circuit. (20)

systole: A period of contraction in a chamber of the heart, as part of the cardiac cycle. (20)

systolic pressure: The peak arterial pressure measured during ventricular systole. (20, 21)

T

tachycardia: Rapid heartbeat, usually over 90 beats per minute. (20)

tactile: Pertaining to the sense of touch. (15)

tarsal bones: The bones of the ankle (the talus, calcaneus, navicular, and cuneiform bones). (8)

tarsus: The ankle. (8)

TCA (tricarboxylic acid) cycle: See **citric acid cycle**. (3, 10, 25)

T cells: Lymphocytes responsible for cell-mediated immunity and for the coordination and regulation of the immune response; includes cytotoxic T cells, helper T cells, regulatory T cells, and memory T cells. (19, 22)

tectospinal tracts: Descending tracts of the medial pathway that carry involuntary motor commands issued by the colliculi. (15)

telodendria: Terminal axonal branches that end in axon terminals. (12)

telomeres: The distal ends of chromosomes. (3)

telophase: The final stage of mitosis, characterized by the disappearance of the spindle apparatus, the reappearance of the nuclear membrane, the disappearance of the chromosomes, and the completion of cytokinesis. (3)

temporal: Pertaining to time (temporal summation) or to the temples (temporal bone). (7)

tendon: A collagenous band that connects a skeletal muscle to an element of the skeleton. (4, 10)

teres: Round. (11)

terminal: Toward the end. (3, 5, 10, 16, 21, 23)

tertiary structure: The protein structure that results from interactions among distant portions of the same molecule; complex coiling and folding. (2)

testes: The male gonads, sites of gamete production and hormone secretion; also called *testicles*. (18, 28)

testosterone: The main androgen produced by the interstitial endocrine cells of the testes. (2, 18, 28)

tetraiodothyronine: T_4 , or thyroxine, a thyroid hormone. (18)

thalamus: The walls of the diencephalon. (14)

therapy: The treatment of disease. (11, 29)

thermoreception: Sensitivity to temperature changes. (15)

thermoregulation: Homeostatic maintenance of body temperature. (1, 25)

thick filament: A cytoskeletal filament in a skeletal or cardiac muscle cell; composed of myosin, with a core of titin. (3, 10)

thin filament: A cytoskeletal filament in a skeletal or cardiac muscle cell; consists of actin, troponin, nebulin, and tropomyosin. (3, 10)

thoracolumbar division: The sympathetic division of the autonomic nervous system. (16)

thorax: The chest. (7)

threshold: The membrane potential at which an action potential begins. (12)

thrombin: The enzyme that converts soluble fibrinogen to insoluble fibrin. (19)

thymine (T): A pyrimidine; one of the nitrogenous bases in the nucleic acid DNA. (2)

thymosins: Thymic hormones essential to the development and differentiation of T cells. (18, 22)

thymus: A lymphoid organ, the site of T cell development and maturation. (18, 22)

thyroglobulin: A circulating transport globulin that binds thyroid hormones. (18)

thyroid gland: An endocrine gland whose lobes are lateral to the thyroid cartilage of the larynx. (18)

thyroid hormones: Thyroxine (T_4) and triiodothyronine (T_3), hormones of the thyroid gland; stimulate tissue metabolism, energy utilization, and growth. (18)

thyroid-stimulating hormone (TSH): The hormone, produced by the adenohypophysis (anterior lobe of the pituitary gland), that triggers the secretion of thyroid hormones by the thyroid gland. (18)

thyroxine: A thyroid hormone; also called T_4 , or *tetraiodothyronine*. (18)

tidal volume (TV): The volume of air moved into and out of the lungs during a normal quiet respiratory cycle. (23)

tight junction: Connection between cells formed by the fusion of membrane proteins. (4)

tissue: A collection of specialized cells and cell products that performs a specific function. (1, 4)

tonic response: An increase or decrease in the frequency of action potentials by sensory receptors that are chronically active. (15)

tonsil: A lymphoid nodule in the wall of the pharynx; the palatine, pharyngeal, and lingual tonsils. (22)

topical: Applied to the body surface. (5)

toxic: Poisonous. (12, 23)

trabecula: A connective tissue partition that subdivides an organ. (22)

trachea: The windpipe; an airway extending from the larynx to the primary bronchi. (23)

tract: A bundle of axons in the central nervous system. (13, 14)

transamination: The reversible chemical reaction between an amino acid and a keto acid in which the amino group from the amino acid is transferred to the keto acid. (25)

transcription: The encoding of genetic instructions on a strand of mRNA. (3)

transection: The severing or cutting of an object in the transverse plane. (1)

translation: The process of peptide formation from the instructions carried by an mRNA strand. (3)

transmembrane potential: See **membrane potential**. (3, 10, 12)

transudate: A fluid that diffuses across a serous membrane and lubricates opposing surfaces. (4)

transverse plane: A horizontal plane that divides the body into superior and inferior portions. (1)

transverse tubules: The transverse, tubular extensions of the sarcolemma that extend deep into the sarcoplasm, contacting cisternae of the sarcoplasmic reticulum; also called *T tubules*. (10)

tricuspid valve: The right atrioventricular valve, which prevents the backflow of blood into the right atrium during ventricular systole. (20)

trigeminal nerve: Cranial nerve V, which provides sensory information from the lower portions of the face (including the upper and lower jaws) and delivers motor commands to the muscles of mastication. (14)

triglyceride: A lipid that is composed of a molecule of glycerol attached to three fatty acids. (2, 25)

triiodothyronine: T₃, a thyroid hormone. (18)

trisomy: The presence of three copies of a chromosome instead of the usual two; trisomy 21 is responsible for Down syndrome. (29)

trochanter: Large process near the head of the femur. (8)

trochlea: A pulley; the spool-shaped medial portion of the condyle of the humerus. (8)

trochlear nerve: Cranial nerve IV, controlling the superior oblique muscle of the eye. (14)

tropomyosin: Fibrous muscle protein that covers active sites on G actin and prevents actin–myosin interaction. (10)

tropinin: Globular muscle protein that binds to tropomyosin. (10)

trunk: The thoracic and abdominopelvic regions (1); a large bundle of spinal nerve axons (13); a major arterial branch. (21)

T tubules: See **transverse tubules**. (10)

tuberculum: A small, localized elevation on a bony surface. (7)

tuberosity: A large, roughened elevation on a bony surface. (6, 8)

tumor: A tissue mass formed by the abnormal growth and replication of cells. (3)

tunica: A layer or covering. (21)

twitch: A single stimulus–contraction–relaxation cycle in a skeletal muscle fiber. (10)

tympanic duct: See **scala tympani**. (17)

tympanic membrane: The membrane that separates the external acoustic meatus from the middle ear; the membrane whose vibrations are transferred to the auditory ossicles and ultimately to the oval window; also called *eardrum* or *tympanum*. (17)

Type A fibers: Large myelinated axons. (12)

Type B fibers: Small myelinated axons. (12)

Type C fibers: Small unmyelinated axons. (12)

U

umbilical cord: The connecting stalk between the fetus and the placenta; contains the allantois, the umbilical arteries, and the umbilical vein. (21, 29)

umbilicus: The navel. (29)

unicellular gland: Mucous cells. (4)

unipolar neuron: A sensory neuron whose cell body is in a dorsal root ganglion or a sensory ganglion of a cranial nerve. (12)

unmyelinated axon: An axon whose neurolemma does not contain myelin and across which continuous propagation occurs. (12)

uracil (U): A pyrimidine; one of the nitrogenous bases in the nucleic acid RNA. (2)

ureters: Muscular tubes, lined by transitional epithelium, that carry urine from the renal pelvis to the urinary bladder. (26)

urethra: A muscular tube that carries urine from the urinary bladder to the exterior. (26, 28)

urinary bladder: The muscular, distensible sac that stores urine prior to micturition. (26)

urination: The elimination of urine; also called *micturition*. (26)

uterus: The muscular organ of the female reproductive tract in which implantation, placenta formation, and fetal development occur. (28)

utricle: The largest chamber of the vestibular apparatus of the internal ear; contains a macula important for providing sensations of gravity and linear acceleration in a horizontal dimension. (17)

V

vagina: A muscular tube extending between the uterus and the vestibule. (28)

vallate papilla: One of the large, dome-shaped papillae on the superior surface of the tongue that forms a V, separating the body of the tongue from the root. (17)

vascular: Pertaining to blood vessels. (19)

vas deferens: See **ductus deferens**. (28)

vasoconstriction: A reduction in the diameter of arterioles due to the contraction of smooth muscles in the tunica media; increases peripheral resistance; may occur in response to local factors, through the action of hormones, or from the stimulation of the vasomotor center. (21)

vasodilation: An increase in the diameter of arterioles due to the relaxation of smooth muscles in the tunica media; decreases peripheral resistance; may occur in response to local factors, through the action of hormones, or after decreased stimulation of the vasomotor center. (21)

vasomotion: Rhythmic changes in the pattern of blood flow through a capillary bed due to the alternate contraction and relaxation of precapillary sphincters. (21)

vasomotor center: The center in the medulla oblongata whose stimulation produces vasoconstriction and an increase of peripheral resistance. (14)

vein: A blood vessel carrying blood from a capillary bed toward the heart. (20, 21)

vena cava: One of the major veins delivering systemic blood to the right atrium; superior and inferior venae cavae. (20, 21)

ventilation: Air movement into and out of the lungs. (23)

ventral: Pertaining to the anterior surface. (1)

ventricle: A fluid-filled chamber; in the heart, one of the large chambers discharging blood into the pulmonary or systemic circuits (20); in the brain, one of four fluid-filled interior chambers. (14)

venule: Thin-walled veins that receive blood from capillaries. (21)

vermiform appendix: See **appendix**. (24)

vertebral canal: The passageway that encloses the spinal cord; a tunnel bounded by the neural arches of adjacent vertebrae. (7)

vertebral column: The cervical, thoracic, and lumbar vertebrae, the sacrum, and the coccyx. (7, 11)

vesicle: A membranous sac in the cytoplasm of a cell. (3)

vestibular duct: See **scala vestibuli**. (17)

vestibular nucleus: The processing center for sensations that arrive from the vestibular apparatus of the internal ear, located near the border between the pons and the medulla oblongata. (14, 17)

vestibulospinal tracts: Descending tracts of the medial pathway that carry involuntary motor commands issued by the vestibular nucleus to stabilize the position of the head. (15)

villus/villi: Slender, finger-shaped projection(s) of a mucous membrane. (24, 29)

virus: A noncellular pathogen. (22)

viscera: Nonskeletal muscle organs, typically in the thoracic and abdominopelvic cavities. (1)

visceral: Pertaining to viscera (internal organs) or their outer coverings. (1)

visceral smooth muscle: A smooth muscle tissue that forms sheets or layers in the walls of visceral organs; the cells may not be innervated, and the layers often show automaticity (rhythmic contractions). (10, 24)

viscosity: The resistance to flow that a fluid exhibits as a result of molecular interactions within the fluid. (21)

viscous: Thick, syrupy. (21)

vitamin: An essential organic nutrient that functions as a coenzyme in vital enzymatic reactions. (24, 25)

vitreous humor: The fluid component of the vitreous body; the gelatinous mass in the posterior cavity (vitreous chamber) of the eye. (17)

voluntary: Controlled by conscious thought processes. (10)

W

white blood cells (WBCs): The granulocytes and agranulocytes of whole blood; also called *leukocytes*. (4, 19)

white matter: Regions in the central nervous system that are dominated by myelinated axons. (12, 13, 14)

white ramus communicans: A nerve bundle containing the myelinated preganglionic axons of sympathetic motor neurons en route to the sympathetic chain or to a collateral ganglion. (13)

Wormian bones: See **sutural bones**. (6)

X

X chromosome: One of two sex chromosomes; females have two X chromosomes. (29)

xiphoid process: The slender, inferior extension of the sternum. (7)

Y

Y chromosome: The sex chromosome whose presence indicates that the individual is a genetic male. (29)

Z

zona fasciculata: The region of the adrenal cortex that secretes glucocorticoids. (18)

zona glomerulosa: The region of the adrenal cortex that secretes mineralocorticoids. (18)

zona reticularis: The region of the adrenal cortex that secretes androgens. (18)

zygote: The fertilized ovum, prior to the start of cleavage. (28, 29)

WORD ROOTS, PREFIXES, SUFFIXES, AND COMBINING FORMS

Each entry starts with the commonly used prefix, suffix, or combining form followed by the word root (shown in *italics*) and its English translation. One example is also given to illustrate the use of each entry.

a-, *a-*, without: avascular
ab-, *ab*, from: abduct
-ac, *-akos*, pertaining to: cardiac
acr-, *akron*, extremity: acromegaly
ad-, *ad*, to, toward: adduct
aden-, **adeno-**, *adenos*, gland: adenoid
adip-, *adipos*, fat: adipocytes
aer-, *aeros*, air: aerobic metabolism
-al, *-alis*, pertaining to: brachial
alb-, *albicans*, white: albino
-algia, *algos*, pain: neuralgia
allo-, *allos*, other: allograft
ana-, *ana*, up, back: anaphase
andro-, *andros*, male: androgen
angio-, *angeion*, vessel: angiogram
ante-, *ante*, before: antebrachial
anti-, **ant-**, *anti*, against: antibiotic
apo-, *apo*, from: apocrine
arachn-, *arachne*, spider: arachnoid
arter-, *arteria*, artery: arterial
arthro-, *arthros*, joint: arthroscopy
astro-, *aster*, star: astrocyte
atel-, *ateles*, imperfect: atelectasis
aur-, *auris*, ear: auricle
auto-, *auto*, self: autonomic
baro-, *baros*, pressure: baroreceptor
bi-, *bi*- two: bifurcate
bio-, *bios*, life: biology
-blast, *blastos*, precursor: osteoblast
brachi-, *brachium*, arm: brachiocephalic
brachy-, *brachys*, short: brachydactyly
brady-, *bradys*, slow: bradycardia
bronch-, *bronchus*, windpipe, airway: bronchial
carcin-, *karkinos*, cancer: carcinoma
cardi-, **cardio-**, *kardia*, heart: cardiac
-cele, *kele*, tumor, hernia, or swelling: blastocele
-centesis, *kentesis*, puncture: thoracentesis
cephal-, *cephalos*, head: brachiocephalic
cerebr-, *cerebrum*, brain: cerebral hemispheres
cerebro-, *cerebros*, brain: cerebrospinal fluid
cervic-, *cervicis*, neck: cervical vertebrae
chole-, *chole*, bile: cholecystitis
-chondrion, *chondrion*, granule: mitochondrion
chondro-, *chondros*, cartilage: chondrocyte
chrom-, **chromo-**, *chroma*, color: chromatin
circum-, *circum*, around: circumduction
-clast, *klastos*, broken: osteoclast
coel-, **-coel**, *koila*, cavity: coelom
colo-, *kolon*, colon: colonoscopy
contra-, *contra*, against: contralateral
corp-, *corpus*, body: corpuscle
cortic-, *cortex*, rind or bark: corticospinal
cost-, *costa*, rib: costal
cranio-, *cranium*, skull: craniosacral
cribr-, *cribrum*, sieve: cribriform
-crine, *krinein*, to separate: endocrine
cut-, *cutis*, skin: cutaneous
cyan-, *kyanos*, blue: cyanosis
cyst-, **-cyst**, *kystis*, sac: blastocyst
cyt-, *cyto*, *kytos*, a hollow cell: cytology
de-, *de*, from, away: deactivation

dendr-, *dendron*, tree: dendrite
dent-, *dentes*, teeth: dentition
derm-, *derma*, skin: dermatome
desmo-, *desmos*, band: desmosome
di-, *dis*, twice: disaccharide
dia-, *dia*, through: diameter
digit-, *digit*, a finger or toe: digital
dipl-, *diploos*, double: diploid
dis-, *dis*, apart, away from: disability
diure-, *diourein*, to urinate: diuresis
dys-, *dys*, painful: dysmenorrhea
-ectasis, *ektasis*, expansion: atelectasis
ecto-, *ektos*, outside: ectoderm
-ectomy, *ektome*, excision: appendectomy
ef-, *ex*, away from: efferent
emmetro-, *emmetros*, in proper measure: emmetropia
encephalo-, *enkephalos*, brain: encephalitis
end-, **endo-**, *endon*, within: endometrium
entero-, *enteron*, intestine: enteric
epi-, *epi*, upon: epimysium
erythema-, *erythema*, flushed (skin): erythematous
erythro-, *erythros*, red: erythrocyte
ex-, *ex*, out of, away from: exocytosis
extra-, *exter*, outside of, beyond, in addition: extracellular
ferr-, *ferrum*, iron: transferrin
fil-, *filum*, thread: filament
-form, *-formis*, shape: fusiform
gastr-, *gaster*, stomach: gastrointestinal
-gen, **-genic**, *gennan*, to produce: mutagen
genicula-, *geniculum*, kneelike structure: geniculates
genio-, *geneion*, chin: geniohyoid
gest-, *gesto*, to bear: gestation
glosso-, **-glossus**, *glossus*, tongue: hypoglossal
glyco-, *glykys*, sugar: glycogen
-gram, *gramma*, record: myogram
gran-, *granulum*, grain: granulocyte
-graph, **-graphia**, *graphein*, to write, record: electroencephalograph
gyne-, **gyno-**, *gynaikos*, woman: gynecologist
hem-, **hemo-**, *haima*, blood: hemopoiesis
hemi-, *hemi*-, one half: hemisphere
hepato-, *hepaticus*, liver: hepatocyte
hetero-, *heteros*, other: heterozygous
histo-, *histos*, tissue: histology
holo-, *holos*, entire: holocrine
homeo-, *homoios*, similar: homeostasis
homo-, *homos*, same: homozygous
hyal-, **hyalo-**, *hyalos*, glass: hyaline
hydro-, *hydros*, water: hydrolysis
hyo-, *hyoeides*, U-shaped: hyoid bone
hyper-, *hyper*, above: hyperpolarization
hypo-, *hypo*, under: hypothyroid
hyster-, *hystera*, uterus: hysterectomy
-ia, *-ia*, state or condition: insomnia
idi-, *idios*, one's own: idiopathic
in-, *in*-, in, within, or denoting negative effect: inactivate
infra-, *infra*, beneath: infra-orbital
inter-, *inter*, between: interventricular
intra-, *intra*, within: intracapsular
ipsi-, *ipse*, itself: ipsilateral
iso-, *isos*, equal: isotonic
-itis, *-itis*, inflammation: dermatitis

karyo-, *karyon*, body: megakaryocyte
kerato-, *keros*, horn: keratin
kino-, **-kinin**, *kinein*, to move: bradykinin
lact-, **lacto-**, **-lactin**, *lac*, milk: prolactin
lapar-, *lapara*, flank or loins: laparoscopy
-lemma, *lemma*, husk: sarcolemma
leuk-, **leuko-**, *leukos*, white: leukemia, leukocyte
liga-, *ligare*, to bind together: ligase
lip-, **lipo-**, *lipos*, fat: lipoid
lith-, *lithos*, stone: cholelithiasis
lys- **lyso-**, *lysis*, a loosening: hydrolysis
macr-, *makros*, large: macrophage
mal-, *mal*, abnormal: malabsorption
mammilla-, *mammilla*, nipple: mammary
mast-, **masto-**, *mastos*, breast: mastoid
mega-, *megas*, big: megakaryocyte
melan-, *melas*, black: melanocyte
men-, *men*, month: menstrual
mero-, *meros*, part: merocrine
meso-, *mesos*, middle: mesoderm
meta-, *meta*, after, beyond: metaphase
micr-, *mikros*, small: microscope
mono-, *monos*, single: monocyte
morph-, **morpho-**, *morphe*, form: morphology
multi-, *multus*, much, many: multicellular
-mural, *murus*, wall: intramural
myelo-, *myelos*, marrow: myeloblast
myo-, *mys*, muscle: myofibril
narc-, *narkoun*, to numb or deaden: narcotics
nas-, *nasus*, nose: nasolacrimal duct
natri-, *natrium*, sodium: natriuretic
necr-, *nekros*, corpse: necrosis
nephr-, *nephros*, kidney: nephron
neur-, **neuri-**, **neuro-**, *neuron*, nerve: neuromuscular
oculo-, *oculus*, eye: oculomotor
odont-, *odontos*, tooth: odontoid process
-oid, *eidos*, form, resemblance: odontoid process
oligo-, *oligos*, little, few: oligopeptide
-ology, *logos*, the study of: physiology
-oma, *-oma*, swelling: carcinoma
onco-, *onkos*, mass, tumor: oncology
oo-, *oon*, egg: oocyte
ophthalm-, *ophthalmos*, eye: ophthalmic nerve
-opia, *ops*, eye: myopia
orb-, *orbita*, a circle: orbicularis oris
orchi-, *orchis*, testis: orchiectomy
orth-, *orthos*, correct, straight: orthopedist
-osis, *-osis*, state, condition: neurosis
ost-, **oste-**, **osteo-**, *osteon*, bone: osteocyte
oto-, *otikos*, ear: otolith
para-, *para*, alongside, near: parathyroid
path-, **-pathy**, **patho-**, *pathos*, disease: pathology
pedia-, *paidos*, child: pediatrician
per-, *per*, through, throughout: percutaneous
peri-, *peri*, around: perineurium
phago-, *phago*, to eat: phagocyte
-phasia, *phasis*, speech: aphasia
-phil, **-philia**, *philos*, love: neutrophil
phleb-, *phleps*, a vein: phlebitis
-phobia, *phobos*, fear: claustrophobia
phot-, **photo-**, *phos*, light: photoreceptor

-phylaxis, *phylax*, a guard: prophylaxis
physio-, *physis*, nature: physiology
-plasia, *plasis*, formation: dysplasia
platy-, *platys*, flat: platysma
-plegia, *plege*, a blow, paralysis: hemiplegia
-plexy, *plessein*, to strike: apoplexy
pneum-, *pneuma*, air: pneumotaxic center
pod-, **podo-**, *podos*, foot: podocyte
-poiesis, *poiesis*, making: hemopoiesis
poly-, *polys*, many: polysaccharide
post-, *post*, after: postanal
pre-, *prae*, before: precapillary sphincter
presby-, *presbys*, old: presbyopia
pro-, *pro*, before: prophase
proct-, *proktos*, anus: proctology
pterygo-, *pteryx*, wing: pterygoid
pulmo-, *pulmo*, lung: pulmonary
pulp-, *pulpa*, pulp: pulpitis
pyel-, *pyelos*, trough or pelvis: pyelitis
quadr-, *quadrans*, one quarter: quadriplegia
re-, *re-*, back, again: reinfection
retro-, *retro*, backward: retroperitoneal
rhin-, *rhis*, nose: rhinitis
-rrhage, *rhegnymi*, to burst forth: hemorrhage
-rrhea, *rhein*, flow, discharge: diarrhea
sarco-, *sarkos*, flesh: sarcomere
scler-, **sclero-**, *skleros*, hard: sclera
-scope, *skopeo*, to view: colonoscope
-sect, *sectio*, to cut: transect
semi-, *semis*, half: semitendinosus
-septic, *septikos*, putrid: antiseptic
-sis, *-sis*, state or condition: metastasis
som-, **-some**, *soma*, body: somatic
spino-, *spina*, spine, vertebral column:
 spinothalamic pathway
stalsis, *staltikos*, contractile: peristalsis
sten-, *stenos*, a narrowing: stenosis
stomy, *stoma*, mouth, opening: colostomy
stylo-, *stylus*, stake, pole: stylohyoid
sub-, *sub*, below; subcutaneous
super-, *super*, above or beyond: superficial
supra-, *supra*, on the upper side: supraspinous fossa
syn-, *syn*, together: synthesis
tachy-, *tachys*, swift: tachycardia
telo-, *telos*, end: telophase
tetra-, *tettares*, four: tetralogy of Fallot
therm-, **thermo-**, *therme*, heat: thermoregulation
thorac-, *thorax*, chest: thoracentesis
thromb-, *thrombos*, clot: thrombocyte
-tomy, *tome*, to cut: appendectomy
tox-, *toxikon*, poison: toxemia
trans-, *trans*, through: transudate
tri-, *tres*, three: trimester
tropho-, *trophe*, nutrition: trophoblast
trophy, *trophikos*, nourishment: atrophy
-tropic, *trope*, turning: adrenocorticotrophic
tropo-, *tropikos*, turning: troponin
uni-, *unus*, one: unicellular
uro-, **-uria**, *ouron*, urine: glycosuria
vas-, *vas*, vessel: vascular
zyg-, *zygotos*, yoke: zygote

COMMON ABBREVIATIONS USED IN SCIENCE

ACh	acetylcholine	FSH	follicle-stimulating hormone	PFC	perfluorochemical emulsion
AChE	acetylcholinesterase	GABA	gamma aminobutyric acid	PG	prostaglandin
ACTH	adrenocorticotrophic hormone	GAS	general adaptation syndrome	PID	pelvic inflammatory disease
ADH	antidiuretic hormone	GC	glucocorticoid	PIH	prolactin-inhibiting hormone
ADP	adenosine diphosphate	GFR	glomerular filtration rate	PIP	phosphatidylinositol
AIDS	acquired immunodeficiency syndrome	GH	growth hormone	PKC	protein kinase C
ALS	amyotrophic lateral sclerosis	GH-IH	growth hormone-inhibiting hormone	PKU	phenylketonuria
AMP	adenosine monophosphate	GHP	glomerular hydrostatic pressure	PLC	phospholipase C
ANP	atrial natriuretic peptide	GH-RH	growth hormone-releasing hormone	PMN	polymorphonuclear leukocyte
ANS	autonomic nervous system	GIP	gastric inhibitory peptide	PNS	peripheral nervous system
AP	arterial pressure	GnRH	gonadotropin-releasing hormone	PR	peripheral resistance
ARDS	adult respiratory distress syndrome	GTP	guanosine triphosphate	PRF	prolactin-releasing factor
atm	atmospheric pressure	Hb	hemoglobin	PRL	prolactin
ATP	adenosine triphosphate	hCG	human chorionic gonadotropin	psi	pounds per square inch
ATPase	adenosine triphosphatase	HCl	hydrochloric acid	PT	prothrombin time
AV	atrioventricular	HDL	high-density lipoprotein	PTA	post-traumatic amnesia; plasma thrombo-
AVP	arginine vasopressin	HDN	hemolytic disease of the newborn		plastin antecedent
BCOP	blood colloid osmotic pressure	hGH	human growth hormone	PTC	phenylthiocarbamide
BMR	basal metabolic rate	HIV	human immunodeficiency virus	PTH	parathyroid hormone
BPG	bisphosphoglycerate	HLA	human leukocyte antigen	PVC	premature ventricular contraction
bpm	beats per minute	HMD	hyaline membrane disease	RAS	reticular activating system
BUN	blood urea nitrogen	HP	hydrostatic pressure	RBC	red blood cell
C	large calorie; Celsius	hPL	human placental lactogen	RDA	recommended daily allowance
CABG	coronary artery bypass graft	HR	heart rate	RDS	respiratory distress syndrome
CAD	coronary artery disease	Hz	Hertz	REM	rapid eye movement
cAMP	cyclic-AMP	ICF	intracellular fluid	RER	rough endoplasmic reticulum
CAPD	continuous ambulatory peritoneal dialysis	ICOP	interstitial fluid colloid osmotic pressure	RH	releasing hormone
		IGF	insulin-like growth factor	RHD	rheumatic heart disease
CCK	cholecystokinin	IH	inhibiting hormone	RLQ	right lower quadrant
CD	cluster of differentiation	IM	intramuscular	RNA	ribonucleic acid
CF	cystic fibrosis	IP₃	inositol triphosphate	rRNA	ribosomal RNA
CHF	congestive heart failure	IPSP	inhibitory postsynaptic potential	RUQ	right upper quadrant
CHP	capillary hydrostatic pressure	IRV	inspiratory reserve volume	SA	sinoatrial
CsHP	capsular hydrostatic pressure	ISF	interstitial fluid	SCA	sickle cell anemia
CNS	central nervous system	IUD	intrauterine device	SCID	severe combined immunodeficiency disease
CO	cardiac output; carbon monoxide	IVC	inferior vena cava		
CoA	coenzyme A	IVF	in vitro fertilization	SEM	scanning electron micrograph
COMT	catechol-O-methyltransferase	kcal	kilocalorie	SER	smooth endoplasmic reticulum
COPD	chronic obstructive pulmonary disease	LDH	lactate dehydrogenase	SGOT	serum glutamic oxaloacetic transaminase
CP	creatine phosphate	LDL	low-density lipoprotein	SIADH	syndrome of inappropriate ADH secretion
CPK, CK	creatine phosphokinase	L-DOPA	levodopa		
CPM	continuous passive motion	LH	luteinizing hormone	SIDS	sudden infant death syndrome
CPR	cardiopulmonary resuscitation	LLQ	left lower quadrant	SLE	systemic lupus erythematosus
CRF	chronic renal failure	LM	light micrograph	SNS	somatic nervous system
CRH	corticotropin-releasing hormone	LSD	lysergic acid diethylamide	SRY	sex-determining region of the Y chromosome
CSF	cerebrospinal fluid; colony-stimulating factor	LUQ	left upper quadrant		
		MAO	monoamine oxidase	STD	sexually transmitted disease
CT	computerized tomography; calcitonin	MAP	mean arterial pressure	SV	stroke volume
CVA	cerebrovascular accident	MC	mineralocorticoid	SVC	superior vena cava
CVS	cardiovascular system	MD	Doctor of Medicine	T₃	triiodothyronine
DAG	diacylglycerol	mEq	milliequivalent; (10 ⁻³)	T₄	tetraiodothyronine, or thyroxine
DC	Doctor of Chiropractic	MHC	major histocompatibility complex	TB	tuberculosis
DCT	distal convoluted tubule	MI	myocardial infarction	TBG	thyroid-binding globulin
DDST	Denver Developmental Screening Test	mm Hg	millimeters of mercury	TDF	testis-determining factor
DIC	disseminated intravascular coagulation	mmol	millimole	TEM	transmission electron micrograph
DJD	degenerative joint disease	mOsm	milliosmole	TIA	transient ischemic attack
DMD	Duchenne muscular dystrophy	MRI	magnetic resonance imaging	T_m	transport (tubular) maximum
DNA	deoxyribonucleic acid	mRNA	messenger RNA	TMJ	temporomandibular joint
DO	Doctor of Osteopathy	MS	multiple sclerosis	t-PA	tissue plasminogen activator
DPM	Doctor of Podiatric Medicine	MSH	melanocyte-stimulating hormone	TRH	thyrotropin-releasing hormone
DSA	digital subtraction angiography	MSH-IH	melanocyte-stimulating hormone-inhibiting hormone	tRNA	transfer RNA
E	epinephrine			TSH	thyroid-stimulating hormone
ECF	extracellular fluid	NAD	nicotinamide adenine dinucleotide	TSS	toxic shock syndrome
ECG	electrocardiogram	NE	norepinephrine	TV	tidal volume
EDV	end-diastolic volume	NFP	net filtration pressure	UTI	urinary tract infection
EEG	electroencephalogram	NHP	net hydrostatic pressure	UTP	uridine triphosphate
EKG	electrocardiogram	NO	nitric oxide	UV	ultraviolet
ELISA	enzyme-linked immunosorbent assay	NRDS	neonatal respiratory distress syndrome	V_A	alveolar ventilation
EPSP	excitatory postsynaptic potential	OP	osmotic pressure	V_D	anatomic dead space
ERV	expiratory reserve volume	Osm	osmolality	V̇	respiratory minute volume
ESV	end-systolic volume	OXT	oxytocin	VF	ventricular fibrillation
ETS	electron transport system	PAC	premature atrial contraction	VLDL	very low-density lipoprotein
FAD	flavin adenine dinucleotide	PAT	paroxysmal atrial tachycardia	VPRC	volume of packed red cells
FAS	fetal alcohol syndrome	PCT	proximal convoluted tubule	VT	ventricular tachycardia
FES	functional electrical stimulation	PCV	packed cell volume	WBC	white blood cell
FMN	flavin mononucleotide	PEEP	positive end-expiratory pressure		
FRC	functional residual capacity	PET	positron emission tomography
